CAPSULE GEOLOGY

The property is underlain by siltstones, quartzites and phyllites of the Proterozoic Aldridge and Creston formations (Purcell Supergroup), intruded by a small quartz monzonite stock of possible Cretaceous age. the sediments adjacent to the intrusion have been altered to produce concentric zones of biotite hornfels and siliceous siltstone. mineralization in the form of molybdenite, scheelite, stibnite and galena occur in a narrow zone near the contact of the intrusion.

CAPSULE GEOLOGY

The True Blue is located east of Kootenay lake, 5 kilometres southwest of Kaslo. It was discovered and explored with 125 metres of underground workings near the turn of the century. Between 1898 and 1902, 96 tonnes produced 8544 kilograms of copper, 5629 grams of silver and 124 grams of gold.

A massive sulphide horizon, averaging 1.2 metres thick, occurs along the contact between volcanic (Permian Kaslo Group) and sedimentary (Upper Mississippian-Permian Milford Group) rocks. Mineralization consists of pyrite, pyrrhotite and chalcopyrite and minor galena and sphalerite hosted in sericite schist. Chip sampling averaged 6.75 per cent copper, 2.76 per cent zinc, 0.12 per cent lead, 37.7 grams per tonne silver, 0.9 gram per tonne gold and 0.05 per cent cobalt (GCNL #182 (September 22), 1998).

Sultan Minerals Inc. optioned the property in 1998 and drilled one hole in 1999.

CAPSULE GEOLOGY

The country rocks are argillite, quartzites, limestone and schists of the Upper Triassic Slocan Group. Small quartz stringers 1 to 15 centimetres wide occur in a steep dipping fracture zone in calcareous black argillite. These stringers carry small amounts of galena, sphalerite, tetrahedrite and argentite.

The property is located on the north side of Woodbury Creek about 6.4 kilometres by road from the main highway. Development work has apparently been confined to two periods, the first from 1938-40, the last in 1946. This was carried out by a number of different owners and leasers. Four adits have been driven on the fracture zone. The two upper adits are about 15.2 metres vertically apart and mineralized stringers occur in both. In the two lower adits the fracture zone is barren.

In 4 years from 1938 to 1946, 29 tonnes of ore were mined. From this ore 142,980 grams of silver were produced, 3,225 kilograms of lead and 889 kilograms of zinc.

CAPSULE GEOLOGY

The Jodi property is predominantly underlain by a northerly-trending sequence of argillite and quartzite units of the Mt. Nelson Formation. This assemblage abuts the older conglomerate unit of the Toby Formation to the west. Molybdenite mineralization occurs in a quartz-pyrite-minor molybdenite stockwork in quartzite and quartz monzonite.

The owner/operator of the Jodi/Sly project is a 50:50 joint venture of Barkhor Resources Inc. and Newen Enterprises Inc. They are testing the old Baker occurrence found and drilled by Cominco almost twenty years ago. Cominco had outlined a strong molybdenum-tungsten-zinc soil anomaly which is 200 metres wide and at least 1200 metres long. The 1997 drilling is systematically testing the area of the anomaly. By year end a total of about 2500 metres had been completed in nine holes on the property. The last seven holes which were drilled on the anomaly all contain visible molybdenite but the only assays reported so far are from the sixth hole in which a 29.0 metre interval averaged 0.0769 per cent molybdenum (Exploration in BC, page 49). The best molybdenite mineralization occurs in a stockwork of very thin quartz veins in a shattered, sericite-rich, phyllitic, white quartzite, which is interbedded with pyroxene-garnet skarn-altered dolomite containing disseminated scheelite. Aplite and quartz monzonite dikes and plugs are numerous and suggest that the altered Mt. Nelson rocks are underlain by an offshoot of the Cretaceous Bayonne batholith.

CAPSULE GEOLOGY

The host rocks of the Vigilant deposit are micaceous and chloritic schists, quartzites and limestones of the Middle Cambrian to Middle Devonian Lardeau Group. Some pegmatitic sills intrude the schist. Many steep fractures containing narrow widths of quartz occur. These veins locally contain lenses of galena with some sphalerite. Veins widths vary up to about 1 metre.

From 1949 to 1953, a total of 4684 tonnes of ore were mined from which 423,467 grams of silver, 62 grams of gold, 319 kilograms of cadmium, 381,669 kilograms of lead and 167,453 kilograms of zinc were recovered.

The Vigilant and Lulu claims lie to the east of Woodbury Creek, between the creek and the Ainsworth-Kaslo highway. The adjoining claims are the Zoa, Diamond Jubilee, Duplex No. 2 and the Dixie Fraction. The claims in this area were originally staked by the King Solomon Mining Co. Ltd. in about 1904. A small amount of exploratory work was done at this time and a few tons of sorted ore shipped. Most of the present claims are relocations of cancelled Crown-grants bearing same name.

All the above claims, along with the August Fraction and Nameless Fraction were obtained by Dr. L.D. Besecker of Woodbury Creek in 1949. This group of claims became known as the Woodbury Group. A lease on the property was obtained by Privateer Mines Ltd. later that same year. About 46 metres of tunnel was driven and 635 tons of ore shipped but the returns were less than expected and the operation was abandoned.

In 1950 J.A. Cooper obtained the Vigilant and Zoa claims on a lease-purchase agreement. On the Vigilant claim, two adits, 190 metres above the creek on the east bank are collared 5 metres apart and follow two steeply dipping quartz veins in a general easterly direction. The veins join and the two adits come together about 12 metres in. The old adits were found to contain replacement ore. Stopping was done over a 46 metre length in the old adit and the tunnel was extended to a total length of 88 metres. Another adit was collared 30 metres above the old adit and the tunnel driven for 96 metres. The vein narrowed toward the face of the tunnel but near the portal it warranted stopping through to the surface. Work on this

MINFILE NUMBER: **082FNE005**

CAPSULE GEOLOGY

claim ceased in 1953. The present tunnel faces are somewhere near the claim boundary.

On the Lulu claim the extension of the fissure vein developed on the adjoining Vigilant claim was traced along strike. An adit was driven to a point below a good surface exposure but the vein was almost barren at this horizon.

On the Dixie Fraction claim some trenching and shallow tunneling was done to investigate a vein which is exposed on the adjoining Budweiser No. 2 claim.

CAPSULE GEOLOGY

The country rocks are chloritic schist, quartzites, limestones and paragneisses of the Cambrian to Devonian Index Formation (Lardeau Group). The ore occurs in quartz veins and as replacement bodies adjacent to the veins. The veins have a general east-west strike and vary in width from 2 to 45 centimetres. The Nameless Fraction has two veins situated about 14 metres apart. The best showing of ore is an oreshoot 60 metres long and averaging 45 centimetres.

From 1950 to 1953, a total of 2792 tonnes of ores was mined from the Nameless deposit. From this 154,954 grams of silver, 165,014 kilograms of lead and 107,408 kilograms of zinc were recovered.

The claims are located on a bluff at the lake shore about 0.4 kilometre north of the mouth of Woodbury Creek. The August Fraction, Zoa, Lulu, Dixie Frac Fraction, Vigilant, Budweiser and Superior are all relocations of cancelled Crown grants bearing the same names. These claims were originally staked by the King Solomon Mining Co. in the early 1900s but very little work was done on them at that time.

Dr. Besecker obtained the Zoa, Lulu, Dixie Frac., Vigilant, Diamond Jubilee, Duplex No. 2, August Frac. and Nameless Frac. claims in 1949. These came to be known as the Woodbury Group. Privateer Mines Ltd. held an option on this group of claims for a year. During the following years the August Frac. was worked by Dr. Besecker while the Nameless Frac. was under lease to C.A. McLeish and V. McCulloch of Kaslo. Dr. Besecker drove a 61 metre tunnel on a fissure vein, known as the "A" vein, which is about 114 metres south of the "B" and "C" veins of the Nameless Fraction.

On the Nameless Fraction claim two adits were collared above the high water mark. The adit on "B" vein was extended for 8709 metres. Near the end of the drift a raise was put up about 15 metres in low grade replacement ore. Ore was removed from the floor of the tunnel by means of an incline that starts just inside the portal and extends for 36 metres at an angle of about 25 degrees. The adit on "C" vein was extended until it joined the adit on "B" vein at about 30 metres from both portals. This property was abandoned early in 1953 after taking some ore from a sublevel at the bottom of the incline. The lower workings are now flooded.

CAPSULE GEOLOGY

This group of claims is located near the mouth of Woodbury Creek. Originally staked by the Canadian Pacific Mining & Milling Co. of Minneapolis in 1896, the group consists of the Amazon, Budweiser No. 2, Superior and Wakefield claims. Three tunnels were driven on the Budweiser claim, one on a fault plane, the other two along fissures. On the Amazon claim a 36.5 metre tunnel was driven on a vein dipping 70 degrees to the south. On the Wakefield claim a 43 metre shaft was put down on a vein containing galena and gold. Apparently no further work was done on this property for about 40 years. In 1939 the owner of the Amazon claim is recorded as J.R. Tuikess of Kaslo. By 1941 ownership of this claim had passed to T. E. Levasseur of Nelson. A leasee worked the property that summer, obtaining 286 tonnes of ore from the old workings.

The Kaslo Base Metals Co. of Vancouver obtained the Budweiser No. 2, Amazon, Superior and Superior Fraction claims in 1951. They did some exploratory work on the Amazon and Budweiser No. 2 claims. The property was taken over by the Woodbury Mines Co. Ltd. in 1952. A tunnel was begun on the Superior claim just above the highway, the proposal being to drive 366 metres of tunnel in order to intersect several veins at a lower depth. By the end of the following year about 244 metres of the proposed tunnel had been completed. The project was abandoned by this company and no further work was done on it until 1956 when the property was taken over again by Kaslo Base Metals Co. Ltd. The exploratory tunnel was extended by 56 metres. At 276 metres from the portal a new vein was intersected. It contained 7 to 10 centimetres of galena and replacement ore extended into the walls to a width of 0.6 metre. At 302 metres from the portal the downward projection of a fissure vein exposed in Woodbury Creek canyon was intersected. This vein had been followed by old drift workings which extended east and west from the canyon 43 and 1 metres respectively. A raise was driven from the Superior tunnel to the west drift, 4.5 metres vertically above. No further work has been done.

