Portable X-ray fluorescence to optimize stream sediment chemistry and indicator mineral surveys, case 1: Carbonatite-hosted Nb deposits, Aley carbonatite, British Columbia, Canada

Duncan A.R. Mackay and George J. Simandl

1 University of Victoria, School of Earth and Ocean Sciences, Victoria, BC, V8P 5C2

Abstract

The Aley carbonatite-hosted deposit is the most important Nb resource in the British Columbia alkaline province. Portable X-ray fluorescence (pXRF) was used effectively to determine concentrations of carbonatite pathfinder elements (Nb, Ta, La, Ce, Pr, Nd, Y, Th, U, Ba, and Sr) in stream sediments. Investigation of sediments of the unnamed creek (“Al creek”) draining the Aley carbonatite area, indicates that the + 250 µm, + 125 µm, and + 63 µm size fractions contain high concentrations of carbonatite pathfinder elements (Nb, Ta, La, Ce, Pr, Nd, U, and Th) relative to other size fractions. The + 125 µm fraction was chosen for systematic evaluation of the pathfinder element distribution in Al Creek sediments because it is suitable for chemical analysis and Quantitative Evaluation of Materials by Scanning electron microscopy (QEMSCAN). This method will be used in the second part of this study, which will concentrate on indicator minerals. The same samples enriched in pathfinder elements are expected to contain minerals characteristic of carbonatites such as pyrochlore, columbite-(Fe), fersmite, monazite-(Ce), rare earth element (REE)-bearing minerals, stream sediment, carbonatite, portable x-ray fluorescence, pyrochlore, fersmite, columbite.

Keywords: Niobium, tantalum, indicator minerals, pathfinder elements, stream sediment, carbonatite, portable x-ray fluorescence, pyrochlore, fersmite, columbite

1. Introduction

Carbonatites, carbonatite complexes, and their weathered equivalents are the main sources of Nb (Mariano, 1989a, b; Birkett and Simandl, 1999; Simandl et al., 2012, 2013a; Talanton-Niobium International Study Center, 2013). They are most common along rift zones in intracratonic settings (Woolley and Kjarsgaard, 2008). The Aley carbonatite is one of a series of carbonatite complexes, syenite complexes, and other alkaline rocks that forms the British Columbia alkaline province (Fig. 1; Pell, 1994). It lies 135 kilometres north of Mackenzie, British Columbia and 20 kilometres northeast of the Ospika Arm of Williston Lake, east of the Rocky Mountain Trench (Fig. 1) and was discovered following base metal exploration (Pride, 1983). It was the subject of further study and exploration over the next 30 years (Mäder, 1986, 1987; Pride, 1987a, b; Robert et al., 2005; Nethery, 2007; Chung and Crozier, 2008). The deposit has a measured resource of 113 million tonnes at 0.41% Nb₂O₅ and an indicated resource of 173 million tonnes at 0.35% Nb₂O₅ with a cutoff grade of 0.20% Nb₂O₅ (Taseko Mines Limited, 2013).

The main objectives of this study are to: 1) determine if stream sediment geochemistry can be used effectively to explore for Aley-type deposits; 2) establish the best stream sediment size fraction for indicator minerals that might point to Nb-bearing carbonatite deposits; 3) characterize the geochemical gradient of potential pathfinder elements (Nb, Ta, REEs, P, Ba, Sr, U, and Th) in sediments downstream from the deposit; and 4) evaluate the usefulness of pXRF analyses for preliminary assessment of indicator mineral and stream sediment studies.

2. Geological setting

Rocks of the British Columbia alkaline province were emplaced during three main events: ~ 800-700 Ma (postulated breakup of Rodinia), ~ 500 Ma (extensional tectonism and attenuation of the continental margin), and ~ 360-340 Ma (renewed extensional tectonics; Pell, 1994; Millonig et al., 2012). Multiple phases of deformation and associated sub-greenschist to amphibolite grade metamorphism overprinted the carbonatites between ~ 155 and 50 Ma (Pell, 1994; Millonig et al., 2012).

