SECTION 1.0 - INTRODUCTION

Numerous environmental studies related to the proposed Hat Creek thermal powerplant development have been conducted over the past five years to define environmental conditions in the region. Some of these studies have been continued to provide more detailed background data. The studies continued during 1980 at the Hat Creek site included the following:

- surface water and groundwater monitoring programmes to better define existing conditions,
- 2. leachate studies to provide a longterm assessment of the characteristics of leachates from waste coal materials, and
- 3. meteorological and air quality monitoring programmes to establish background weather and air quality data.

The environmental trace element studies to determine trace element concentrations naturally present in the terrestrial and aquatic environments in the vicinity of Hat Creek were completed in 1979 and were not continued in 1980.

During 1977 an extensive reclamation test programme was initiated using materials from the Bulk Sample Program. The land reclamation tests were designed to assess, on a large scale, the revegetation potential of various coal waste and overburden materials and to evaluate other variables pertinent to the successful revegetation of these waste materials. In 1978 and 1979 the results of the reclamation programme were assessed and modifications were made to improve or expand the tests. In 1980 the reclamation programme was continued and a new test was added to expand the revegetation test programme.

HC25

The amount of precipitation in the Hat Creek valley during 1980 was exceptional. The rainfall was the highest on record since 1961 and the snowfall was the second lowest since 1961. This abnormal precipitation influenced the 1980 results, as well, and will likely affect the 1981 results of the continuing environmental field studies at Hat Creek.

This report presents the results of the reclamation and environmental studies during 1980. Data from previous years are also presented and compared to the 1980 results. Similar reports were prepared in 1978 and 1979. Detailed descriptions of the field test plots and the sampling and analytical procedures followed in the environmental studies are presented in these reports (2,3,4) and are not repeated in detail in this 1980 report.