Quartz tension veins occur in the Middle Cambrian Index

CAPSULE GEOLOGY

Formation ('Early Bird Formation') (Lardeau Group). Calcareous mica schist cuts a lamprophyre dyke. Other veins are in a dolomitized area. The veins are short, en echelon down dip. The rake of the ore is to the east 70 degrees as derived from a slope area and bearing of a calcite vug. A garnet mica schist with Meta autunite is present near the portal.

In 3 years between 1939 and 1965 a total of 2,987 tonnes of ore were produced. From this 83,388 grams of silver, 93 grams of gold, 274 grams of cadmium, 39,733 kilograms of lead and 54,306 kilograms of zinc were produced.

CAPSULE GEOLOGY

The Noah deposit is hosted in schist, quartzite and limestone of the Middle Cambrian to Middle Devonian Index Formation, Lardeau Group. Quartz and galena occur in a fissure vein that varies in width up to 25 centimetres. Ore, varying in width up to 60 centimetres occurs in limestone adjacent to the vein.

In 1952, 349 tonnes of ore was mined and 15,614 grams of silver, 14,696 kilograms of lead and 9,444 kilograms of zinc were recovered.

This claim is located on the lakeshore just South of Woodbury Creek. It was Crown granted to the King Solomon Mining Co. in 1904 but apparently was not worked prior to 1951. Western Mines Ltd. acquired the claim, along with the Florence, and a number of others, and did a small amount of development work on it during 1951-52. A 9-metre adit was driven 6 metres below the highway in an effort to intersect a fissure vein exposed on the hillside above. During 1952 the adit was extended to a length of 5 metres.

CAPSULE GEOLOGY

The Wakefield showing is underlain by the Early Bird Formation, equivalent to the Middle Cambrian to Middle Devonian Index Formation (Lardeau Group). Several quartz-siderite veins in limestone host galena, sphalerite and pyrite. The bedding of the formation strikes nearly north-south and dips westerly at about 45 degrees. The veins cut across the formation at right angles and dip steeply south. The property was first developed in the 1890s and at least three main veins have been developed by tunnels. A Sample from one of the tunnels assayed 11.40 per cent lead, 6.90 per cent zinc and 99.43 grams per tonne silver across 70 centimetres (Starr, 1952 (Property File)).

This group of claims is located near the mouth of Woodbury Creek. Originally staked by the Canadian Pacific Mining & Milling Co. of Minneapolis in 1896, the group consists of the Amazon, Budweiser No. 2, Superior and Wakefield claims. Three tunnels were driven on the Budweiser claim, one on a fault plane, the other two along fissures. On the Amazon claim a 36 metre tunnel was driven on a vein dipping 70 degrees to the south. On the Wakefield claim a 43 metre shaft was put down on a vein containing galena and gold. Apparently no further work was done on this property for about 40 years. In 1939, the owner of the Amazon claim is recorded as J.R. Tuikess of Kaslo. By 1941, ownership of this claim had passed to T. E. Levasseur of Nelson. A leasee worked the property that summer, obtaining 286 tonnes of ore from the old workings.

The Kaslo Base Metals Co. of Vancouver obtained the Budweiser

CAPSULE GEOLOGY

No. 2, Amazon, Superior and Superior Fraction claims in 1951. They did some exploratory work on the Amazon and Budweiser No. 2 claims. The property was taken over by the Woodbury Mines Co. Ltd. in 1952. A tunnel was begun on the Superior claim just above the highway, the proposal being to drive 366 metres of tunnel in order to intersect several veins at a lower depth. By the end of the following year about 244 metres of the proposed tunnel had been completed. The project was abandoned by this company and no further work was done on it until 1956 when the property was taken over again by Kaslo Base Metals Co. Ltd. The exploratory tunnel was extended by 56 metres. At 276 metres from the portal a new vein was intersected. It contained 7 to 10 centimetres of galena and replacement ore extended into the walls to a width of 0.6 metre. At 302 metres from the portal, the downward projection of a fissure vein exposed in Woodbury Creek canyon was intersected. This vein had been followed by old drift workings which extended east and west from the canyon 43 and 1 metres respectively. A raise was driven from the Superior tunnel to the west drift, 4.5 metres vertically above. No further work has been done.

CAPSULE GEOLOGY

The Silver Glance area is underlain by schist and limestone of the Mississippian to Lower Permian Milford Group. Several quartz-bearing fissures are mineralized with galena, sphalerite, pyrite and marcasite. Assays from 1896 are reported to be high in silver and gold.

No record of production exists but the Annual Report for 1898 mentions that 163 tonnes was sorted for shipment.

This group of claims lies along the western edge of the Highland and Florence properties and covers an area extending from near Cedar Creek to the South Fork of Woodbury Creek.

The group consists of the Hercules, Sullivan, Noranda, Silver Bell, Glen Ellen, Harrison, Free Silver and Silver Glance claims. Three of the claims, formerly called the Pataha, Bugaboo and Ellen were relocated in 1951 under the respective names of Hercules, Sullivan and Noranda.

Most of the development work on the Hercules claim was done about 1890. The workings now consist of 36.5 metres of tunnel in two adits, a shaft 4.5 metres feet deep and some trenching. On the Sullivan claim a 23 metre shaft was put down about 1895. Apparently no work has been done on the Noranda claim. Nubar Mines Ltd. of Toronto hold an option on the claims in 1951 and are reported to have done some diamond drilling. The Asbestos-Corporation Ltd. did about 914 metres of diamond drilling in 30 holes in 1952. The results of this work have apparently not been released by the company.

The Silver Glance claim, which lies astride the South Fork of Woodbury Creek, about 3 kilometres from its mouth, has had the most development work done on it. The property was located in 1896 and was apparently worked intermittently for about 4 years. A tunnel at creek level follows the vein in a 110 degree direction for 66 metres. Here the vein splits and is followed by two branches of the tunnel, one going 85 degrees for 23 metres, in which the vein appears to pinch out, the other branch extending for 18 metres at 110 degrees with the vein still in the face.

In 1952 Guichon Mine Ltd., owners of the Buckeye claim, held an option on all the above claims, however their work was apparently confined to the Buckeye.

CAPSULE GEOLOGY

This group of claims lies along the western edge of the Highland and Florence properties and covers an area extending from near Cedar Creek to the South Fork of Woodbury Creek. Refer to the Silver Glance group (082FNE010) and the Noranda (082FNE038) for details of the deposit description.

The group consists of the Hercules, Sullivan, Noranda, Silver Bell, Glen Ellen, Harrison, Free Silver and Silver Glance claims. Three of the claims, formerly called the Pataha, Bugaboo and Ellen were relocated in 1951 under the respective names of Hercules, Sullivan and Noranda.

Most of the development work on the Hercules claim was done about 1890. The workings now consist of 36.5 metres of tunnel in two adits, a shaft 4.5 metres feet deep and some trenching. On the Sullivan claim a 22.8 metre shaft was put down about 1895. Apparently no work has been done on the Noranda claim. Nubar Mines Ltd. of Toronto hold an option on the claims in 1951 and are reported to have done some diamond drilling. The Asbestos-Corporation Ltd. did about 914.4 metres of diamond drilling in 30 holes in 1952. The results of this work have apparently not been released by the company.

The Silver Glance claim, which lies astride the South Fork of Woodbury Creek, about 3.2 kilometres from its mouth, has had the most development work done on it. The property was located in 1896 and was apparently worked intermittently for about 4 years. A tunnel at creek level follows the vein in a S 70° E direction for 65.6 metres. Here the vein splits and is followed by two branches of the tunnel, one going N 85° E for 22.8 metres, in which the vein appears to pinch out, the other branch extending for 18.2 metres S 70° E with the vein still in the face.

In 1952 Guichon Mine Ltd., owners of the Buckeye claim, held an option on all the above claims, however their work was apparently confined to the Buckeye.

CAPSULE GEOLOGY

The Crown occurs at the contact of grey and white limestone with dark grey to black limey argillite. The area is mapped as rock of the Missippian to Lower Permian Milford Group. The property was developed by two adits and a number of open cuts.

The No. 1 adit follows closely spaced branching faults that strike northwest and dip steeply southwest. Locally they carry white quartz and pyrite. The No. 2 adit follows the contact of argillite and limestone. Gossanous rock is exposed in the adit and trenches to the north. This gossan contains a few narrow calcite-siderite veins and locally minor pyrite, galena and sphalerite. The workings from which gossanous rock run 3291 grams per tonne silver were collected are located 100 metres south of adit No. 2 (Bulletin 53).

In 4 years from 1962 to 1972, 139 tonnes of ore were shipped from the Crown property. From this ore, 158,377 grams of silver, 4,477 kilograms of lead and 5,961 kilograms of zinc were recovered.

CAPSULE GEOLOGY

The Gallagher property, located 2.5 kilometres west of the Florence townsite, was worked from 1888 to 1890 and again from 1907 to about 1920. A number of shafts and open pits and one adit were excavated.

The property occurs in a thick mass of fine-grained grey and white limestone of the Mississippian to Lower Permian Milford Group. Production has consisted of high-grade silver ore, mainly from pods of rusty gossan near the surface. One pit exposed a narrow sheared zone striking 050 degrees and dipping 30 degrees to the north along which galena and minor chalcopyrite are scattered. One of the dumps contain blocks of vein calcite with clusters of galena and reddish sphalerite.

CAPSULE GEOLOGY

The country rock of the Buckeye area is reported to be argillite, limestone, quartzite and schist of the Mississippian to Lower Permian Milford Group. The ore is associated with a system of northwest striking fissures but occurs as replacement in the north-south striking limestones in the zones of intersection. The ore consists of pyrite, sphalerite, galena and their oxidation products in a gangue of silicified limestone, calcite and quartz.

In 1953 and 1954, a total of 498 tonnes of ore was mined, from which 35,644 grams of silver, 25,902 kilograms of lead and 24,578 kilograms of zinc were recovered.

The Buckeye and Buckeye No. 2 claims are located north of Cedar Creek and just to the west of the Highland property (082FNE015). They were Crown granted to Dalglish and Parker in 1904 and have been worked infrequently since that time.