The Aley carbonatite cuts Lower to Middle Paleozoic sedimentary rocks of the western Cordillera foreland fold and thrust belt (Figs. 1, 2). The regional geology of the area was originally mapped at the scale of 1:253,440 by Irish (1970). The deposit is in the Cassiar terrane, which includes a platformal assemblage of siliciclastic and carbonate rocks...
that were deposited along the western margin of Laurentia (Mäder, 1986; Pell, 1994). The Kechika Formation (Cambrian to Early Ordovician) unconformably overlies the Rosella Formation (Lower Cambrian; Pyle and Barnes, 2001). It consists of argillaceous limestone, calcareous siltstone, and dolostone. The Skoki Formation (Lower to Middle Ordovician) is generally in fault contact with the Kechika Formation and consists of dolostone and volcanic rocks (Mäder, 1986). The Road River Group (Lower to Upper Ordovician-Silurian) caps the succession, locally unconformably overlies the Skoki Formation, and consists of cherty dolostone, shale, argillaceous limestone, and rare quartzite and quartz pebble conglomerate (Mäder, 1986; Pyle and Barnes, 2001). Regional metamorphism reached lower greenschist facies (Mäder, 1986) and coincided with convergent tectonism and orogenesis between ~155 and 50 Ma (Pell, 1994; Millonig et al., 2012).

The metasedimentary sequence was intruded by the Aley carbonatite, REE-bearing carbonatite dikes, the Ospika diatreme, and lamprophyre dikes (Fig. 2; Mäder, 1986; Pell, 1994; McLeish, 2013). Zircon from the dolomite carbonatite phase of the Aley carbonatite contains insufficient radiogenic Pb for U-Pb geochronology (Mäder, 1986; McLeish, 2013), but McLeish (2013) reported a U-Pb titanite age of 365.9 ± 2.1 Ma for the Ospika diatreme. The Aley carbonatite displays an early phase of deformation lacking in the Ospika diatreme indicating that it is older than ~366 Ma (McLeish, 2013). The Road River Group, (Lower to Upper Ordovician-Silurian, based on conodont biostratigraphy; Mäder, 1986; Pyle and
Fig. 2. Geological setting of the Aley carbonatite and locations of stream sediment samples. Yellow markers (A-B-C) denote location of profile in Figure 6. Modified after Pride (1983), Mäder (1986), Massey et al. (2005), and McLeish (2013). UTM zone 10, NAD 83.

Barnes, 2001), is the youngest unit overprinted by this early deformation that is cut by lamprophyre dikes (considered related to the Aley carbonatite and Ospika diatreme) suggesting that the Aley carbonatite is older than 366 Ma and younger than the Road River Group (McLeish, 2013).

3. Geology of the Aley carbonatite complex

The Aley carbonatite outcrops intermittently over an area 3 to 3.5 km in diameter (Fig. 2; Mäder, 1986). It intruded sedimentary host rocks as a sill and was subsequently folded within a recumbent nappe (McLeish et al., 2010; McLeish, 2013). The main phase of the carbonatite consists of layered or banded dolomite carbonatite surrounded by minor calcite carbonatite (Mäder, 1986). Kressall et al. (2010) observed that the dolomite carbonatite phase contains apatite, pyrite, calcite, and Nb-bearing minerals such as fersmite \([\text{[Ca, Ce, Na}} (\text{Nb, Ta, Ti})_2(\text{O, OH, F})_6]\), pyrochlore \([\text{[Na, Ca}}_2\text{Nb}_2\text{O}_9(\text{OH, F})]\), columbite-(Fe) \([\text{[Fe, Mn}}\text{Nb}_2\text{O}_6]\) and rare, fine-grained acicular aggregates of Nb-rich rutile \([\text{[Ti, Nb, Fe}}\text{O}_5]\). Pods or lenses of magnetite (10s of centimetres to metres in size) are found throughout the dolomite carbonatite phase and contain apatite, phlogopite, Nb-bearing minerals, zircon, and interstitial carbonates (Kressall et al., 2010). The magnetite pods likely represent deformed and distended cumulate layers (Kressall et al., 2010). Monazite commonly co-exists with fersmite in pseudomorphs after primary columbite-(Fe) or pyrochlore (Mäder, 1986; Kressall et al., 2010).