SECTION 2.0 - REVEGETATION PROGRAMMES

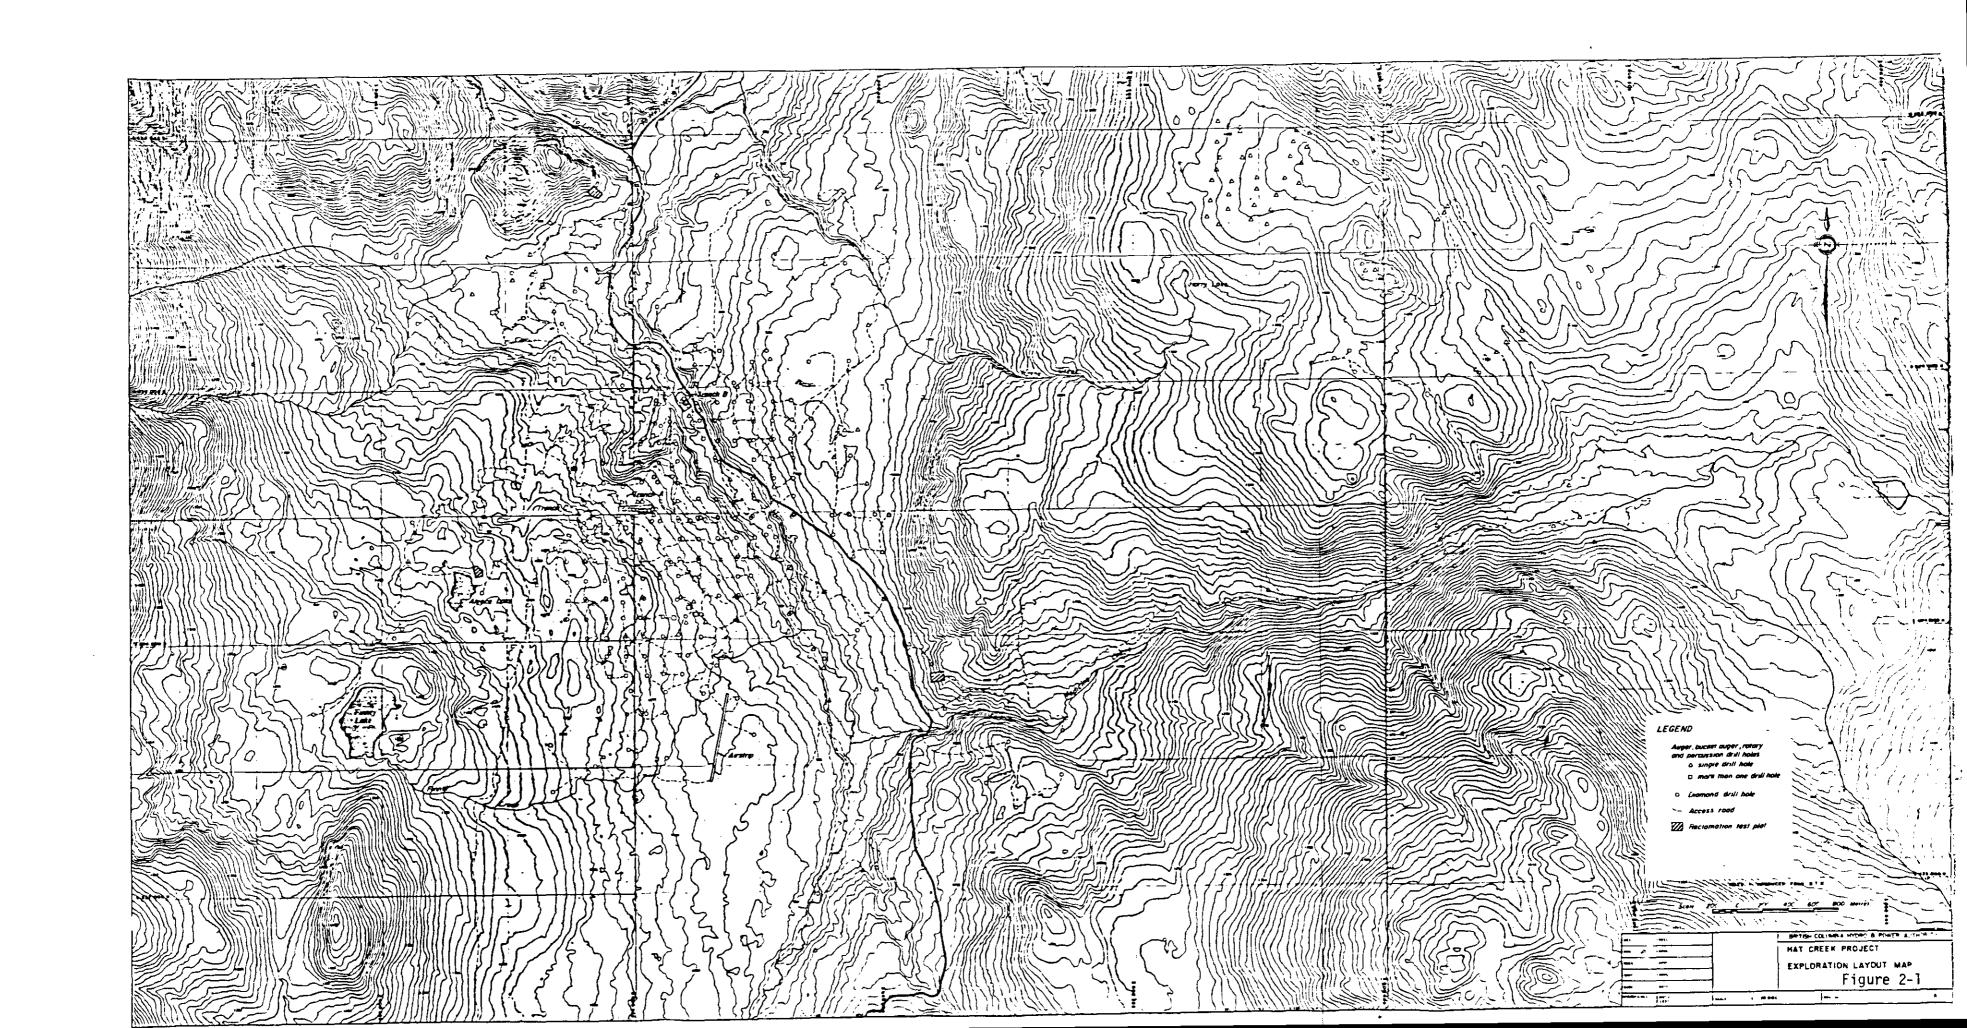

2.1 INTRODUCTION

Detailed exploration of the Hat Creek coal deposits was undertaken during 1974 to 1978. The exploration involved an extensive drilling programme and excavation of three test trenches to extract a bulk sample of coal for testing and to examine slope stabilities. Reclamation of land areas disturbed by the exploration was commenced in 1974 and is continuing. No major exploration work has been done since the end of 1978. All areas except those still in use, such as access roadways and camp facilities. have been reclaimed. Special revegetation test plots were established in 1977 using overburden and coal waste materials obtained from the Bulk Sampling Programme. The revegetation programme is designed to provide large scale field data for rehabilitation of waste materials during operation of the coal mine.

The revegetation test programme during 1980 included application of fertilizer on various test plots; visual surveys of the revegetated areas and test plots in April, June and September; nutrient analyses of vegetation samples collected from the Aleece Lake test plots, and establishment of a special garden where 21 varieties of grasses and shrubs were planted. In this section the 1980 revegetation test programme is described and the results of the three visual surveys and the vegetation analyses are presented. The locations of the revegetated areas and the test plots are shown in Fig. 2-1.

2.2 FERTILIZER ADDITIONS

The soils and waste materials used in the revegetation programme were analysed for plant nutrients and physical and chemical characteristics

in 1977 when the test plots were established. Further analyses of the soils for plant nutrients were carried out in 1978 and 1979. In the spring of each year fertilizer additions were made based on the results of the soils analyses. In April 1980, fertilizer was applied to the test plots using a cyclone hand broadcaster. The amounts of fertilizer applied were the same as that applied in 1979, as shown in Table 2-1.

A summary of the fertilizer additions made to the test plots since 1977 is presented in Table 2-2. In 1979 and 1980 lime was applied, at a rate of 2250 kg/ha, to a 15 m x 15 m test plot on top of the coaly waste pile at Trench A.

In 1979, a five year test program designed to assess the length of time that maintenance fertilizer must be applied for the establishment of abundant, self-sustaining vegetation was started. Five test areas where different fertilizer application schedules could be evaluated were established. These areas include; the 3140 (baked clay) and 3120 (gritstone) dumps at Trench A, the large gravel dump at Trench B, the colluvium parent material at the Houth Meadows test area, and the bentonitic clay dumps at Trench C. At each of the five areas, five plots of approximate equal area were designated, as shown in Figs. 2-2, 2-3, 2-4 and 2-5.

In 1977 and 1978 the dumps at Trench A were fertilized. The gravel pile at Trench B and the Houth Meadow colluvium were fertilized in 1977 but not in 1978. The Trench C areas were fertilized only in 1978. In 1979 segments numbered 1 at each location were not fertilized and others received the recommended fertilizer additions. In 1980 segments numbered 1 and 2 were not fertilized and the remaining three segments were fertilized. After five years these plots will have received maintenance fertilizer additions for a period ranging from one to seven years.

The maintenance fertilizer addition tests are assessed during the vegetation surveys and the results are reported in section 2.3, Vegetation Surveys.

2.3 VEGETATION SURVEYS

(a) Introduction

Qualitative assessments of vegetation growth on the test areas at Hat Creek were made three times during 1980. Surveys were carried out in early spring and fall to evaluate growth and changes during the growing season. An additional survey, in which plant cover, species composition and plant condition were recorded, was conducted in June. The results of the June survey were used to assess the overall progress of the reclamation tests at Hat Creek over the past three years since planting in 1977. This assessment is the subject of a report entitled "Revegetation Potential of Waste Materials" prepared by Monenco Consultants Pacific Ltd. (1)

The results of the spring and fall surveys and a summary of the June survey results are presented in this report. The detailed results of the June survey, which include nutrient analyses of plant material from selected plots, are presented in the Monenco report. (1)

In 1980 the total precipitation, measured at the I. Lehman ranch, was 358 mm, about 13 percent above the normal level of 317 mm. During the spring and summer rainfall was considerably above normal. In June rainfall totalled over 110 mm. This abnormally high level of moisture created excellent conditions for plant growth.

In the spring and fall visual surveys plant cover was estimated using four ranges: 0 to 25, 26 to 50, 51 to 75 and

76 to 100 percent coverage. Species composition are rough estimates with native species referred to collectively as weeds. Plant conditions were noted where appropriate.

The results of the visual surveys are summarized in the following sections. Photographs of many of the test plot areas are included for reference.

(b) <u>Aleece Lake Test Plots</u>⁽²⁾

In general all of the Aleece Lake test plots showed good growth during the 1980 growing season. Of note was the poor performance of sainfoin, the legume in Seed Mix II. This may have been due to competition with other species. Rodent activity was evident on almost all plots, particularly on the topsoiled portions. However, evidence of rodents was not observed on the bentonite clay plot.

(i) <u>Colluvium</u>

<u>Seed Mix I</u> - In early spring plant cover on the topsoiled portions of the plot was clearly less than on the bare material. However, by fall both halves of the plot showed essentially the same uniform cover of between 75 and 100 percent. Vegetation was dominated by crested wheatgrass with \leq 5 percent alfalfa. As indicated in previous reports this is attributed to the early competition from fall rye with which these species were seeded. Canada bluegrass remained essentially absent.

<u>Seed Mix II</u> - There was almost no difference between topsoiled and non-topsoiled halves both showing 100 percent cover in both spring and fall. Vegetation was about half slender wheatgrass and half Russian wild rye. Sainfoin,

HC25

which was prolific in 1979 was almost absent this year; presumably it was outcompeted by the grasses.

<u>Seed Mix III</u> - There was essentially 100 percent cover with approximately half streambank wheatgrass and half smooth bromegrass. Legumes were absent except for the odd red clover plant on the perimeter of the plot.

<u>General</u> - Weeds were present but in small numbers on the topsoiled half of the plot, they did not appear to affect the agronomics. The degree of plant maturity and size of grasses of Seed Mix I and II was less than expected. This could be due to excessive competition or browsing by animals. The latter is clearly a possibility as a large number of deer droppings were noted on the plots.

(ii) <u>Baked Clay</u>

<u>Seed Mix I</u> - Overall cover improved from 50 to 75 percent in the spring to 100 percent in the fall. Alfalfa was present in minor amounts about the edges of the plot. Crested wheatgrass was the only grass present and accounted for most of the cover.