Development work in 1918 consisted of 2 inclined shafts, 30 metres apart, each about 12 metres deep, and one tunnel 61 metres long driven in under the shafts. The tunnel, which is about 23 metres below the surface showings, was driven as a crosscut for 21 metres. At that point a body of zinc ore was intersected and followed for 14 metres. A second tunnel, driven 30 metres below the outcrop was not extended far enough to reach the limestone.

Guichon Mine Ltd. acquired the claims along with an option on the Silver Bell, Ellen Glen, Free Silver, Harrison and Silver Glimmer. In 1952 the main adit was extended along what appears to be the most easterly of three narrow cross-fissure veins in echelon to the northwest. Two narrow, bedded fissure veins appear to displace the cross-fissure for a metre at 12 and 73 metres respectively from the portal. At 73 metres from the portal a raise was driven 24 metres to connect with the bottom of one of the shafts. A sublevel was started 12 metres below the surface and replacement ore, to a width of 4.5 metres, was mined adjacent to the shaft. Diamond drilling completed during the year amounted to 287 metres in 9 holes. In 1954 leasers drove a short drift to investigate the diamond drill results.

CAPSULE GEOLOGY

The Highland claim, Crown granted to J.C. Rykert in 1891, is located about 1.6 kilometres west of Kootenay Lake and 300 metres north of Cedar Creek, at about the 900 metre elevation. A main haulage tunnel was driven on the vein for about 207 metres. A second tunnel, 30 metres above the first, was driven for 27 metres. A raise was driven on an ore shoot connecting the two tunnels.

The Highland Mining Co. Ltd. of London, England, took over the claim in 1900 and worked it through 1904. In 1905 the property was leased to P. Burns and Co. The Highland-United Co. secured a lease on the mine in 1909 and operated it for part of the year. In 1910 the mine was reopened by the Kootenay Silver Lead Mines Ltd. of Vancouver and their operations continued through 1912.

The Consolidated Mining & Smelting Co. Ltd. acquired the property in 1914 and operated it more or less continuously for the next 13 years. Development work in 1919 included 998 metres of diamond drilling. The mine closed in 1927 and remained idle until 1940 when lessors became interested in working it. The tailings dump was dredged from Kootenay Lake and shipped to the mill. Other groups of leasers removed ore from the old mine workings in 1950-52.

In 1956 Cominco did 600 metres of diamond drilling to check on electromagnetic results. The workings at the present time consist of 5 tunnels along the strike of the vein, the upper three approximately 30 metres apart and two lower about 61 metres apart, thus giving a depth of 214 metres below the outcrop. The total length of the workings is approximately 4000 metres, part of this being on the

CAPSULE GEOLOGY

adjoining Josephine claim.

The Highland occurrence is hosted by micaceous quartzites of the Mississippian to Lower Permian Milford Group and hornblende schists of the Permo-Triassic Kaslo Group. The rocks are cut by bedding-parallel "mica" or "non-mica" dykes (lamprophyres). Close to the veins, hornblende schists and dykes are highly altered to soft whitish yellow material and quartzites are silicified.

The vein system consists of a series of related discontinuous faults with senestral lateral displacements of 3 to 40 metres. The faults with largest displacement appear to contain more ore. The orebodies occur as tabular masses located preferentially close to the hornblende schists-quartzite contact. Wall rock of hornblende schists are badly decomposed whereas those in quartzite are regular and well defined. Good ore shoots in hornblende schist pass rapidly to narrow and less mineralized veins in the quartzites. The ore consists of coarse to fine-grained, sheared galena with locally abundant sphalerite in banded, comb-textured to massive quartz with some siderite and locally fluorite.

From 1896 until 1954, 88,127 tonnes of ore was mined from the Highland. Commodities recovered included 10.5 million grams of silver, 9.4 million kilograms of lead, 0.38 million kilograms of zinc, 548 kilograms of cadmium and 62 grams of gold.

CAPSULE GEOLOGY

This Kootenay Florence property lies along the west side of Kootenay Lake between Cedar Creek and the South Fork of Woodbury Creek. The mining operations have been confined largely to the Florence Fraction, Laura M., Twin, Hope Fraction and Illinois claims.

Some of these claims were staked as early as 1899 but apparently little development was done until 1911. The Florence Mining Co. of Spokane took over the property in 1912 and operated it more or less continuously until 1923. Five levels were established, the lowest one (No. 5) was the main haulage level. Considerable stoping was done between No. 5 and No. 4 levels and above No. 2 level. Leasers operated the mine in 1923-24.

In 1926 the Kootenay-Florence Mining Co. Ltd. acquired 18 claims in the area, including those listed above. A new low level tunnel (No. 9 level) was driven for 2433 metres to explore the downward continuation of the orebodies found in the old workings. A raise was driven from No. 9 to No. 5 level, partly for ventilation purposes. Intermediate levels were established from this raise. Most of the stoping was done between No. 9 and No. 8 levels.

The mine closed down late in 1929 and was not opened again until 1942 when it was taken over by the Wartime Metals Corporation. They continued operations until May 1944 when operations ceased. Ainsmore Consolidated Mines Ltd. owned and operated the mine from 1945 through 1950.

Western Mines Ltd. of Vancouver obtained the property in 1951. The Consolidated Mining and Smelting Co. Ltd. obtained an option on the property and carried out a geological and geophysical survey of the surface. A diamond drilling program, totalling 7010 metres, was carried out to investigate a gentle arc in the limestone beds. Very little ore was found so the option was dropped. Leasers carried out small scale mining operations on the Lakeshore and Florence claims in

MINFILE NUMBER: **082FNE016**

CAPSULE GEOLOGY

1958-1960.

The Florence occurrence is hosted by limestones, schist and greenstones of the upper part of the Mississippian to Lower Permian Milford Group. A series of parallel fissures striking east-west and dipping 40 degrees south, cut the rocks. Two types of ore deposits occur. Replacements in limestone usually occur at the contact of the limestone with the overlying schist. fissure vein ore occurs at the contact of the quartz and the schist and in sheared greenstone. The ore is coarsely crystalline galena and sphalerite with some pyrite and chalcopyrite. The gangue is altered limestone, calcite, quartz and fluorite.

The ore consists of pods and lenses, up to 5 metres thickless evenly distributed in the veins in a gangue of quartz and calcite. Where the veins intersect limestone beds, replacement occurs along the walls. Replacement is reported to be more extensive in the upper parts of the deposit. Vein and replacement bodies are surrounded by a halo of silicified and chloritized host rocks.

CAPSULE GEOLOGY

The Early Bird area is underlain by micaceous and chloritic schist, quartzite and limestone of the Middle Cambrian to Middle Devonian Index Formation, Lardeau Group. Two parallel fissures, striking 285 degrees and dipping 80 degrees south are exposed. Near the portal of a tunnel, stringers of ore several centimetres wide are found. In the last 15 metres of the adit the fissure is tight and no ore is visible. The ore consists of quartz, calcite, galena and sphalerite with minor amounts of pyrite and chalcopyrite. The vein is in calcareous and siliceous mica schists and limy silicate gneiss.

The Early Bird produced 137 tonnes of ore from 1914 to 1916 (inclusive). A total of 47,276 grams of silver, 57,643 kilograms of lead and 1,264 kilograms of zinc were recovered.

This claim, located on the shore of Kootenay Lake about 2.4 kilometres north of Ainsworth, was Crown granted to J.L. Retallack in 1895. The records of the development work done on this claim are incomplete. Apparently the original owner drove about 23 metres of tunnel on the property in 1896. The next mention of the property is in 1914 when leasers made a trial shipment of 25 tons of ore.

In 1916 the Wolverine Mining and Development Syndicate operated the Early Bird, Carey Fraction and Nicolet claims. Their operations were largely confined to the Carey Fraction and only about 4.6 metres of tunnel was driven on each of the other two claims.

In 1921 the Lakeshore Mining Co. acquired about 12 claims running from the lakeshore up the hill and covering a strip of ground between the Florence and Highland properties. The Early Bird claim may have been included in the Lakeshore Co. property. The Kootenay-Florence Mining Co. Ltd. acquired the property of the Lakeshore Mining Co. in 1928.

The owner of the property in 1949 was a Mr. Pringle of London, England. He gave an option to F.W. Robinson. An old adit beside the highway was reopened and extended to a length of 24 metres. An adit was collared 18 metres lower in slide rock below the highway. This adit was driven until it broke into the old workings. A drift on the vein was extended an additional 23. Work ceased in the fall of 1951. The owners of the property at this time was Messrs. Robinson, Watson

CAPSULE GEOLOGY

On the Lakeshore property, sulphide mineralization occurs in limestone of the Mississippian to Lower Permian Milford Group. Hosting the ore are fractures that strike about 290 degrees and dip about 65 degrees to the south. These are tight fractures containing clusters, pods and grains of galena, sphalerite, pyrite and pyrrhotite, generally without quartz and carbonates. A green manganese-iron silicate, knebelite (generally associated with pyrrhotite) as well as chlorite and iron carbonate are minor alteration products.

The Lakeshore workings are mainly on the Carey Fractional Crown-granted claim a few hundred feet south of Princess Creek. The early work on the Lakeshore mine was done between 1916 and 1928, and the property gained its name from the Lakeshore Mining Company, of Spokane, which owned it between 1921 and 1923. By the end of 1929, the Lakeshore was added to the Florence group (082FNE016).

In 1954, Cominco Ltd. made an agreement for eventual control of the property. Geological and geophysical surveys were done in 1954 followed in 1956 and 1957 by diamond drilling totalling 7000 metres, mainly from surface. This work was designed to test for replacement ore in the limestones like that at Bluebell, and initial results were encouraging.

In 1957, Cominco extended the lower Lakeshore adit by a total of 230 metres of drifts, crosscuts, and raises and drilled eight holes totalling 427 metres from underground. This work exposed fractures in limestone adjacent to which there is a limited amount of replacement mineralization. Some of this mineralization was mined by leases in 1958 and 1959 and no work has been done since then.

A total of 714 tonnes of ore production is recorded for the Lakeshore deposit in four years from 1926 to 1959, with 653 tonnes produced in 1959 alone. From this, 45,969 grams of silver, 70,157 kilograms of lead, 33,359 kilograms of zinc and 100 kilograms of cadmium were recovered.