Massive fenite surrounds the carbonatite intrusion (Fig. 2). It displays a characteristic dark blue-green colour and contains abundant richterite, arfvedsonite, and aegirine (Mäder, 1986; Kressall et al., 2010). The fenite contains brecciated metasedimentary and feldspathic material. The feldspathic breccia clasts resemble altered syenite fragments; however, they are probably strongly fenitised and albited fragments of the Kechika Formation.

Carbonatite dikes exposed on the northwest ridge above the main deposit (Fig. 2) contain significant concentrations of light rare earth elements (LREE; Mäder, 1986). The LREE mineralisation consists of REE-bearing carbonates and fluorocarbonates (Mäder, 1986). The dikes probably represent late differentiated phases of the Aley carbonatite melt (Mäder, 1986).

4. Methods

4.1. Sample collection

Twelve stream sediment samples were collected from a creek (“Al”, Fig. 2) draining the Aley carbonatite during the 2013 field season (Table 1). One sample was collected upstream of the deposit to assess background geochemistry. Four samples, spaced 200 to 300 m apart, were collected along...
4.2. Sample preparation and portable XRF analyses

Samples were dried in an oven at 40°C, weighed, and dry sieved into + 4 mm, 2 mm to 4 mm, 1 mm to 2 mm, 500 μm to 1 mm, 250 μm to 500 μm, 125 μm to 250 μm, 63 μm to 125 μm, and - 63 μm fractions. To shorten the text and simplify figures, the following notation was used throughout for the same grain size intervals; + 4 mm, + 2 mm, + 1 mm, + 500 μm, + 250 μm, + 125 μm, + 63 μm, and - 63 μm. Each size fraction was weighed individually. Selected size fractions were split using a riffle splitter with a portion being kept as a witness sample, a portion for magnetic separation, and a portion for XRF analyses. Samples for XRF analyses were milled using ring and roller bowl tungsten carbide mills. Standard XRF sample pulp cups were then prepared and analysed by portable XRF. Analyses were carried out using a portable Thermo Fisher Scientific Niton FXL-950 instrument. A complete description of equipment, specifications, sample preparation, and laboratory methods and information about standards, operating procedures, instrument settings, limits of detections, and data quality control are in Luck and Simandl (2014).

The factory-calibrated pXRF data are internally consistent and have acceptable precision; however, they were not recalibrated using results of standard laboratory analyses [lithium metaborate inductively couple plasma mass spectrometry (LMB ICP-MS)] as described in Simandl et al. (2013b) to improve accuracy by correcting for matrix effects and analytical bias. For example, good accuracy is expected for La and Nb. Other elements (e.g. Sr) are underestimated.

the dry tributary of Al Creek directly over the deposit (Fig. 3). The remaining seven samples were collected along the creek, downstream from the deposit, 1.5 to 3 km apart as access allowed (Figs. 2, 4). The bed of the creek consists mainly of boulders, cobbles, and pebbles (Fig. 4). Sample sites included dry pools (Fig. 3), and the lee areas of boulders and fallen trees, and bars (Table 1). Matrix material between cobbles and boulders, generally from an area < 1 m², was sampled (Fig. 4; Table 1). Organic material (conifer needles, leaves, and twigs) was scrapped from the surface of samples sites. Not all of the organic material could be avoided during sample collection, and minor amounts were retained in the coarser fractions (+ 500 μm and coarser). Material was wet sieved through a + 8 mm screen, except where noted in Table 1. Weights for dried samples range from 4.1 to 21.8 kg. Sample AL-13-18B is a pre-concentrate (washed by hand using a pan) of stream sediment close to sample AL-13-18.

</table>
Remaining elements, including U and Th, are overestimated. Based on strong positive correlation between 11 U and 15 Th pXRF, and corresponding LMB-ICPMS analyses of stream sediments from Aley, Lonnie and Wicheeda (unpublished) processed in exactly the same manner as those in the present study, U and Th are overestimated of the order of 35% and 90% respectively. The pXRF is not a substitute for traditional laboratory methods where high accuracy and precision are required.