<u>Seed Mix II</u> - As with Seed Mix I the cover improved from 50 to 75 percent to 100 percent during the year. Slender wheatgrass accounted for the majority of this but good productivity and cover was also exhibited by Russian wild rye and sainfoin.

<u>Seed Mix III</u> - Streambank wheatgrass and smooth bromegrass both showed good cover with the former doing particularly well on the topsoiled half of the plot. Cover improved during the year although the topsoiled portion showed less

Photo 1. Aleece Lake - Baked Clay April 1980.

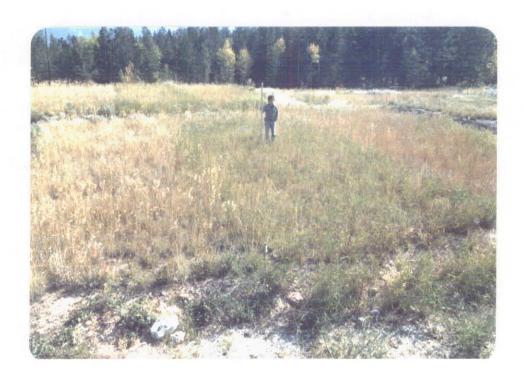

Photo 2. Aleece Lake - Baked Clay September 1980.

100

-

-

-

than 100 percent in the fall. Legume was present only about the plot perimeter.

(iii) Glacial Gravel

<u>Seed Mix I</u> - No major changes in cover were noted during the year with 75 to 100 percent cover on the non-topsoiled portion and 50 to 75 percent on the topsoiled area in September. Grass dominated in both cases although alfalfa showed improved performance in terms of size and maturity during the year especially on the bare material.

<u>Seed Mix II</u> - Cover improved towards 100 percent during the year with Russian wild rye the dominant species present. Sainfoin showed excellent performance accounting for about 30 percent of the cover.

<u>Seed Mix III</u> - This plot improved from the spring assessment of 50 to 75 percent cover to 75 to 100 percent cover in September. Grasses, streambank and smooth brome, dominated, the former better on the topsoil portion and the latter better on the non-topsoil side of the plot. Legume was present in limited quantities about the plot perimeter. Plants were mature.

(iv) Gritstone (Sandstone, Claystone)

<u>Seed Mix I</u> - This plot showed improved cover during the year with the topsoiled half approaching 100 percent cover by September. Crested wheatgrass accounted for almost all of this cover, alfalfa with 2 to 5 percent cover made up the balance.

<u>Seed Mix II</u> - Cover improved substantially over the year with 100 percent cover in the fall on the topsoiled portion.

Photo 3. Aleece Lake - Gritstone April 1980.

Photo 4. Gritstone September 1980.

HC25

Sainfoin was affected by the increased competition provided by slender wheatgrass and Russian wild rye. In the spring the legume appeared in abundance but by September it represented less than 5 percent of the vegetation cover. The two grasses were present in approximately equal quantities.

<u>Seed Mix III</u> - This portion of the plot showed clearly the advantage of even a thin layer of topsoil. Approximately 50 percent cover was present with many patchy areas on the non-topsoiled section while on the topsoiled half cover was close to 100 percent. The double cut red clover was present in small quantities at the plot edges. The two grasses, streambank and smooth brome were present in about equal quantities.

(v) Bentonitic Clay

<u>Seed Mix I</u> - The non-topsoil portion showed patchy cover of about 25 percent comprised almost exclusively of crested wheatgrass. The plants appeared healthy with a good level of maturity. The presence of topsoil was beneficial, cover was in the 50 to 75 percent range and uniform.

<u>Seed Mix II</u> - Overall cover did not change appreciably during the year. On the non-topsoil portion of the plot cover was approximately 25 percent and patchy. Vegetation consisted mostly of grasses with about 5 percent sainfoin. Plants appeared healthy and about half of the plants were mature. With topsoil the cover became more uniform and averaged about 75 percent. A similar species mix to that on the non-topsoil side was evident.

<u>Seed Mix III</u> - Cover on the topsoil portion improved slightly during the year to 75 percent with streambank wheatgrass dominating. Without topsoil, cover was patchy and

HC25

Photo 5. Aleece Lake - Carbonaceous Shale April 1980.

Photo 6. Aleece Lake - Carbonaceous Shale September 1980.

averaged about 50 percent. Grasses showed good maturity on both halves of the plot. Legume, double cut red clover, was essentially absent.

(vi) Carbonaceous Shale

<u>Seed Mix I</u> - Vegetation was essentially absent from the non-topsoiled portion of the plot while on the topsoiled half patchy growth of crested wheatgrass to an overall cover of 25 to 50 percent was present.

<u>Seed Mix II</u> - Non-topsoil side was bare of vegetation. Patchy growth ranging from 0 to 75 percent cover was present with topsoil. Dense patches the grasses on the topsoil showed good growth, although they had a low level of maturity. The patchy cover may be partially due to different thicknesses in the surface layer of topsoil. Sainfoin was present (<5%) only on the topsoiled portion of the plot.

<u>Seed Mix III</u> - Moisture appeared to have collected in a depression on the non-topsoil portion of the plot and resulted in a good catch of streambank and smoothbrome. Plants near this depression appeared healthy. The balance of the non-topsoil portion of the plot was bare. With topsoil the cover was 25 to 50 percent and more uniform. It was mostly streambank wheatgrass.

(vii) Coaly Waste

<u>Seed Mix I</u> - Without topsoil growth was patchy with overall cover to 25 percent comprised almost exclusively of crested wheatgrass; one large Canada bluegrass plant was present. Plants were relatively large in the fall and showed good maturity. With topsoil, cover increased to 50 to 75 percent and showed similar size and maturity to the non-topsoil area. Only crested wheatgrass was present.

<u>Seed Mix II</u> - Improved cover from previous years was evident although no major improvement was noted during the 1980 growing season. On the non-topsoil plot overall cover was about 25 percent although a large number of bare spots existed. With topsoil, cover improved both in uniformity and density to 25 to 50 percent. Slender wheatgrass dominated the vegetation with Russian wild rye and some sainfoin also present. Plants generally showed good maturity.

<u>Seed Mix III</u> - Vegetation on the non-topsoil portion of the plot improved slightly during the growing season less than 25 percent and patchy. With topsoil, cover was more uniform and averaged approximately 50 percent during the year. Streambank wheatgrass was the dominant species present with smoothbrome amounting to less than 10 percent of the cover.

(viii) <u>Fly Ash</u>

<u>Seed Mix I</u> - Cover improved on the non-topsoil side from 25 to 50 percent in the spring to 50 to 75 percent by fall. On topsoil, the vegetative cover remained at the same level throughout the year, 50 to 75 percent. Crested wheatgrass was the only species present on the bare materials, while on topsoil, alfalfa accounted for 5 percent of the cover. The grass exhibited reddish stems, possibly due to magnesium deficiency, and the legumes were chlorotic.

<u>Seed Mix II</u> - The non-topsoil portion of the plot was very poorly covered, less than 25 percent and patchy. Vegetation was present in clumps, mostly Russian wild rye, some of which appeared healthy while others were stunted. With topsoil, the cover was greatly improved, 75 to 100 percent, again

Photo 7. Aleece Lake Fly Ash - April 1980.

Photo 8. Aleece Lake Fly Ash - September 1980.

dominated by Russian wild rye. Sainfoin was present particularly around the edges of the plot. On both sides the Russian wild rye showed excellent maturity.