CAPSULE GEOLOGY

Ore is reported to occur in limestone of the Mississippian to Lower Permian Milford Group. The Nicolet is a mineralized fracture comparable to the Lakeshore mine (082FNE018) to the north. The Nicolet mineralization is along a single mineralized fracture that strikes 285 degrees and dips 80 degrees south. It contains galena, sphalerite, pyrite, pyrrhotite and minor chalcopyrite, locally associated with siderite. Pieces of ore from the dump also contain some quartz, calcite and knebelite. The fracture has been traced for about 100 metres to the east, and throughout its exposed length the sulphides are only several centimetres thick, locally expanding along the foliation or subsidiary fractures.

The Nicolet claim was Crown-granted in 1897. The Nicolet was added to the Kootenay Florence group (082FNE016) in the late 1920s. The principal work recorded was done in 1916 and 1917 and between 1950 and 1952 when a total of 607 tonnes of ore was mined (571 tonnes mined in 1952 alone). From this ore, 46,438 grams of silver, 37,069 kilograms of lead and 19,244 kilograms of zinc were recovered.

CAPSULE GEOLOGY

A replacement shoot of ore is reported to occur on the Manitoba claim (Richardson, 1957 (Property File)). As part of the Highland group (see 082FNE015), Cominco explored the Manitoba by drilling four holes in 1956.

J.T. Fyles shows the location of the mineralized vein to be in limestone of the Mississippian to Lower Permian Milford Group (Bulletin 53, Figure 3). The characteristics of the mineralization are not reported and assumed to be silver-lead-zinc ore.

CAPSULE GEOLOGY

The original work on the New Jerusalem was done before 1900. This included surface stripping and underground stoping and an adit crosscut. A raise from the crosscut to the surface workings was driven in 1937 and 1938. Ore was mined from the raise in 1951 and 1952. Ore production is recorded for 1907 (17 tonnes) and 1952 (223 tonnes) totalling 240 tonnes. From this, 22,426 grams of silver, 249 grams of gold, 38 kilograms of cadmium, 16,226 kilograms of lead and 5,674 kilograms of zinc were recovered.

The main vein of the New Jerusalem is in a fine-grained hornblende schist of the Permo-Triassic Kaslo Group. It has a well-developed foliation dipping 20 to 25 degrees west. A lenticular quartz vein which strikes 290 to 300 degrees and dips 75 degrees to the south contains galena, sphalerite, minor chalcopyrite, pyrite and pyrrhotite. The vein is up to 1 metre thick with lenses and clusters of medium to coarse-grained sulphides 15 to 20 centimetres thick. Vugs and comb structures are common. The vein is exposed on surface for about 100 metres and has been mined for half this length. Where exposed in the drift about 30 metres below surface, it is only 30 centimetres or so thick and poorly mineralized.

CAPSULE GEOLOGY

The Tiger claim was Crown-granted in 1893 and considerable work, including hundreds of metres of underground exploration, was done before 1912. A small shipment of ore (22 tonnes) was made from the claim by T.B. Hansen in 1928 and 5785 grams of silver, 31 grams of gold, 4211 kilograms of lead and 2335 kilograms of zinc were recovered. There is no record of other work on the claim. The old workings are presently obscured by undergrowth. A diagram of the workings can be seen in Figure 30, Bulletin 53 (page 113).

Rocks on the claims are grey knotted schist, with narrow interlayers of fine-grained grey limestone, of the Mississippian to Lower Permian Milford Group. A relatively thick layer of limestone continues northward from the Star property (082FNE026), and thin discontinuous layers found east of it contain the Tiger mineralization. The rocks dip to the west at moderate angles.

The mineralization is associated with two small faults striking northwest and dipping 60 to 70 degrees to the southwest. Veins along the fault contain galena, sphalerite, pyrite and minor chalcopyrite associated with quartz and siderite. Rusty-weathering siderite extends irregularly out from the veins into the limestone and locally carries sulphides. The veins and rusty siderite together form mineralized zones up to 1.2 metres thick. The zone in No. 1 adit is 6 metres long and the one near No. 3 adit is 30 metres long. Lenses with appreciable sulphides are generally less than 60 centimetres thick and follow the veins.

CAPSULE GEOLOGY

The Ayesha property covers several layers of fine-grained blue-grey to light-grey limestones separated by fine-grained grey knotted schist, all of the Mississippian to Lower Permian Milford Group. The rocks strike north to northeast and dip to the west at moderate angles. At least three limestone layers several metres thick are exposed. They are lenticular and have a branching outcrop pattern suggesting structural repetitions produced by folding.

The principal showings are along the western contact of one layer of limestone where it is transected by three faults. The faults which strike northwest and dip 60 to 65 degrees to the southwest have offset the contact 4.5 to 6 metres to the left. The showings consist of lenses of rusty-weathering siderite in the limestone and contain galena, sphalerite, pyrite and minor chalcopyrite. The siderite replaces the limestone near the faults and occurs as a vein-like filling along the faults. The most extensive replacement is near the faults, where, in one place, siderite with scattered sulphides forms a lens as much as 1.2 metres thick extending about 9 metres from a fault.

These claims are located on Cedar Creek about 4 kilometres by road from Ainsworth. The Ayesha claim was Crown granted to E.W. Herrick in 1891. Very little work has been reported on these claims prior to 1948. Mr. L. McPhee acquired the Ayesha, No. 5, Anna May, No. 5 Free., Kate, New York and Cecilia May Fraction sometime prior to 1948. Silver Hill Mines Ltd. was formed to develop the claims. The top adit on the Ayesha claim was extended 23 metres to make a total length of 41 metres. A tunnel on the No. 5 claim was driven for over 122 metres without intersecting the vein exposed on the surface above.

Northern Exploration Ltd. acquired the property in 1950 and began work on a surface showing above the Ayesha adit. A 3.6-metre wide lead-zinc replacement zone in limestone was exposed and traced for 9 metres.

In 1951, Ayesha Lead-Zinc Mines Ltd. acquired the property. Leasers began a raise 18 metres from the Ayesha portal. Replacement mineralization up to 1.5 metres in width was found in small pockets.

S.A. Liening, of Seattle, held an option on the property in 1953. The Ayesha tunnel was extended to a length of 116 metres. Narrow veins were intersected at 58 and 104 metres from the portal.

CAPSULE GEOLOGY

On the second vein, 27 metres of drifting and a raise through to the surface were completed.

Triumph Mines Ltd. acquired the property in December 1953. The following year a 64-metre adit was driven on a fissure vein exposed on the No. 5 claim. At the end of the drift a 52-metre cross cut was driven to intersect another vein which had been explored from the surface about 30 metres above by a shaft 9 metres deep. A drift about 9 metres long was driven on this second vein.

The only work reported on the Anna May claim was done in about 1920. A tunnel was driven but apparently not far enough to reach the ore bearing zone.

The Ayesha has recorded ore production for 1911 and for 1949 to 1952, inclusive. A total of 70 tonnes of ore was produced, from which 28,739 grams of silver, 17,831 grams of lead and 9,306 of zinc were recovered.

CAPSULE GEOLOGY

This group of claims is located on Cedar Creek at an elevation of about 1300 metres. The main adit is on the Dellis claim to the south of the creek and may be reached by about 11 kilometres of road from Ainsworth.

The Dellie claim was Crown granted to S.S. Bailey in 1893, however, small scale mining operations were being carried out at this location as early as 1889. The operation continued intermittently until 1896 when it was closed down. During 1901-02 the Little May claim was being worked and about 21 metres of shaft and 67 metres drift was completed.

The Silver Hoard Mining Co. of Spokane took over the mine in 1911 and operated it through 1917. Leasers then took over the property and worked it through 1927. By 1923 the company had acquired 5 Crown granted claims, the Silver Hoard Fr., Dellie Fr., Dellie, Nellie Fr. and Little May. The ore zone had been developed by a 61 metre inclined shaft and about 610 metres of workings. Apparently the Consolidated Mining and Smelting Co. Ltd. acquired ownership of the property in 1925 and held it through 1949 although there is no record of any work having been done by the company.

From 1949 to 1951 the property apparently changed hands three times, being owned successively by H. Giegerich, Now Jason Mines Ltd., Toronto, and Silver Hoard Mines Ltd., of Toronto. Leasers worked the property during this period. Silver Hoard Mines Ltd. did some diamond drilling and surface exploration on the property in 1952, however, no further activity has been reported.

The orebodies in the Dellie mine are associated with shear zones at or near the contact of folded limestone and argillite of the Mississippian to Lower Permian Milford Group. Silver is found in the replacement ore which occurs in the limestone. Silver also occurs as wires in cavities in the limestone. The ore is a mixture of coarse galena and sphalerite with minor amounts of pyrite and chalcopyrite. The gangue consists of green fluorite, calcite, siderite and quartz.

A total of 3070 tonnes of ore was mined in 23 years from 1889 to 1973. From this, 4,039,438 grams of silver, 31 grams of gold, 83,481 kilograms of lead and 37,873 kilograms of zinc were recovered.

CAPSULE GEOLOGY

The No. One occurrence occurs in the "No. 1 Limestone" which is intercalated between dark-grey argillites of the Mississippian-Pennsylvanian Milford Group. Small intrusions of "gneissic granite" are reported in the vicinity of the deposit.

The deposit consists of replaced limestones along a shear zone (northwest 45) and brecciated host rocks near or at the upper contact of the "No. 1 Limestone" with black argillites. The ore is generally oxidized, consisting mainly of iron oxide, some lead carbonates and wide silver and forming a dark brown, decomposed mass. Original sulphides are observed in places. Gangue consists mainly of calcite with locally some siderite and quartz growing in cavities in the calcite cement. Limestones in the ore are reported to be silicified.

CAPSULE GEOLOGY

This Star property is located directly west of Ainsworth at an elevation of 1036 metres and may be reached by about 9.6 kilometres of road from the village. The portals of the tunnels are on the Sunlight claims, the workings extending into the Star claim to the west.

Development work on the Sunlight claim was begun in 1895 and the first shipment of ore was made the following year. The Star claim was Crown-granted to Messrs. Strobeck and Hardie in 1898. The work continued intermittently through 1910. The workings at this time consisted of about 229 metres of tunnel, 91 metres of crosscuts and 30.5 metres of shaft.