5. Results

Samples AL-13-02, AL-13-18, and AL-13-18B, were chosen for systematic study of all size fractions. The particle size distributions for samples AL-13-02 and AL-13-18 are skewed toward coarser size fractions, whereas AL-13-18B displays a nearly normal distribution (Fig. 5).

In samples Al-13-18 and AL-13-18B, Nb, Ta, Y, La, Ce, Pr, Nd, U, Th, and P are enriched in the + 125 μm, and + 63 μm size fractions relative to other sizes (Fig. 5). Similar trends exist for Al-13-02, however, the + 250 μm, and + 500 μm fractions also contain relatively high Nb, Ta, Y, La, Ce, Pr, Nd, U, and Th concentrations. Phosphorus is detectable in the + 125 μm fraction for AL-13-18 and AL-13-18B, but is below the limit of detection in the + 125 μm fraction for sample AL-13-02. High abundances of pathfinder elements (relative to other size fractions from the same samples) are also observed in the + 125 μm and + 63 μm size fractions in sediments from the nearby Lonnie (Luck and Simandl, 2014) and Wicheeda (Mackay and Simandl, 2014) carbonatite study areas. The + 125 μm fraction was chosen for systematic study because of these higher abundances and because it is a suitable size for indicator mineral studies.

The ranges in abundance of selected major oxides (Table 2) are: < 16.5 to 45.8 wt% SiO2, < 1.8 to 7.0 wt% Al2O3, 1.3 to 15.2 wt% Fe2O3, 10.9 to 31.8 wt% CaO, < 0.1 to 0.3 wt% TiO2, < 1.4 to 6.4 wt% MgO, and 0.2 to 2.6 wt% K2O. Concentration ranges for trace elements (Table 2) are: 15 to 9988 ppm Nb, < 7 to 166 ppm Ta, 14 to 170 ppm Y, 70 to 2010 ppm La, 115 to 2977 ppm Ce, 147 to 1579 ppm Nd, 80 to 661 ppm Pr, 140 to 910 ppm Ba, 177 to 2018 ppm Sr, < 90 to 9412 ppm P, < 1 to 62 ppm U, and 9 to 570 ppm Th.

6. Discussion

High concentrations of Nb, Ta, La, Ce, Pr, Nd, U, and Th in the + 250 μm, + 125 μm, and + 63 μm fractions (Fig. 5) probably reflect the presence of carbonatite indicator minerals. The highest values typically coincide with the Aley carbonatite (samples AL-13-04, AL-13-05, AL-13-06; Figs. 6, 7). As expected, relative concentrations as high as 9988 ppm Nb, 133 ppm Ta, 2010 ppm La, 2977 ppm Ce, 171 ppm Y, 44 ppm U, 570 ppm Th, and 2018 ppm Sr occur over or directly downstream of the deposit and decrease with increasing distance downstream to between 3495 and 3311 ppm Nb, 79 and 73 ppm Ta, 596 and 561 ppm La, 936 and 866 ppm Ce, 72 and 71 ppm Y, 35 and 26 ppm U, 266 and 251 ppm Th, and 827 and 711 ppm Sr (Figs. 6, 7; Table 2). Barium does not follow this trend, suggesting barite input from dolostones and argillaceous limestones of the Skoki and Kechika formations.

Samples taken immediately below slides (greater than 200 m²) and scree slopes (such as AL-13-07) show a decrease in the concentrations of Nb, Ta, La, Ce, Y, U, Th, and Sr relative to adjacent upstream (AL-13-06) and downstream samples (AL-13-02; Figs. 6, 7). This demonstrates the effect of dilution of pathfinder elements by incorporation of unmineralized material (unconsolidated overburden and slate and limestone scree). Sample AL-13-02, taken in an active stream channel, has higher concentrations of pathfinder elements relative to AL-13-07 (Fig. 6), possibly due to concentration of indicator minerals by winnowing. Sample AL-13-09, obtained upstream of the Aley carbonatite (Fig. 7), has low concentrations of carbonatite pathfinder elements relative to samples downstream of the deposit. Subrounded to subangular carbonatite, feniite, and diatreme boulders were found immediately downstream of AL-13-18 and AL-13-18B (Figs. 6, 7; Table 2). It is unclear if these boulders were derived from the Aley carbonatite or a different occurrence. Sample AL-13-16, downstream of this site, displays an increase in Nb, Ta, La, Ce, Y, U, Th, and Ba relative to AL-13-18 and AL-13-18B, which may be related to the boulders.