(c) Slope Test Plots

(i) Houth Meadows

<u>22° Slope</u> - Reclamation of the topsoiled half of the test plot continued to be less successful than the bare material. In early years native species, the seeds of which were transported with the topsoil, provided excessive competition to the agronomics seeded. This situation appeared to be changing, in 1980 crested wheatgrass accounted for 90 percent of the cover present on the lower portion of the topsoiled plot. On the upper slope, native weed still accounted for 80 percent of the cover. In both cases overall cover was less than 50 percent. Alfalfa was present but only in small numbers.

Without topsoil, cover and species diversity is much improved. The grass:legume ratio was approximately 1:1 (crested wheatgrass:alfalfa) and cover was up to 75 percent. Erosion was not evident.

<u>26° Slope</u> - The topsoiled plot showed marked improvement from 1979 with weeds accounting for less than 20 percent of the cover on both lower and upper slopes. Of the agronomic species planted crested wheatgrass was by far the most successful. Alfalfa was present but in limited quantities.

Without topsoil reclamation was excellent, 75 to 100 percent cover with close to a 1:1 grass:legume mix on both upper and lower slopes. On the upper slope there was a slight

dominance of alfalfa. The plots displayed good improvement during the 1980 growing season.

<u>30° Slope</u> - Both halves of the plot showed improvement during the year. On the topsoil side the lower slope showed about 50 percent cover in the fall, up from less than 25 percent in the spring. Grass:legume ratios were approximately equal with only a 5 percent contribution to total cover from weeds. Reclamation of the upper slope with topsoil was poor although improvements did take place during the growing season. Weeds accounted for 90 percent of the ground cover.

Without topsoil reclamation was satisfactory with up to 50 percent overall aerial cover. Plants were uniformly distributed and weeds were not significant. Grass and legumes were present in approximately equal proportions.

<u>General</u> - Overall the slope plots at Houth Meadows showed good reclamation on the bare material. Improvements were evident on the topsoil where the seeded agronomics were overcoming the competition from weed species. Nevertheless the non-topsoil slopes remained superior. Rodent activity and browsing occurred throughout the slopes which may have accounted for the indications of lower than expected plant maturity. Slopes showed no signs of waterborne erosion even though rainfall was greater than normal particularly in June.

<u>Parent Material</u> - The harrow seeded area of parent materials at Houth Meadows exhibited excellent reclamation cover which improved from about 50 percent in the spring to essentially 100 percent by fall. Crested wheatgrass and alfalfa were present at about 2:1 ratio. The grasses exhibited purplish stems, possibly indicative of phosophorus deficiency.

HC25

Photo 9. Houth Meadows Test Area April 1980.

Photo 10. Houth Meadows Test Area September 1980.

On the hydro seeded area, where in previous years alfalfa dominated, crested wheatgrass developed very well during 1980. The grass:legume ratio was 1:2 in the fall. Cover was essentially complete and similar to the harrow seeded area.

(ii) Medicine Creek

 22° Slope - An increase in cover and an improvement in legume (alfalfa) development occurred during the year. Cover averaged about 50 percent with less on the upper slope and more on the lower slope. Crested wheatgrass was dominant but Canada bluegrass was present in minor quantities.

 26° Slope - This slope showed excellent improvement over the year, progressing from approximately 25 percent to 50 to 75 percent cover. Legume development was limited especially on the upper half of the plot where it made up less than 20 percent of the vegetation. The dominant species was crested wheatgrass.

<u>30° Slope</u> - This slope displayed excellent reclamation with cover, in the fall, of 50 to 75 percent, improved from the spring assessment of 25 to 50 percent. Crested wheatgrass was the dominant species, alfalfa was present in minor amounts (5%) especially on the upper slope. Some fall rye was present presumably as a result of self-seeding.

<u>General</u> - The Medicine Creek slopes showed no signs of waterborne erosion. Rodent activity and browsing was extensive throughout the test area. Lower slopes generally exhibited a better catch and productivity of legume. A rust-type fungal infection was evident on crested wheatgrass and fall rye. This was manifest as oversized, black seeds on the spikes.

Photo 11. Trench A - 3160 Dump - Furrowed Area 4 - September 1980.

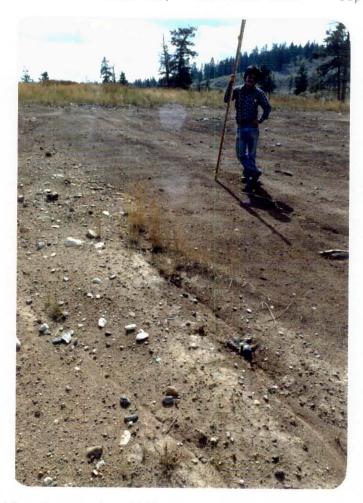

Photo 12. Trench A - 3160 Dump - Area 3 - September 1980.

(d) Trench A

(i) 3160 Carbonaceous Shale Dump

<u>3160 Dump Surface</u> - The carbonaceous shale dump surface was divided into five areas and reseeded in 1978. The areas and the seeding pattern are shown in Fig. 2-2.

Areas 4 and 5 were furrowed prior to seeding to provide improved moisture retention. Growth in the furrows was excellent and it seemed to be expanding along the furrows. The fine texture of the carbonaceous shale resulted in the progressive filling in of the furrows; however, this did not appear to have reduced plant growth in the furrows. Individual species sown have not developed in such a manner to warrant individual assessments.

Area 3 was seeded without any surface treatment, no topsoil or furrows. It was essentially devoid of vegetation except for the odd weed or where water had eroded a channel and grasses and growing in the channel.

Areas 1 and 2 were topsoiled (15 cm) prior to seeding but no furrows were created. In these two areas weeds developed rapidly and have provided appreciable competition to the agronomics. Relative abundance of agronomics and weeds, overall cover and cover type are shown in Table 2-3. Area 2 had fewer weeds and better growth of agronomics than Area 1 although no reason for this was evident. Growth on these areas showed a major improvement during 1980.

<u>3160 Dump Face</u> - The area graded to 26° showed poor growth during 1980 probably due to the erosion of this very fine textured and hydrophobic material. Large areas were essentially devoid of cover although those plants present

were large and displayed good maturity. Germination seemed to be the major problem with this material rather than any inherent toxicity.

The area left at its natural angle of repose of about 34° showed much better results. Erosion was not as much a problem since some coarse material present stabilized the surface. Cover approached 100 percent with an approximately 1:1 grass:legume mix. The upper quarter of the dump, which is carbonaceous material, was essentially bare.

(ii) <u>3140 Baked Clay Dump</u>

<u>3140 Dump Surface</u> - This dump displayed excellent reclamation with 100 percent cover. Growth during the year was excellent. The relative abundance of the agronomic species was as follows: smooth bromegrass 30 percent, crested wheatgrass 30 percent, slender wheatgrass 25 percent, sainfoin 10 percent and alfalfa 5 percent. All species showed good maturity and productivity. However, grazing by deer was extensive, particularly on the legumes.

<u>3140 Dump Face</u> - The baked clay dump face also showed very good reclamation. The area sloped to 26° had 100 percent cover, the area left at its natural angle of repose had 50 to 75 percent cover. Grass:legume ratio, that is crested wheatgrass:alfalfa, on the 26° slope was greater than on the natural dump, 3:1 and 1:1 respectively. Both areas showed. good plant maturity and biomass production. There was evidence of rodent activity and grazing by wildlife.