The mine was closed from 1910 until 1945 when it was acquired by A.G. Norcross of Nelson. By 1950 the workings consisted of two adits, 56 metres apart vertically, the upper one 76 metres long, the lower one about 244 metres long. A 15 metre sub level is connected by a 15 raise to the upper adit and also to the surface by an old shaft.

During 1951-52 Privateer Base Metals Ltd. held an option on the property and completed a diamond drilling program amounting to 1067 metres in 30 holes. The purpose of this was to trace the continuation of the fault to the northwest and to explore both walls of the fault zone for further replacement deposits. Very little ore was found so the option was dropped. In 1955, the owner, A.G. Norcross, did some stoping in the old workings.

Argillites, limestones and schists of the Mississippian to Lower Permian Milford Group are intruded by Upper Triassic to Middle Jurassic quartz diorite sheets and lamprophyre dykes. The ore occurs in a cross fault zone 30 to 60 centimetres wide, that is filled with coarsely crystalline calcite. Galena and sphalerite occur in equal proportions in small veins in the calcite. Replacement ore is found locally in the limestone wallrocks.

A total of 726 tonnes of ore was mined in 5 years between 1949 and 1956 (inclusive). From this, 167,893 grams of silver, 65,336 kilograms of lead, 55,124 kilograms of zinc and 559 grams of gold

CAPSULE GEOLOGY

The main showing on the Jewel Crown grant claim is a galena-bearing vein of calcite and siderite in grey fine-grained mica schist and calcareous mica schist with grey marble lenses. The vein strikes 290 to 300 degrees and dips 70 degrees to the south and is about 1 metre thick at the widest place. It has been followed for about 60 metres in an adit from which small amounts of ore have been mined. Other similar veins are reported near the shore of Kootenay lake, east of the vein.

In 1937, 24 tonnes of ore was mined from which 6221 grams of silver and 6855 kilograms of lead were recovered.

RELATIONSHIP: Pre-mineralization GRADE: Amphibolite

CAPSULE GEOLOGY

The Spokane occurrence is hosted by quartzites, hornblende schists and siliceous limestones of the Mississippian-Pennsylvanian Milford Group intruded by some lamprophyre dykes or sills, less than 2.5 metres thick, that closely conform to bedding and foliation.

The deposit consists of two subparallel veins, that conform to bedding and foliation. The two veins are less than 2 metres apart, they merge and split locally. They are offset by small senestral or dextral northwestern cross-faults. A gouge and breccia band less than 7 metres thick, commonly occurs along the western vein. The ore occurs as lenses scattered along the vein or at the intersection of the northwest cross-faults. The ore consists of massive cubic to fine-grained and sheared galena with some sphalerite in a massive to porous gangue of quartz. Fragments of quartzite occurs in the vein.

Located on the Munn Creek slope, about 4.8 kilometres by road from Ainsworth, the claims lie in a north-west trending line across the southwest corner of the Ainsworth townsite. Both claims were Crown-granted to the Pacific Bullion M. Co. in 1893. The owners worked the property from 1888 to 1896 and from 1915 through 1920. Leasers operated the mine from 1921 to 1929.

By 1920 the deposit had been developed by two adit levels. The upper level, at an elevation 61 metres below the outcrop, was driven for over 274 metres along the vein. Over 122 metres of this was in an overshoot that was stoped through to the surface. The lower adit was started not far from the portal of the upper and only 8 metres vertically below it, and driven for 110 metres on the fissure. The last 67 metres of this tunnel was on the main ore zone and 55 metres of this part of the drift has been stoped through to the level above.

The Maestro Silver Lead Mines Ltd. was formed in 1937 to develop the Maestro and Spokane mines but no work was done, and the company became defunct in 1940. Ainsworth Vines Ltd., formed in 1936 to

CAPSULE GEOLOGY

operate the Banker mine, gained control of the Spokane and development work was resumed in 1941.

In 1942 Ainsmore Mines Ltd. (later Ainsmore Consolidated Mines Ltd.) was formed to operate the Spokane. A shaft was sunk from the lower adit for 30 metres and from this new level 22 metres of drift and a raise were put in.

Yale Lead & Zinc Mines Ltd. acquired the property in 1949 and leasers worked the mine intermittently through 1957.

CAPSULE GEOLOGY

The Banker deposit is a quartz vein paralleling the bedding in quartzite of the Mississippian to Lower Permian Milford Group. Galena is associated with sphalerite and pyrite in a gangue of quartz, calcite and crushed country rock. The ore shoots seem to have been localized in zones where the vein and strata dip flatly.

A total of 4346 tonnes of ore was mined from the Banker, primarily from 1927 to 1937 but also in 1909, 1959 and 1960. From this ore, 1,916,941 grams of silver, 1,016,876 kilograms of lead, 24,567 kilograms of zinc and 31 grams of gold were recovered.

The Banker claim is located on a high bluff to the west of Ainsworth. The orebody is found on the extension of the vein through the Highlander and Albion claims. Originally staked in 1890 by A.D. Wheeler, the claim has been worked intermittently since that time. H. Giegerich acquired the claim prior to 1909. The Consolidated Mining and Smelting Co. Ltd. held a lease on the property from 1913 to 1928.

Underground workings up to 1928 consisted of an inclined shaft following the dip of the vein for about 60 metres. Two drifts extend southerly along the vein at depths of 7 and 18 metres, the upper one 49 metres long has been largely stoped through to the surface, the lower one was driven for 21 metres. A crosscut tunnel was driven from the bottom of the bluff to explore the vein at a depth of about 116 metres. The tunnel was extended to 218 metres. At 190 metres from the portal drifts were run north and south, the northerly one 96 metres long.

From 1928 to 1937 the property was worked intermittently by a number of leasers, the greater amount of work being done by Banker Mines Ltd. and Ainsworth Mines Ltd.

The property was acquired by Yale lead & Zinc Mines Ltd. in 1949 and was worked, along with the Highlander, Albion and other claims, up until 1959. A raise was driven from the Highlander workings to the 2,500 Banker adit. A 2,300 sublevel was driven off the raise and stoping carried out from this level and from the 2,150 level. A raise was driven from the 2,500 level to connect with the bottom of the old Banker shaft workings. A31 the ore was taken out through the Highlander tunnel. In 1956 the 1,900 level Highlander Tunnel was being driven toward the Banker orebody but apparently no ore was found at this depth. The company closed down in 1938 but leasers continued operations through 1959 and part, of 1960.

and Black Diamond (082FNE149). The north drift on the Highlander vein was extended to 640 metres and raises, following the dip of the Highlander vein, were driven to the Albion and Banker workings. Stopping was carried out on 3 levels. In 1955 a new adit was driven 60 metres below the old adit. The end of the ore body was reached in 1959 and the mine closed. Leasers worked the Highland vein in 1959 and 1960.

CAPSULE GEOLOGY

The Dictator claim is underlain by limestone and quartzite of the Mississippian to Lower Permian Milford Group. A narrow quartz-calcite-galena-sphalerite vein striking 130 degrees with vertical dip occurs. Fine-grained disseminated sphalerite also occurs in the adjacent limestone. A 1980 drill hole near the vein encountered a 0.9-metre wide quartz-calcite vein hosting a small amount of sphalerite. Some tunnelling occurred on the Dictator in the 1890s.

CAPSULE GEOLOGY

On the north side of Woodbury Creek, the western contact of a garnet mica schist unit (Princess formation) of the Middle Cambrian to Middle Devonian Index Formation (Lardeau Group) is marked by a sheared and crushed zone. It is a zone 30 to 60 metres wide of sheared and crushed dark-grey carbonaceous rock containing scattered pyrite. Three tonnes taken from this zone in 1964 yielded 964 grams of silver, 699 kilograms of lead and 66 kilograms of zinc.

CAPSULE GEOLOGY

The area of the Jack Pot is underlain by micaceous quartzite, mica schist and limestone of the Mississippian to Lower Permian Milford Group.

The Highlander vein outcrops from near Loon Lake to Munn Creek, a distance of about 1.6 kilometres. The fault zone in which it occurs continues even further. The vein curves from a strike of almost due north near Loon Lake to 340 degrees on the Jack Pot. Galena and sphalerite occurs in a gangue of quartz and calcite.

It is reported that in 1953, 352 tonnes of ore from the Jack Pot was milled.

CAPSULE GEOLOGY

The Eden and Crescent claims extend in a general north-south direction across Coffee and Krao creeks. The mine may be reached by a 2.4 kilometre long road up Coffee Creek from the Nelson-Kaslo highway.

The claims cover a layer of crystalline grey limestone in micaceous quartzites and mica schist of the Mississippian to Lower Permian Milford Group. The workings follow two shear zones about 75 metres apart which strike north and dip 45 degrees to the west.

The most easterly zone, followed by an adit contains highly sheared and dark-grey to black schist in a zone 1.2 to 1.5 metres wide that near the portal contains lenses of quartz but no sulphides. The most westerly fault is in mica schist and micaceous quartzite just west of a prominent limestone. It contains fine-grained quartz with many vugs, minor calcite and siderite as well as resinous brown sphalerite, galena and pyrite.

Both claims were Crown-granted to the Columbia Mining Co. in 1894. Small scale mining operations were first reported in 1890 but the details of this and later operations have not been recorded.

Development work was begun in 1916 when the property was worked by leasers under an option from the Larson estate. In 1919 the Eden and Crescent Mining Co. acquired the property along with 7 other claims plus a fraction. They drove a crosscut 168 metres to intersect the vein at a depth of about 44 metres and then drifted on the vein for about 9 metres. Two shafts, 30 metres apart, were sunk on the Crescent vein, one 12 metres deep, the other 8 metres deep. The company ceased operations in 1919 and the mine remained closed until 1937. Leasers worked the property during 1937-38.

The Yale Lead and Zinc Mines Ltd. acquired the property in 1949 and leasers mined on a contract basis until 1956 when the operation was abandoned. A stope, about 15 metres long, was carried up the vein to the surface. An inclined shaft was sunk 37 metres on the vein from the adit level. Some stoping was carried out up to the adit level but very little ore was found to either side of the shaft.

CAPSULE GEOLOGY

On the Belle Aire, a quartz vein in mica and garnet schists of the Mississippian to Lower Permian Milford Group strikes parallel to the foliation of the schists. The vein is 45 centimetres wide at the portal but becomes narrow and lenticular in the adit. The hanging wall is a fault plane with slickensides parallel to the dip. Ore consists of galena and sphalerite occurring as small lenses. Four tonnes were mined in 1950 and 249 grams of silver, 327 kilograms of lead and 28 kilograms of zinc were recovered.