High coefficients of determination for pathfinder elements (Fig. 8) probably represent indicator mineral chemistry and mineral assemblages. The strong linear dependence between Nb and Fe2O3 (R² = 0.97; Fig. 8a) likely represents the coincidence of Nb-bearing minerals and magnetite in the stream sediments. Correlation between Nb and Ta (R² = 0.83; Fig. 8b) agrees with the expected presence of pyrochlore, columbite-(Fe), and/or fersmite in the stream sediments. The Nb:Ta ratio of pyrochlore and columbite-(Fe) from carbonatites is typically high and is reflected in the high (on average 50:1) Nb:Ta ratio of the sediments (Table 2). Niobium and La (R² = 0.81; Fig. 8c) display a strong relationship which is likely the result of coincidence of Nb-bearing and REE-bearing minerals in the stream sediments. It remains unclear if most of the REEs are in the crystal structure of Nb-bearing minerals rather than REE-bearing carbonates, fluorocarbonates, and/or phosphates. Poor linear dependence between Nb and TiO2 (R² = 0.20; Fig. 8d) is likely the result of low Ti concentrations expected in pyrochlore sourced from carbonatites. It may also indicate negligible concentrations of Nb-rutile in stream sediments, mirroring the low abundances in the deposit reported by Kressal et al. (2010). Samples AL-13-04, AL-13-05, and AL-13-06 have the highest Nb contents (Fig. 7-a-d) and fail to plot directly on the best-fit line (Fig. 8a). These samples were taken from a dry tributary of Al creek; the higher Nb contents might reflect reduced levels of fluvial reworking in an intermittent stream. Alternatively, they might be the consequence of local variations in the concentration of fersmite, columbite, and pyrochlore in underlying mineralisation.

Cerium correlates strongly with La (R² = 0.99) and well with Nd (R² = 0.95), Pr (R² = 0.94), and Y (R² = 0.85). This
is expected because REEs have similar physical and chemical properties and commonly substitute for each other in monazite, REE-bearing carbonates and fluorocarbonates, and Nb-bearing minerals. Strong correlation between Ce and Th ($R^2 = 0.90$) may reflect accumulations of monazite. Zirconium correlates well with Ce ($R^2 = 0.95$), Nd ($R^2 = 0.88$), and Pr ($R^2 = 0.87$), La ($R^2 = 0.86$), and Y ($R^2 = 0.82$) and may relate to concentrations of zircon and co-occurrence with REE-bearing minerals. As expected, a significant relationship exists between Th and U concentrations ($R^2 = 0.70$).

An unknown analytical error may explain < 90 ppm P values for samples collected from directly over the deposit (Figs. 6, 7), which contains local apatite (2-10%, Kressall et al. 2010). As P is a light element; it has to be present in high concentrations to be a useful pathfinder due to error induced by the matrix effects of Ca and Fe (Simandl et al., 2013b).