(iii) 3120 Baked Clay and Gritstone Dump

<u>3120 Baked Clay Dump Surface</u> - This area showed very good reclamation with 50 to 75 percent cover. The species mix was as follows: tall wheatgrass 80 percent, streambank wheat grass 10 percent, slender wheatgrass 5 percent and alfalfa 5 percent. Birdsfoot trefoil was absent. The alfalfa present was mostly at the edge of the area.

<u>3120 Gritstone Dump Surface</u> - This area had improved cover and biomass productivity although there were still substantial areas without vegetation. The overall cover was less than 25 percent. Crested wheatgrass dominated with the balance, which was less than 10 percent, alfalfa.

<u>3120 Gritstone Dump Face</u> - Reclamation on the slope graded to 20° was satisfactory with cover of 25 percent to 50 percent. Alfalfa was present but not abundant. On the 30° slope, vegetation was present predominantly along the equipment tracks. As with the 20° slope the vegetation was almost exclusively crested wheatgrass. The free dumped slope 38° was starting to fill in, although, overall cover remained poor at less than 25 percent. Again crested wheatgrass was the dominant species present.

(iv) Coaly Waste Pile

On the surface of the coaly waste pile the cover was patchy although there was improvement during the year. Overall cover in the fall was less than 25 percent. The slopes, particularly the north facing one, was much improved with cover to 50 percent in some areas. Biomass production was good and the vegetation appeared to be healthy.

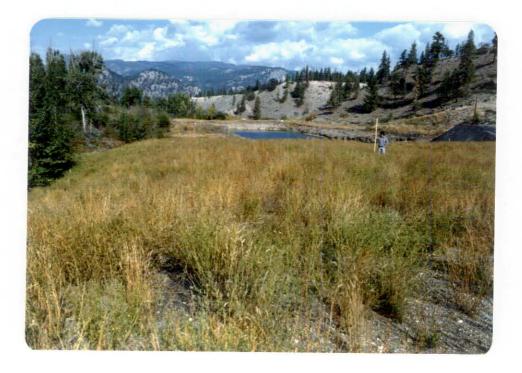

Photo 15. Trench B - Gravel Pile September 1980.

(e) <u>Trench B</u>

(i) Topsoil Pile

Vegetation on the topsoil pile was dominated by weeds. However, crested wheatgrass had progressed and accounted for up to 15 percent of the vegetation, a marked improvement over previous years. Overall cover was approximately 100 percent.

(ii) <u>Subsoil</u> Pile

This subsoil area showed excellent reclamation, 100 percent cover and good biomass production. Crested wheatgrass was the dominant species at 85 percent while alfalfa at 10 percent and Canada bluegrass at less than 5 percent made up the vegetation cover. This was one of the few areas where Canada bluegrass was found.

(iii) <u>Gravel Pile</u>

The harrow seeded area continued to display more complete reclamation than the hydro seeded area. Cover on the harrow seeded area was 75 to 100 percent with few bare patches. Biomass productivity was excellent. The proportion of alfalfa to crested wheatgrass was approximately 1:2. On the hydro seeded area, alfalfa showed excellent productivity and accounted for 55 percent of the vegetation. Overall cover was uniform in the range 50 to 75 percent.

(f) Trench C - Bentonitic Clay

The three waste dumps at Trench C were seeded and fertilized in the fall of 1978. In 1979 the three dumps were divided into five areas for the long term fertilization tests. The Trench C areas and the seeding pattern are shown in Fig. 2-5.

HC25

(i) Dump 1 Surface

Initial patchy growth on the topsoiled area improved greatly during the year and had 50 to 75 percent cover by fall. Some patches still remained. Species diversity was good, tall wheatgrass did particularly well and alfalfa showed good establishment.

Cover also improved on the bare material although many patches remained. Growth was good on the area surfaced with baked clay (for vehicle traction). Legumes were stunted and generally chlorotic as were some of the grasses. Overall cover was less than 25 percent.

(ii) Dump 1 Slopes

Patchy cover was present on the topsoiled slope with overall cover of less than 25 percent. The plants present were large. On the non-topsoiled slopes cover was not as good as the topsoiled area. Improvement occurred over the year. Tall wheatgrass showed good growth while legumes did not.

The relative abundance of agronomics and weeds on the Dump 1 plots are shown in Table 2-4.

(iii) Dump 2 Surface

Surface preparation before seeding at Dump 2 included the ploughing to create furrows to improve water collection. On both topsoil and non-topsoil areas the furrows proved most effective in promoting plant growth. Cover on the topsoil was uniform and approached 50 percent. Legumes success was limited while tall wheatgrass was the most successful of the grasses. On the bare material growth was essentially restricted to the furrowed areas. Overall cover was less

2 - 17

than 25 percent. In the furrows the vegetation showed good growth and the grasses were dominant.

(iv) Dump 2 Slopes

The non-topsoiled portion of the dump faces showed unexpected good growth, cover was 50 to 75 percent with excellent growth of both tall wheatgrass and alfalfa. On the topsoiled slopes there were many large patches without any vegetation.

The relative abundance of agronomics and weeds on the Dump 2 plots are shown in Table 2-5.

(v) Dump 3 Surface

The surface was seeded with individual agronomic species and with a seed mix. The individual species results are summarized in Table 2-6.

The area at Dump 3 that was seeded with Seed Mix VI showed mixed results. On the topsoiled area reclamation was excellent. Uniform cover approaching 100 percent was evident with the vegetation dominated by grasses. On the non-topsoil area, which previously had been essentially barren, several species appeared to be established. Plants were not as productive as on the topsoil but were in reasonable good condition. The overall cover was less than 25 percent.

(vi) Dump 3 Slopes

The topsoiled slopes did not do as well as the surface with topsoil. Vegetation was present in patches but where present there was good biomass production. Without topsoil growth was very patchy. In both areas the overall cover was less than 25 percent.

The relative abundance of agronomic and weeds on the surface and sloped areas of Dump 3, that were planted with Seed Mix VI, are shown in Table 2-7.

(g) <u>Drill Sites</u>

Reclamation of exploration drill sites and roads was completed in the fall of 1978.

During September 1980, 12 drill sites that were disturbed in different years were selected and the progress of reclamation evaluated.

In most instances reclamation has progressed well with drill sites in better condition than the surrounding native vegetation. Details of those drill sites inspected and photographs of some of the sites are given below. Data on ground cover, species and cover type are provided along with general comments concerning the reclaimed sites and surrounding area.

2.4 VEGETATION EVALUATION PLOTS

In April of 1980 a test area was established at Hat Creek in which all species of grasses and legumes used at Hat Creek could be grown and collected for preparation of museum samples. The area was located between the B.C. Hydro house trailer and the road, about 5 m north of the camp well (BAH77-01). This location was selected because it was close to the B.C. Hydro trailer (office), the soil appeared to be of good quality and there was water available for irrigation.

In mid April a 9 m x 9 m area was scarified using a backhoe, roto-tilled and then worked by hand to remove weeds, roots and large rocks. Twenty-five 1 m x 1 m square test plots raised about 20 cm above normal ground level were constructed in the 9 m x 9 m area and it was fenced with barbed wire to keep out grazing animals. The plots were fertilized with monoammonium phosphate (11-48-0), urea (46-0-0) and borate 68 (0-0-0-21) at rates of 140, 40 and 16 kg/ha respectively.