The early history of the development of this mineralized vein, outcropping just above the Coffee Creek bridge on the Nelson-Kaslo highway, is not clear. Apparently the Belle Aire claim is a relocation of an earlier Crown-granted claim, either the Blizzard or the Sunnyside. Exploration work on the Blizzard claim in 1917 consisted of a 10 foot tunnel, a shallow shaft and two open cuts. An adit visa to have been collared at creek level to explore the vein or depth.

In 1950, S. Hallgren staked the Belle Aire claim astride Coffee Creek, adjacent to the bridge. He worked the property intermittently until 1958. An old adit, which had been collared above the high-water mark on the north side of the creek, was extended to a length of 37 metres. Another adit, 9 metres vertically above, was driven for 6 metres.

CAPSULE GEOLOGY

This Daisy Bell property is located south of the South Fork of Woodbury Creek (Lendrum Creek), about 3 kilometres by road from the Kootenay Florence mine.

A rusty vertical fracture striking east and containing several centimetres of quartz and locally galena is followed in the workings. The host rock is reported as either a fine-grained mica schist or limestone of the Mississippian to Lower Permian Milford Group.

One report describes the ore as occurring as fissure and cavity fillings and replacement bodies in limestone. The limestone occurs in relatively thin bands and tends to be vuggy and cavernous in places.

From 1948 to 1951, the Daisy Bell recorded a total ore production of 150 tonnes. From this 35,147 grams of silver, 23,352 kilograms of lead and 9,490 kilograms of zinc were produced.

In 1901 the King Solomon Mines Co. obtained 35 claims at the mouth of Woodbury Creek and built a concentrator there. In 1903 the company obtained the Daisy claim. By the end of 1904 this company owned 60 Crown-granted claims in this vicinity. A small number of men were employed through 1910, the latter years being limited to assessment work only. After this period of activity these claims apparently reverted to the Crown and no further activity is reported until 1928.

The Princess Creek Mining Co. Ltd. was organized in 1928 to develop the R.F.G. and Bell groups consisting of 7 claims. Some exploration work was carried out the following year on the R.F.G. group. No further activity is reported until 1948. At this time the property consisted of 3 claims, the Florence M, the Daisy, and the Bell, and was owned by J. Cossetto of Ainsworth. Leasers worked the Florence MI. claim during 1948 and 1949. The Woodbury Mines Co. Ltd. was formed in 1950 to develop the Daisy Bell group of 6 claims, their holdings later being increased to 10 claims. Some drifting was done on the Daisy vein and about 1524 metres of diamond drilling was completed. In 1952 the Woodbury Mines Co. extended its holdings to the shore of Kootenay Lake by acquiring the Amazon, Budweiser, Budweiser Frac., and Superior claims from Kaslo Base Metals Ltd. This group of claims had originally been staked by the Canadian Pacific M. & M. Co. in 1696. After 1952 most of the work done by

CAPSULE GEOLOGY

Woodbury Mines Co. was confined to this new group of claims. A total of 396 metres of tunnel was driven, 253 metres of it being on the Superior claim. Diamond drilling underground amounted to 158 metres in four holes. All work by this company ceased in 1953.

The Kaslo Base Metals Co. resumed work on the Amazon-Budweiser group in 1956. The adit on the Superior claim was extended an additional 56 metres. At 302 metres from the portal a fissure vein was intersected which contained a 7 to 10 centimetre width of galena and replacement ore up to a width of 0.6 metre.

CAPSULE GEOLOGY

This group of claims lies along the western edge of the Highland and Florence properties and covers an area extending from near Cedar Creek to the South Fork of Woodbury Creek.

The principal rocks of the Noranda are schists and limestone of the Mississippian to Lower Permian Milford Group. Granite also outcrops in the vicinity. The property was developed along with the Silver Glance (082FNE010) in the 1950s and 1960s.

The mineralization on the claim group is described as consisting of quartz and siderite containing galena, sphalerite, pyrite, pyrrhotite and minor chalcopyrite. In the Noranda adit, lead-zinc mineralization over 1 metre thick was followed for over 30 metres and was eventually mined out in 1964 and 1965, amounting to 2177 tonnes of ore (Bulletin 53).

The Hercules-Silver Glance group consists of the Hercules, Sullivan, Noranda, Silver Bell, Glen Ellen, Harrison, Free Silver and Silver Glance claims. Three of the claims, formerly called the Pataha, Bugaboo and Ellen were relocated in 1951 under the respective names of Hercules, Sullivan and Noranda.

Most of the development work on the Hercules claim was done about 1890. The workings now consist of 36 metres of tunnel in two adits, a shaft 4.5 metres feet deep and some trenching. On the Sullivan claim a 23 metre shaft was put down about 1895. Nubar Mines Ltd. of Toronto held an option on the claims in 1951 and are reported to have done some diamond drilling. The Asbestos Corporation Ltd. did about 914 metres of diamond drilling in 30 holes in 1952. The results of this work have apparently not been released by the company.

The Silver Glance claim, which lies astride the South Fork of Woodbury Creek, about 3 kilometres from its mouth, has had the most development work done on it. The property was located in 1896 and was apparently worked intermittently for about 4 years. A tunnel at creek level follows the vein in a 110 degree direction for 66 metres. Here the vein splits and is followed by two branches of the tunnel, one going 85 degrees for 23 metres, in which the vein appears to pinch out, the other branch extending for 18 metres at 110 degrees with the vein still in the face.

In 1952 Guichon Mine Ltd., owners of the Buckeye claim, held an option on all the above claims, however their work was apparently

confined to the Buckeye. Between 1951 and 1957 considerable work was done by Triumph Mines Limited. In 1964 and 1965 ore was mined from the Noranda adit and shipped to the Yale mill in Ainsworth. By 1967, the property was owned by Blue Star Mines limited.

CAPSULE GEOLOGY

Vuggy quartz vein with clusters of galena occur lying parallel to foliation in a schist-marble-quartzite succession of the Cambrian to Devonian Index Formation, Lardeau Group. The vein is discontinuous down slope for 50 metres in elevation.

CAPSULE GEOLOGY

In 1825, a botanist discovered sulphide ore at the Bluebell site. In later years, Hudson Bay Company trappers used galena from this site to make bullets. The site was staked by R.E. Sproule in 1882. The Bluebell occurrence consists of three main zones approximately 500 metres apart along strike of the Lower Cambrian Badshot Formation marble. The Comfort zone (082FNE044) occurs at the north end of Riondel Peninsula, the Bluebell zone (082NE043) in the centre, and the Kootenay Chief at the south end. The zones are localized along steep cross-fractures that trend west-northwesterly and dip 80 to 90 degrees north. Within the zones are tabular ore shoots that are transverse to the bedding and plunge westward following the intersection of the fractures with the marbles. The ore occurs as replacement deposits along steep cross fractures in the marbles. Bedding planes and minor structures tend to localize the deposit. The ore consists of galena, sphalerite, pyrrhotite, pyrite, arsenopyrite, and chalcopyrite. The gangue occurring with the sulphides consists of carbonates, coarsely-grained quartz and knebelite. Oxidation of the deposit has occurred to depths well below lake level.

The large surface showing was known to early fur traders and was brought to the attention of mining capital as early as 1865. The first claims were located in 1852 and development work was begun two years later. By 1891 about 70 claims had been staked in the surrounding area. From 1888 to 1896 the mine was operated by the Kootenay Mining & Smelting Co. Ltd.

CAPSULE GEOLOGY

In 1906 the property was taken over by the Canadian Metal Co. Ltd. Due to financial difficulties the company was reorganized in 1911 under the name of the New Canadian Metal Co. They worked the property intermittently for about 20 years. There are three known centres of mineralization in the mine, spaced at approximately 457 metre intervals along the strike of the limestone. These three ore zones are known from north to south as the Comfort, the Bluebell, and the Kootenay Chief. At the time the mine closed an inclined shaft had been sunk on the Comfort ore zone and an adit driven on the Kootenay Chief claim.

The Consolidated Mining and Smelting Company of Canada Ltd. acquired the property in 1931 and did some exploration work on the Bluebell, Comfort and Kootenay Chief claims, however the mine was not reopened. Further diamond drilling was done in 1942 but the results were not encouraging. In 1947 diamond drilling was done along about 1524 metres of limestone outcrop and the three orebodies mentioned above were outlined. The mine was reopened the following year.

Since 1947 an inclined shaft, located between the Bluebell and Kootenay Chief ore zones, has been sunk for 572 metres to a vertical depth of 247 metres. Development work has been carried out on all levels from 69 to 267 metres. A large volume of water enters the lower workings of the mine. By 1957 most of the ore production was reported to be coming from the Kootenay Chief.

Development work during 1961-62 consisted of 3500 metres of drifting and crosscutting, 2,413 metres of raising and 10,394 metres of diamond drilling.

The mine closed in December 1971 due to depletion of the Ore reserves.

Approximately 500,000 tons of mill tailings containing zinc, lead and silver were dumped on the shore of Kootenay Lake in the early 1900s. Most of this material eventually slid to the bottom of the lake, 128 metres deep and 290 metres offshore. (Mining Magazine, December 1983, p. 446)

CAPSULE GEOLOGY

The property is located on the east shore of Kootenay Lake in the vicinity of Indian Creek, less than 1.5 kilometres north of Riondel.

Galena and sphalerite veins occur in limestone within the Middle Cambrian to Middle Devonian Index Formation, Lardeau Group. In 1918 and 1920 a total of 85 tonnes was mined from which 51,755 grams of silver was produced.

The Tam O'Shanter claim (Lot 401) was Crown-granted to the Montreal-Kootenay Mining Co. in 1896. The company drove a 43 metre long adit from the waters edge on a 0.6 metre wide vein sparsely mineralized with iron and galena. The company ceased operations in about 1899. Leasers worked the property intermittently during the period 1918-20; a 15 metre raise was driven and some ore shipped.

Pacific Silver Mines & Oils Ltd. acquired the property, consisting of 36 claims, in 1965. The old workings were rehabilitated and a geophysical survey was carried out. The survey detected a series of five anomalous zones on which diamond drilling is planned.