Lack of linear dependence between Sr and Ba ($R^2 = 0.06$) suggest that these elements are not present as a uniform barite-
Fig. 6. Downstream variation in carbonatite pathfinder elements concentrations (+ 125 μm size fraction) with increasing distance from the Aley carbonatite. Yellow star-fenite, carbonatite, and Ospika diatreme boulders. Green arrow-landslides. A thick layer of overburden is located downhill of the Aley carbonatite. Legend for geology is the same as in Figure 2. For location see yellow markers (A-B-C) on Figure 2. Fig. 7. Carbonatite pathfinder elements in creeks draining the Aley carbonatite complex. a) Location of samples and landslides (greater than 200 m$^2$). b) Nb and Ta. c) La, Ce, and Y. d) P, U, and Th. e) Ba and Sr. All concentrations in ppm. Concentrations of Nb, Ta, La, Ce, Y, U, Th, and Sr show a decreasing trend with increasing distance downstream of the deposit. Sample AL-13-07 shows the effects of significant dilution of source detritus. Sample AL-13-09 (upstream of the deposit) shows the background concentrations of trace elements.
Table 2. Relative concentrations of major and trace element analysed by factory-calibrated pXRF. Samples are listed in order of increasing distance downstream of the deposit. Concentrations in ppm excepted were otherwise indicated. The data are internally consistent but have not been recalibrated as described in Simandl et al. (2013b) to improve accuracy by correcting for matrix effects and biases. Based on strong positive correlation between 11 U and 15 Th pXRF, and corresponding LMB-ICPMS analyses of stream sediments from Aley, Lonnie, and Wicheeda (unpublished) processed in exactly the same manner as those in the present study, systematic overestimation of U and Th, of the order of 35% and 90% respectively, is expected. Total Fe as ferric oxide (Fe$_2$O$_3$).

Mackay and Simandl
celestite solid solution. Sr is commonly a minor constituent of aragonite and calcite and is found in higher concentrations in REE-bearing carbonates, fluorocarbonates, and strontianite. Ba is also common in some REE-bearing carbonates, fluorocarbonates, and barite. All these minerals were reported by Mäder (1986) from Aley deposit and/or associated dikes; however, barite input from non-carbonatite sources such as dolostones of Kechika and Skoki Formations is an alternative explanation.

Ongoing work using a Frantz isodynamic separator and modern laboratory methods such as EMP, LA-ICP-MS, and QEMSCAN, will provide quantitative information on the indicator mineral signature of the Aley carbonatite deposit. The use of QEMSCAN is favored over grain-picking because many potential carbonatite indicator minerals are difficult to identify under binocular microscope. The pXRF chemical analyses presented here will be compared to and calibrated against laboratory chemical analysis for major and trace elements in an attempt to confirm and better quantify our data.

7. Conclusion
Stream sediment geochemistry represents a valid exploration method for Aley type carbonatite deposits. Niobium, Ta, La, Ce, Pr, Nd, Y, Th, U, and Sr in combination with each other, or alone, are good pathway elements in stream sediments. The Ba signature of the Aley deposit, if present, is masked by barite derived from dolostones. As P is a light element, it has to be present in higher concentrations than the above elements to be a useful pathway. The + 125 μm size fraction of the stream sediments is a useful geochemical sampling media and the most promising candidate for study of carbonatite related indicator minerals using QEMSCAN methods. Based on this study and the mineralogy of the Aley deposit, pyrochlore, columbite-(Fe), and fersmite are expected to be useful indicators. Monazite, REE-bearing carbonates, and fluorocarbonates, and to some extent fersmite and apatite are also possible indicator minerals based on the mineralogy of the deposit and chemical composition of stream sediments. Factory-calibrated pXRF is a cost effective method for determining relative concentrations of key pathway elements, such as Ni, Ta, La, Ce, Y, Th, U, and Sr in stream sediments; however, without recalibration, depending on the element, analyses can be strongly biased (e.g. Th or U). Additional mineralogical studies using modern laboratory methods such as EMP, LA-ICP-MS, and QEMSCAN, are required to establish relative concentrations of indicator minerals in stream sediments with increasing distance from the carbonatite.

Acknowledgments
This project received funding and support from Targeted Geoscience Initiative 4 (2010-2015), a Natural Resources Canada program carried out under the auspices of the Geological Survey of Canada. Logistical and helicopter support by Taseko Mines Limited is greatly appreciated. Critical review by Pearce Luck (British Columbia Ministry of Energy and Mines), John Gravel (ACME Analytical Laboratories Ltd.), and Jeremy Crozier (Hunter Dickinson Inc.) greatly improved earlier versions of this manuscript. The authors would also like to thank Pearce Luck for his assistance with sample preparation and analyses.