Each test plot was planted with a single species. The grasses and legumes were sown to achieve a uniform seed distribution of about 2150 seeds/m². Cuttings of willow and root cuttings from rose and poplar were also planted. Three cuttings each of rose and poplar were

planted immediately following sampling. A further three cuttings of each were stored in water for approximately 40 days and then planted out. The plots were weeded weekly and watered as required throughout the growing season.

The planting program for the vegetation evaluation plots is shown in Table 2-8.

During 1980, all of the grass and legumes germinated and grew well. The roses and willows also grew well. Only one of the six poplar cuttings grew. Vegetation samples were collected by Acres Consulting Services Limited on 8 July and 17 September. These were dried and preserved as museum samples in a booklet entitled "Reclamation Species Descriptions and Samples" prepared for B.C. Hydro by Acres Consulting Services Limited. No quantitative sampling to evaluate growth, biomass production or nutrient levels were carried out in 1980. The growth on these plots during 1980 is shown in the photographs in this section.

SECTION 3.0 - WATER QUALITY MONITORING

3.1 INTRODUCTION

Since 1977 several water quality monitoring programmes have been started to provide background data and to monitor possible effects of the mining activities on surface and groundwater quality in the Hat Creek area. During 1980 the following water quality monitoring programmes were conducted:

- <u>Surface Water Quality</u> samples were collected at five stations that were monitored in previous surveys.
- <u>Hat Creek Water Level</u> the level of water in Hat Creek adjacent to Trench B and in the Trench B excavation itself were measured throughout the year. The groundwater levels in drill holes near Trench B were also measured. Both of these monitoring programmes were started in the fall of 1979.
- <u>Groundwater Quality</u> groundwater samples were collected from three wells that were sampled in previous years and from one well which had not been sampled previously.
- 4. <u>Coliform Survey</u> samples were collected monthly from two stations in Hat Creek and from the B.C. Hydro camp well and analysed for total and faecal coliforms. This programme was initiated in the fall of 1979 and continued through 1980.
- 5. <u>Coal Waste Leachates</u> determination of the volumes and chemical characteristics of leachates from the two specially prepared coal waste piles was continued during 1980. Selected daily leachate samples were sent for detailed physical-chemical analyses.

 Surface Water Mercury Levels - in May 1980 monthly sampling of Hat Creek and the Bonaparte River was commenced to obtain samples for low level mercury analyses.

The procedures and results of the water quality monitoring programmes completed during 1980 are presented in this section. Where possible the current data is compared to that obtained in previous years.

3.2 SURFACE WATER

Surface water sampling has been carried out since 1977 to establish background water quality information in the Hat Creek area. During 1980 surface water samples were collected at five stations, three in Hat Creek, and in Medicine Creek and Aleece Lake. The locations of the sampling stations are as follows:

Hat Creek Station 1 - Immediately east of Hillman house.

- 2 Upstream of Trench B adjacent to the bunkhouses.
- 3 Approximately 0.5 km downstream of Trench B upstream of the Hat Creek Road bridge.
- Medicine Creek Approximately 6 km upstream of its confluence with Hat Creek.

Aleece Lake - Near centre of lake \sim 70 m from North shore. Radiochemical samples taken through ice \sim 7 m from shore.

Hat Creek stations 1 and 3 and Medicine Creek were sampled in previous years whereas Hat Creek station 2 was last sampled in 1977. The Aleece Lake station was a new sampling station established in 1980.

The water quality samples were collected from various stations by B.C. Hydro personnel in July, October and November. The samples were filtered and preserved in the field as required (following procedures detailed in the report by Beak Consultants Limited, May 1978⁵) and analysed at the B.C. Hydro research and development laboratory in Surrey. The radiochemical parameters were determined by Chemex Labs Ltd., North Vancouver.

The results of the surface water quality monitoring programme for 1980 and previous years are presented in Tables 3-1 to 3-5. As expected the surface water quality in Hat Creek and Medicine Creek has not changed significantly from that found in the previous surveys.

During the freshet in May and June, samples were obtained from Hat Creek and Medicine Creek for suspended solids and other analyses. Samples were collected from Hat Creek at its confluence with Anderson Creek, at the Highway 12 Hat Creek Road junction and from Medicine Creek about 1 km from the confluence with Hat Creek. Further samples were also collected on 12 August when the turbidity in Hat Creek was noticably increased. The samples were collected by B.C. Hydro personnel and frozen until delivered to the B.C. Hydro research and development laboratory for analyses.

The results of the solids surveys are presented in Table 3-6. The concentrations of suspended solids in Hat Creek were substantially higher than during the same period in 1979. This reflects the higher flows in Hat Creek during the 1980 freshet (peak flow $9.55 \text{ m}^3/\text{s}$ on 7 June 1980, measured at Upper Hat Creek); in 1979 the peak flow was only 1 m³/s. The high levels of suspended and dissolved solids on 12 August were caused by increased runoff after a short period of heavy rainfall.