CAPSULE GEOLOGY

The property is located at a 1524 metre elevation on an east fork of Crawford Creek about 1.6 kilometres west of Rose Pass and some 45 kilometres west of Kimberley.

Quartz veins in black argillaceous rock contain galena, sphalerite chalcopyrite, stannite and pyrite. The area is underlain by phyllite, quartzite and grit of the Upper Proterozoic Horsethief Creek Group (Windermere Supergroup).

The Humbolt (Lot 2015) and Sailor Boy (Lot 2016) were Crown-granted in 1900 to J.B. MacLaren. Workings dating from that period include open cuts and 42 metres or more of drifts and crosscuts in two adits.

The property was acquired under lease by G. Foulkes, of Kaslo, in 1922 and sorted ore was shipped in 1923. The Humbolt claim was owned in 1940 by Oscar Burden, of Kaslo. Canadian Exploration Company Limited in 1946 re-opened the workings to examine the showings. Small ore shipments were made by lessees R. and G. Golak in 1948, by Talmor Mines Ltd. in 1952, and by D. Fulton and R. Sutton, of Cranbrook, in 1963.

The Humbolt and Sailor Boy claims were owned in 1964 by E.T. Coleman, of Nelson. An option was acquired by D. Wade and associates, of Calgary, and 5.4 tonnes of ore was shipped from a bulldozed section of flat lying vein. Messrs. Wade, Sutton, Fulton and associates in 1966 incorporated Rose Pass Mines Ltd. to acquire the Humbolt and Spring Creek properties. The company subsequently staked 84 adjacent claims. Work on the Humbolt property in 1966-68 included potential surveys and 849 metres of diamond drilling in 23 holes on IP anomalies.

Further diamond drilling was reported on the Humbolt property in 1971 and 1973. The company name (Rose Pass) was changed in 1974 to Range Industries Ltd.

In 5 years from 1923 to 1964 a total of 51 tonnes of ore was mined, from which 70,230 grams of silver, 24,100 kilograms of lead and 3,561 kilograms of zinc were produced.

CAPSULE GEOLOGY

The Old Skyline group, comprising the Skyline, Perhaps and Morning Star claims, is situated at an elevation of 1500 metres, 9.6 kilometres from Ainsworth.

The area is underlain by rocks of the Upper Mississippian to Lower Permian Milford Group. The showings are in limestone and in dark-grey to black phyllites and associated argillite. The eastern margin of the Nelson batholith is within a few hundred metres. The ore consists of porous siliceous rock carrying a dark mineral (argentite?), native silver, galena, and iron and copper pyrites. Values in gold and zinc are also reported from assays.

The mine was worked in the early 1980s and the ore shipped partly to the Pilot Bay smelter and partly to American smelters. The mine is reported to have been closed down in 1896. The workings at that time included an incline 26.5 metres deep, and a shaft further to the west sunk to a depth of 61 metres with a drift on the bottom level 37 metres in length.

In 1917, A.W. McCune drove a crosscut tunnel to tap the vein about 137 metres below the surface at the old workings. The vein was encountered approximately 366 metres from the portal. The vein was then drifted on for some distance, but little sulphide mineralization was encountered. Work was abandoned in 1918 and all equipment removed. In the period 1919-1921 the property was worked under lease and bond and a small amount of ore mined, mostly from surface exposures and from the upper part of the old workings. During this period also a raise was begun from the adit level to connect with the old workings. In 1921 all work on the property came to an end. In 1961 Mr. T.R. Buckham re-staked the prospect.

Mine production started in 1889 and continued intermittently until 1896. The mine produced again from 1918 to 1921 with the last recorded production occurring in 1969. Most of the production came in 1895 and 1896. Total mine production was 3,109 tonnes with 6,832,553 grams of silver and 2,130 kilograms of lead being recovered.

CAPSULE GEOLOGY

A quartz-rich schist, interlayered with calcareous rock, probably of the Lower Cambrian Hamill Group, is mineralized adjacent granite-pegmatite with pyrrhotite, minor pyrite and trace chalcopyrite. Mineralization is also concentrated along fractures in both the schist and pegmatite dike. The only assay recorded from the property was 48.34 grams per tonne gold and 99.43 grams per tonne silver (Annual Report 1925).

More than 100 metres of underground development occurred in two tunnels by 1918.

CAPSULE GEOLOGY

The area of the Otto occurrence is underlain by limestone and schist. Regionally, the area is mapped as Lower Cambrian Hamill Group, Middle Cambrian to Middle Devonian Lardeau Group and Lower Cambrian Badshot Formation.

Galena and sphalerite are reported to occur in small amounts replacing limestone bands (GSC Summary Report 1928). Starr (Property File) reports that on the Otto a shear of considerable width occurs, parallel to the strata. It is mineralized with pyrite and a little gold. This zone was tunnelled on for about 4 metre (as of 1926). It consisted of a soft gossan with some pyritic streaks. A sample over 90 centimetres yielded 2.74 grams per tonne gold (Starr, 1926 (Property File)).

CAPSULE GEOLOGY

The property is located at approximately the 2130 metre elevation at the head of Morris Creek, on the southerly side of the ridge between St. Mary River and Dewar Creek some 35 kilometres west-northwest of Kimberley.

Mineralization consists of pods and stringers of chalcopyrite, pyrite, galena and sphalerite in quartzites of the Middle Proterozoic Creston Formation, Purcell Supergroup. Siderite gangue is observed.

The Great Dane claim (Lot 5285) was Crown-granted to the Sawyer brothers and Georgina LaPointe in 1901. Two adjacent claims have been Crown-granted, the White Star (Lot 5286) and Fisher (Lot 5287). The White Star was Crown-granted to Fred Coyle & Associates in 1903. Along strike on the Coppery Creek side of the ridge two claims have been Crown-granted, the Mogul (Lot 4940) and Alta (Lot 4941).

Development work on the Great Dane in about 1901 included a drift adit driven about 20 metres. A crosscut was driven in barren quartzite from the face of the adit for 69 metres at 280 degrees. On the other side of the ridge, in the vicinity of the Mogul claim about 30 metres of shallow trenching was done.

CAPSULE GEOLOGY

The Proterozoic Purcell Supergroup in southeastern British Columbia constitutes a thick prism of dominantly clastic sediments exceeding 10,000 metres in thickness with the base unexposed. Earliest known sedimentation are Fort Steele Formation fluvial/deltaic sequences of quartz arenite, quartz wacke and mudstone at least 200 metres thick. Fine-grained clastic beds at the top of the formation grade into very rusty-weathering, fine-grained quartz wacke and mudstone of the Aldridge Formation (1433 Ma +/- 10 Ma), at least 5000 metres thick in the Purcell Mountains. The Aldridge Formation grades upward over 300 metres through a sequence of carbonaceous mudstone with minor beds of grey and green mudstone and fine-grained quartz wacke to the 1800 metre thick Creston Formation, composed of grey, green and maroon quartz wacke and mudstone with minor white arenite. Conformably overlying the Creston Formation are 1200 metres of green and grey dolomitic mudstone, buff-weathering dolomite and minor quartz arenite of the Kitchener Formation. The Kitchener is in turn overlain by 200 to 400 metres of green, slightly dolomitic and calcareous mudstone of the Siyeh Formation. Although poorly defined in the Purcell Mountains west of the Rocky Mountain Trench, the Siyeh is readily recognized in the Rocky Mountains and is conformably and locally unconformably overlain by 0 to 500 metres of basaltic to andesitic flows of the Purcell Lava (1075 Ma) which are taken to mark the close of Lower Purcell sedimentation (1075 to 1500 Ma). To the northwest and west in the Purcell Mountains, the Purcell Lava is only sparsely represented by weathered tuffaceous beds.

Resting with apparent conformity on the Lower Purcell rocks are about 1200 metres of grey to dark grey, calcareous and dolomitic mudstone and minor quartz wacke of the Dutch Creek Formation. This formation is overlain by about 1000 metres of grey, green and maroon mudstone and calcareous mudstone of the Mount Nelson Formation. The close of Purcell sedimentation is marked by folding during the East Kootenay Orogeny (825 to 900 Ma) and disruption of the basin by large-scale vertical faults concurrent with deposition of basal sedimentary rocks of the Windermere Supergroup.

Middle Proterozoic igneous activity in the Purcell sedimentary basin is dominated by intrusion of gabbroic sills of two ages. The oldest are the Moyie Intrusions which are most common in the Aldridge Formation. Sills and slightly discordant sheets predominate; locally, however, dykes and step-like discordant sheets are abundant near Kimberley. Gabbroic sills can aggregate 2000 metres of thickness in a typical Aldridge section and are most abundant in the lower part of the section. The youngest event of gabbro intrusion is thought to be comagmatic with the Purcell Lavas, and is represented by abundant sills in the upper part of the Creston Formation, and in the Kitchener and Siyeh formations. The pegmatitic Hellroaring Creek stock (Middle Proterozoic) and related satellites intrude metamorphosed and deformed Aldridge sedimentary rocks and Moyie Intrusions sills, in an area about 15 kilometres southwest of the Sullivan mine.

Lower Purcell sedimentary rocks have undergone metamorphism to at least greenschist facies. There is a general increase in metamorphic grade with depth in the stratigraphic pile; minor areas of amphibolite facies are restricted to the cores of fold structures displaying large magnitude structural relief.

Purcell rocks are folded about north trending axes to form the Purcell Anticlinorium. Folds comprising the large structure are open and gentle with north plunging axes. Some folds are overturned to the east and some display axial plane schistosity. Large areas within the anticlinorium have nearly flat-lying strata. Major faults with a history of complex movement disrupt the Purcell terrain and separate large regions further disrupted by block faulting. Two of these major faults, the Moyie and St. Mary faults, pass south of Kimberley and throughout much of their extent have a northerly trend, but then abruptly arc to the east into the Rocky Mountain Trench. Both of these faults repeat Lower Purcell strata on their north and west, upthrown sides. The Sullivan orebody occurs on the east side of this regional structure, on the east limb of an open anticline.