3 - 3

3.3 HAT CREEK WATER LEVEL

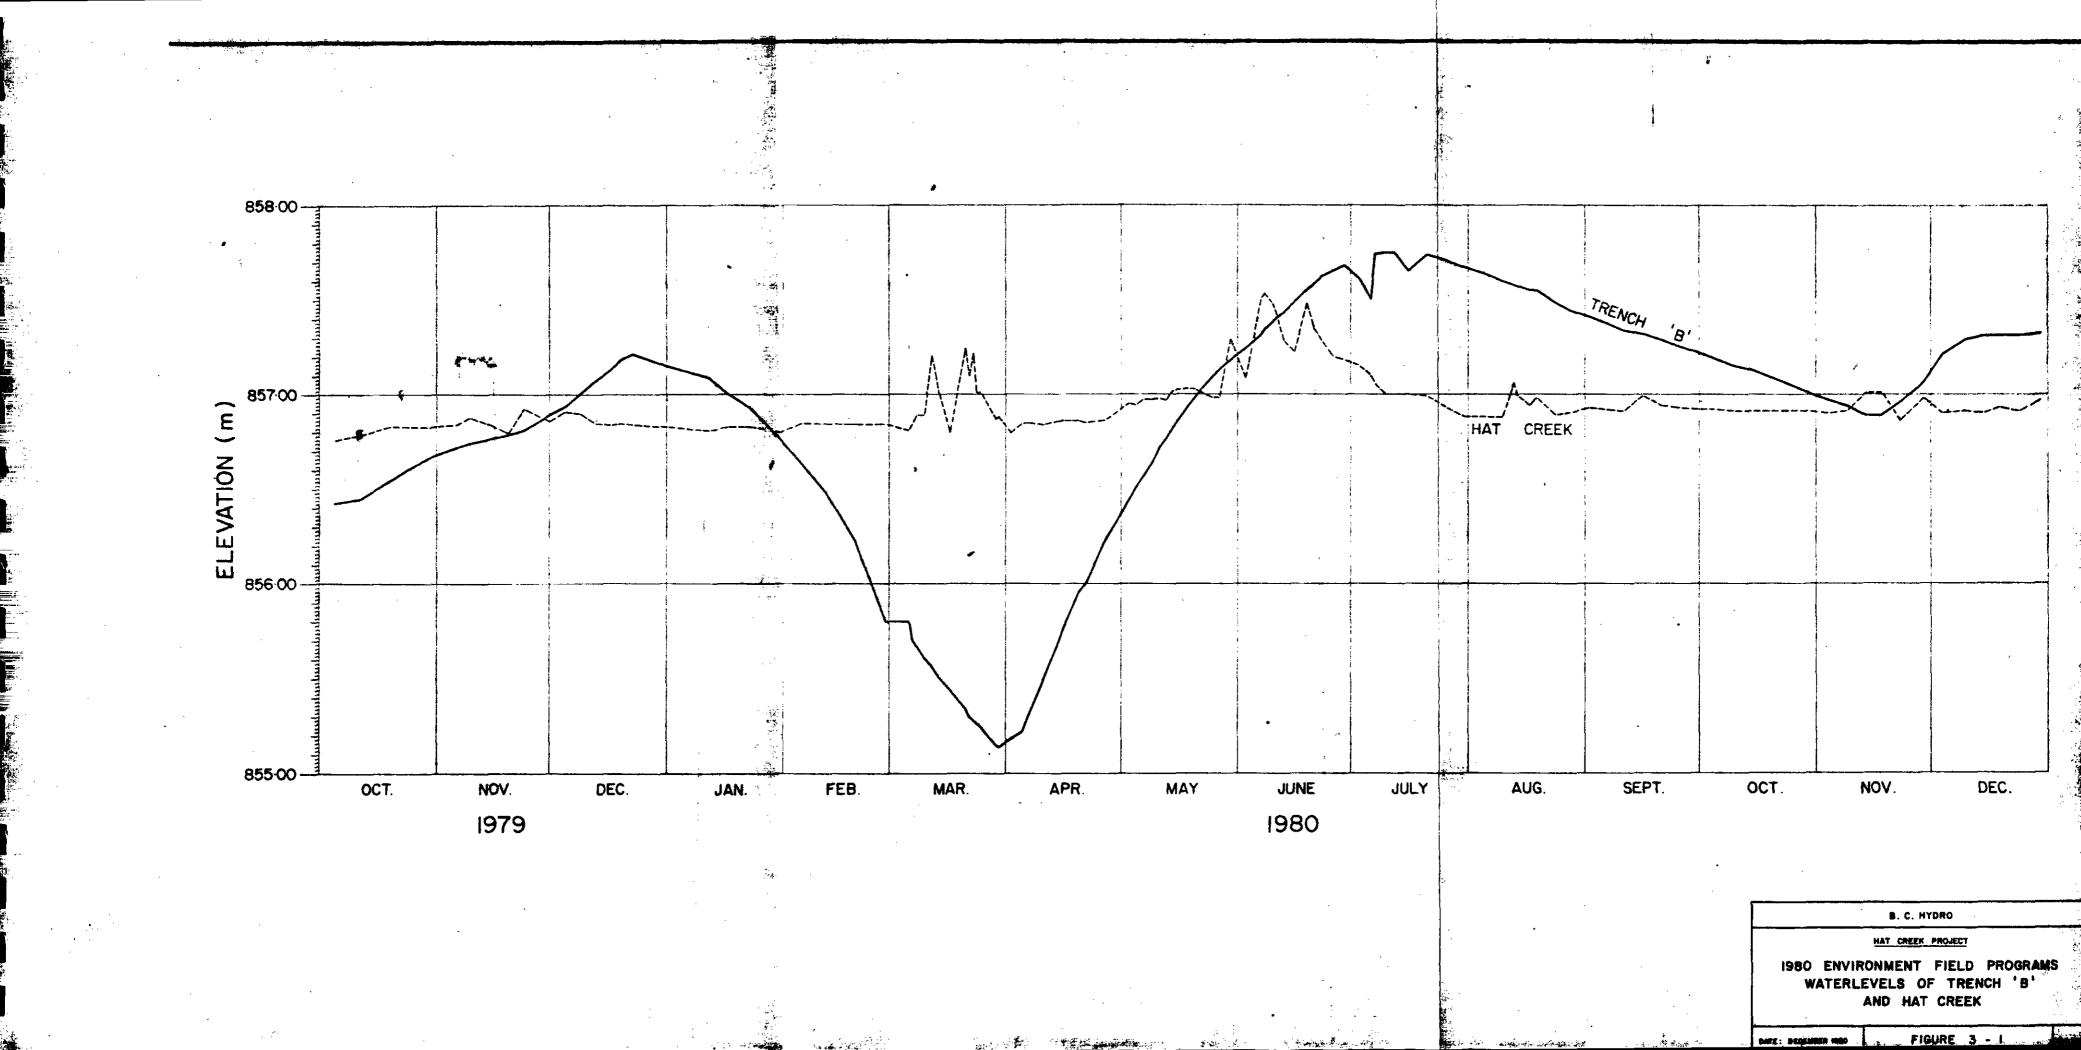

In October 1979 a monitoring programme was initiated to compare the water levels in Hat Creek and in the Trench B excavation which is adjacent to the creek. It was suggested that the flow in Hat Creek may be reduced by this excavation. This programme was continued during 1980.

Two measurement stakes were installed, one at the south end of Trench B in the middle of the excavation and the other on the west side of Hat Creek, directly west of the trench stake. The stakes were calibrated from a known benchmark. Water level readings were taken periodically during the year. When there was ice cover water level readings were taken through the ice.

The results of the water level monitoring are presented in Fig. 3-1 and in Table 3-7. The data indicate that the water levels in Hat Creek and the adjacent Trench B excavation move independently. The water level in Trench B varied over a range of about 2.5 m. The Hat Creek water level varied less than 0.8 m during the year.

The levels of groundwater in drill holes in the area of Trench B were also monitored during 1980. These results are shown in Tables 3-8 and 3-9.

The level of water in the Trench B excavation followed closely the level of groundwater found in nearby drill holes. The level of groundwater in drill hole R77-28, which is between the excavation and Hat Creek followed the water level in Hat Creek more closely and was probably influenced more by the creek than local groundwater. Analyses of the groundwater levels seems to indicate that water in the Trench B excavation is influenced by an aquifer which lies on the east side of the valley and south of the excavation, which slopes to the north-northwest. This aquifer may intersect with Hat Creek downstream of the excavation area.

Samples were frozen following collection. Suspended solids is now commonly called non-filterable residue. Dissolved solids is now commonly called filterable residue. 2

3.4 GROUNDWATER

On 13 July and 21 October water samples were collected from groundwater wells No. 2 and 3 near Trench B. The wells had been pumped out the previous day. The samples were preserved in the field and sent to the B.C. Hydro research and development laboratory in Surrey for analyses. Some of the samples were quite muddy and were very slow filtering. On 18 October a sample of water in the Trench B excavation was collected. preserved and sent for analyses. On 17 November, samples were collected from a well at the Steele Bros. limestone plant which is located beside Highway 12 about 4 km west of the Hat Creek - Highway 12 junction. This sample was taken from a tap after the water had run for about five minutes. This well had not been sampled previously in the B.C. Hydro monitoring programme. On 17 November water samples for radiochemical analyses were collected from groundwater wells No. 2 and 3 and from Trench B. The radiochemical samples were sent to Chemex Labs Ltd. for analyses. On 18 November samples for cyanide analyses were collected from groundwater wells No. 2 and 3, the Steele Bros. well and from Trench B. The cyanide samples were sent to the B.C. Hydro lab for analyses. All of the sampling was carried out by B.C. Hydro personnel.

The results of these analyses are presented in Tables 3-10 to 3-13. The 1980 results for groundwater wells No. 2 and 3 and Trench B were similar to the previous analyses.

3.5 COLIFORM SURVEY

In 1979 a programme was initiated to monitor background levels of coliform bacteria in Hat Creek and in the B.C. Hydro camp water supply well. This monitoring program was continued during 1980. Monthly samples were collected from three station; two surface water stations in Hat Creek near the Lehman ranch and near the B.C. Hydro trailer at Highway 12 and a groundwater sample from the B.C. Hydro camp well.

i

This well is in an aquifer about 12 m deep. The samples were collected in special sterile bottles supplied by the South Central Health Unit. The samples were sent to the Health Branch in Vancouver for analyses.

The results of the total and faecal coliform tests on Hat Creek samples are presented in Table 3-14.

Coliform bacteria were not detected in any of the monthly samples from the camp well.

The coliform levels in Hat Creek were variable but were generally higher during the warmer months. The December 1980 sample, which had higher coliform levels than normal at the station near Highway 12, may have been affected by runoff into the creek as temperatures were above freezing the week the sample was collected. The variable coliform levels in Hat Creek probably result from runoff from livestock grazing areas throughout the valley. According to provincial and other drinking water standards the waters of Hat Creek are not acceptable for human consumption without treatment.

3.6 WASTE COAL LEACHATES

During the Bulk Sample Program in 1977 two leachate collectors, made of plastic liners and perforated pipes, were placed on sloped ground near the Trench A excavation. A large pile of coaly waste material, which covers about 1050 m², was placed on one leachate collector and low grade coal, covering about 280 m², was placed on the other collector. Since 1978 the volume and physical-chemical characteristics of leachate from these two waste material piles has been determined. This monitoring programme was continued during 1980. From the spring thaw in March until December the daily volume of leachate was measured and pH and conductivity were determined. An unpreserved sample of leachate from the coaly waste pile was collected and sent for analyses on 8 July. On 20 October a second sample of coaly waste pile leachate was

collected and preserved before it was sent for analyses. These samples were analysed at the B.C. Hydro research and development laboratory in Surrey. The volume of leachate from the low grade coal pile was not sufficient to provide samples for detailed analyses (see Table 3-17).

The daily volume of leachate that flowed from each waste pile and the pH and conductivity of the leachate are presented in Table 3-15. Leachate began to flow from the coaly waste pile during the spring thaw in early April 1980. The daily volume of leachate collected during April, May and June was relatively constant at about 30 L/d. Near the end of June the daily volume of leachate from the coaly waste pile began to increase and reached a peak in mid July when over 100 L/d was collected. This increase is probably related to the abnormally high rainfall that occurred in early June and continued through most of the month. The monthly rainfall in June 1980 was almost five times the normal level. From mid July until the end of the year the leachate volume gradually decreased. Unlike previous years the leachate did not stop with the onset of freezing temperatures. During December about 40 L/d was collected. However, the early winter was mild with above freezing temperatures and rain during December.

The total volume of leachate collected from the coaly waste pile during the year was 14 300 L, more than ten times the volume collected during 1979. This volume represents over four percent of the precipitation which fell on the pile during the year. In 1979, the volume of leachate collected from the coaly waste pile was about 0.9 percent of the volume of rain which fell onto the pile. The reasons for this large increase are not evident. The pH and conductivity of the leachate were relatively constant throughout the year and were similar to values measured during 1979. The average 1979 and 1980 data are shown in Table 3-16. The leachate was clear and yellow in colour as it was in previous years.

AVERAGE CHARACTERISTICS OF COAL WASTE LEACHATES

The results of physical-chemical analyses of the leachates from the coaly waste pile are presented in Table 3-17. The trace metals and other cations showed a general increase in the 1980 results. Copper, lead and zinc levels were significantly higher than in previous years.

In 1980 the samples were analysed at the .B.C. Hydro research and development laboratory and by Beak Consultants Limited in previous years. A comparison of surface water analytical results for these two laboratories was carried out in 1978. The results from the two laboratories compared favorably, although the B.C. Hydro results tended to be higher than those from Beak. In 1979 and 1980 commercial fertilizers were added to the revegetation test plot on the coaly waste pile. The cation concentrations in the leachate may have been influenced by these chemical additions.

During March daytime temperatures were often above freezing and leachate from the smaller low grade coal pile began to flow in March, one month earlier than from the coaly waste pile. The volume of leachate from the low grade coal pile generally followed the level of rainfall more closely than the larger coaly waste pile. The daily volume of leachate from the low grade coal pile was very high during the heavy rains in June. The flow of leachate stopped in mid-October when freezing temperatures occurred, except for a small amount during the warmer temperatures in December. The total volume of leachate

collected during the year was 194 L, about three times that collected during 1979. This volume was about 0.2 percent of the rainfall that fell on the pile, the same ratio that was recorded in 1979.

The average pH and conductivity of the leachate from the low grade coal pile were 3.7 and 4000 μ mhos/cm respectively. The leachate was clear and colourless as in previous years. Physical-chemical analyses were not carried out on the leachate from the low grade coal pile during 1980.

3.7 MERCURY SAMPLING

Mercury is an important trace element with respect to potential environmental contamination. The minimum detectable concentration (MDC) in the procedure normally used for analysis of the Hat Creek environmental programme water samples is $0.25 \ \mu g/L$. During 1980 selected surface water samples were analysed using a more sensitive analytical procedure that had a MDC of $0.05 \ \mu g/L$. Commencing in May, monthly samples were collected for special mercury analyses.

Samples were collected from two sites; in Hat Creek about 2 km upstream of the confluence with the Bonaparte River, and in the Bonaparte River about 2 km upstream of Hat Creek. The samples were collected and preserved by B.C. Hydro personnel using special equipment and preservatives supplied by the provincial Ministry of the Environment, Environmental Laboratory in Vancouver. The samples were taken 7.5 to 15 cm below the surface. Total samples were presenved with 6 percent potassium dichromate and 6 percent concentrated sulphuric acid. Samples for dissolved mercury analyses were filtered through 0.45 micron filters before preserving chemicals were added. The samples were analysed at the Ministry of the Environment laboratory in Vancouver.

The results of these mercury analyses are presented in Table 3-18. Only five of the 32 samples analysed had mercury concentrations that were greater than 0.05 μ g/L, the MDC, and those five were close to the MDC. All four of the November samples had mercury levels greater than the MDC. Though whether this observation is real or an artifact of sampling and/or analytical procedure is in doubt. Overall, the results show that the mercury concentrations at these locations in Hat Creek and the Bonaparte River are very low.

SECTION 4.0 - METEOROLOGICAL AND AIR QUALITY MONITORING

In 1974 B.C. Hydro established a network of meteorological stations in the Hat Creek region to collect data for the initial project development studies. Since 1977 additional meteorological and air quality monitoring stations have been established to better define and document local atmospheric conditions. Collection of this information was continued during 1980 by the Environmental Services Section, Operations Group. An inventory of the meteorological and air quality monitoring program is presented in Table 4-1. These data, which are collected by B.C. Hydro and various consultants, have been reduced, varified and assembled by the Environmental Services group and are available from their files. TABLE 4-1