The Middle Proterozoic Aldridge Formation (Purcell Supergroup-

CAPSULE GEOLOGY

Lower Purcell Group), has the characteristics of a flysch sequence at least 3800 metres thick. It is composed of a monotonous and repetitious sequence of alternating beds of very fine-grained quartz wacke and mudstone and lesser amounts of very fine- to coarse-grained quartz arenite. The Aldridge Formation is metamorphosed to middle to upper greenschist facies. The Aldridge Formation in the Purcell Mountains has been divided into three map units; the Lower, Middle and Upper Aldridge. Lower Aldridge sedimentary rocks (at least 1500 metres thick - base not exposed) are composed of a rhythmic succession of thin to medium-bedded, typically graded beds of very fine-grained quartz wacke. Interbedded with the rhythmic sequence of graded beds are laminated sequences of mudstone ranging from a few millimetres to several metres thick. Laminae and discontinuous blebs of pyrrhotite emphasize layering in the laminated mudstone and weathering of the pyrrhotite imparts a conspicuous rusty colour to outcrops. Massive to poorly bedded, elongate lenses of intraformational conglomerate occur locally near the top of the Lower Aldridge. The Middle Aldridge (2000 metres thick) is marked by the appearance of distinctive graded arenaceous beds whose lighter weathering colours contrast sharply with the rusty weathering Lower Aldridge. Thinly bedded, rusty weathering rocks similar to those in Lower Aldridge sequences are interbedded with thicker, graded arenites but are definitely subordinate. The graded arenaceous rocks are mostly turbidites. Thin bedded to laminated carbonaceous mudstone becomes the dominant lithology of the 300 metre thick Upper Aldridge. The contact between the Middle and Upper Aldridge is gradational over stratigraphic thicknesses ranging from a few to tens of metres. Disseminated grains and blebs of pyrrhotite aligned along bedding occur in places in carbonaceous mudstone of the Upper Aldridge and here the rock is rusty weathering.

The Sullivan orebody is located at the western edge of the Rocky Mountain Trench and on the eastern flank of the Purcell Mountains. The orebody is a conformable iron-lead-zinc sulphide lens enclosed by clastic metasedimentary rocks of the Middle Proterozoic (Helikian) Aldridge Formation, the basal formation of the Purcell Supergroup (further subdivided into the Lower Purcell Group). Regional metamorphism is upper greenschist facies. The orebody occurs near the top of the Lower Aldridge Formation and has the shape of an inverted and tilted saucer. The maximum north-south dimension is about 2000 metres and the east-west dimension is about 1600 metres. It has flat to gentle east dips in the west, moderate east to northeast dips in the centre, and gentle east to northeast dips in the east. The footwall rocks are composed of intraformational conglomerate and massive lithic wacke overlain by quartz wacke and pyrrhotite-laminated mudstone. The ore zone is overlain by several upward-fining sequences of quartz wacke and mudstone. The orebody attains a maximum thickness of 100 metres approximately 100 metres northwest of its geographic centre, and thins outward in all directions (averages 21 metres in thickness). To the east, it thins gradually to a sequence of pyrrhotite-laminated mudstone 3 to 5 metres thick that persists laterally for some distance. To the north, the orebody thins less gradually and is truncated by the Kimberley fault. To the west, the orebody thins abruptly and is cut by dyke-like apophyses of the footwall gabbro. The gabbro (of the Middle Proterozoic Moyie Intrusions) lies beneath the orebody and is typically concordant about 500 metres below its eastern edge. To the west, the gabbro rapidly transgresses upward to meet the footwall of the orebody near its western margin but, continuing westward it transgresses downward to resume its sill-like form at approximately its original stratigraphic position. To the south, within the limit of economic mineralization, thickness changes are generally irregular and abrupt.

The Sullivan orebody lies on the folded and faulted eastern limb of a broad north trending anticline. The structure plunges gently to the north and is locally asymmetric and overturned to the east. Detailed structural mapping has revealed three phases of folding. Phase 1 is characterized by isoclinal folds with axial planes parallel to bedding planes and north trending fold axes. Phase 2 is characterized by relatively open folds with gentle north or south plunges and with moderately west dipping axial planes. Both Phase 1 and 2 folds indicate easterly vergence. Phase 3 folds are associated with east dipping thrusts; axial planes have steep dips and folds have variable plunges to northwest and southeast.

The Kimberley, Ryot and Hidden Hand fault systems, the 010 degree trending Sullivan-type faults and other minor faults form an intricate mosaic disrupting the fold limb. The Kimberley and Hidden Hand faults lie across the regional structure and are generally parallel to east trending segments of the Moyie and St. Mary faults. The Kimberley fault dips 45 to 55 degrees north and truncates the ore

CAPSULE GEOLOGY

zone to the north. With over 3000 metres of stratigraphic displacement, the fault juxtaposes rocks of the Creston and Kitchener formations against rocks of the Lower Aldridge. Displacement on the north dipping Hidden Hand fault is of the order of a few hundred metres of apparent normal dip-slip movement. The Sullivan-type faults cut the orebody with a consistent west side down normal displacement ranging from a few metres to 30 metres. The largest member of the group, the Sullivan fault, occurs near the western margin of the orebody. At the northwestern margin of the orebody, a northeast trending fault apparently truncates the westward extension of the Kimberley fault although earlier phases of movement along the Sullivan-type faults may have occurred.

The Sullivan orebody consists of sulphide rock composed of more than 70 per cent sulphides in thick, gently dipping conformable units enclosed by unaltered or altered quartz wacke and mudstone. In the western part, massive pyrrhotite containing occasional wispy layers of galena is overlain by sulphide rock in which conformable layering consists of pyrrhotite, sphalerite, galena and pyrite intercalated with beds of clastic sedimentary rock. The ore passes outward on the north, east and south to delicately-bedded sulphide rock interbedded with fine-grained clastic sedimentary rocks. Eastward across a transition zone, the orebody is composed of five distinct conformable units of well-bedded sulphide rock interbedded with clastic sedimentary rock. Each bed of sulphide rock thins eastward from the transition zone. The transition zone is commonly only a few metres or tens of metres wide. Three bedded sulphide sequences occur above the main orebody, particularly in the area of the transition zone. Locally, these are ore. Sulphide vein mineralization is present in the footwall in and adjacent to a zone of tourmalinite and very rare elsewhere. Irregular veins commonly form networks composed dominantly of pyrrhotite, galena and sphalerite. Generally minor amounts of quartz, arsenopyrite, chalcopyrite, cassiterite, tourmaline or scheelite occur in some veins. Major differences exist in footwall rocks, ore zone and hanging wall rocks in different areas of the mine.

Much of the orebody is underlain by locally derived intraformational conglomerate which is more than 80 metres thick in the west and thins to the east. Footwall rocks are cut by tabular bodies of chaotic breccia containing blocks of conglomerate and bedded sedimentary rock; these extend downward unknown distances from the sulphide footwall in the west. Footwall mineralization consisting of thin conformable laminae, veins and locally intense fracture-filling is common in the west and very rare in the east.

The footwall and hanging wall rocks and locally the orebody in the west have been extensively altered by hydrothermal solutions. A crosscutting zone of tourmalinite underlying the sulphide lens in the west is 1000 by 1500 metres across at the sulphide footwall and extends at least 500 metres beneath the orebody. Albite-chlorite-pyrite alteration occurs in crosscutting zones in the footwall tourmalinite and extends more than 100 metres into the hanging wall over the western part of the orebody. A zone of pyrite-chlorite alteration 300 metres in diameter crosscuts massive sulphide rock immediately overlying footwall albite-chlorite-pyrite alteration zones.

Extensive volumes of altered rock occur below, within and above the ore zone in the western part of the mine. Tourmalinite is included with wallrock alteration because most of the tourmalinite, except for that near the sulphide footwall, has crosscutting relations. Altered rocks unusually rich in chlorite, albite, pyrite, biotite, garnet and calcite occur in restricted crosscutting footwall structures, in a zone which crosscuts the orebody, and also occupy an extensive volume of rock in the hanging wall. Accessory minerals in altered hanging wall rocks include tourmaline, sphene, subordinate white mica, zircon, scapolite, calcite and quartz. Although minerals in altered rock have a metamorphic texture, their occurrence is interpreted as reflecting pre-metamorphic chemical modifications.

Pyrrhotite and pyrite (ratio of 7:3) are the most abundant sulphides in the Sullivan orebody. Galena and sphalerite (marmatite is the iron-rich variety) are the principal ore minerals. Minor but economically important minerals include tetrahedrite, pyrrargyrite, boulangerite and arsenopyrite (deleterious). Cassiterite is an important minor constituent in the western part of the orebody. Minerals constituting less than 1 per cent include chalcopyrite, jamesonite, magnetite and less abundant scheelite and stannite. Trace or small amounts of chalcostibite and gudmundite have also been identified along with cerussite and pyromorphite. Principal non-sulphide minerals are quartz and calcite with abundant tourmaline, chlorite, muscovite, albite, pale brown to reddish-brown mica, garnet, tremolite, epidote, actinolite, cordierite and

CAPSULE GEOLOGY

hornblende. Either quartz or calcite may make up 50 to 70 per cent of the non-sulphide suite, chlorite 30 per cent and the other minerals up to about 20 per cent.

In 1945 a pink mineral occurring as open-space fracture-fillings was found in a development raise in the southwest part of the orebody in an area where both ore and enclosing sedimentary rocks are highly manganeseiferous. This area is now an open pit and the pink mineral, tentatively identified as friedelite, is no longer to be found. Thirty-one years later a routine X-ray check was made from one of many hand specimens stored. Further work identified the mineral as a new mineral, mcgillite, the fifth member of the pyrosmalite group. Mcgillite is most often associated with very dark sphalerite and small amounts of boulangerite, galena, jamesonite and milky quartz.

Processing of Sullivan ore include recoverable amounts of cadmium, gold, bismuth, indium, iron, sulphur and antimonial lead and tin concentrate.

The Sullivan orebody is interpreted as a hydrothermal synsedimentary deposit which formed in a sub-basin on the Aldridge marine floor. It is located directly over conduits through which mineralizing fluids passed. Cross-strata permeability developed along synsedimentary faults and fractures; fluid escape along these led to development of chaotic breccia zones. Footwall conglomerate was extruded from breccia pipes or was laid down when locally oversteepened sediments collapsed. Boron-rich fluids percolated up the zones of cross-strata permeability, soaking adjoining footwall sediments and discharging onto the sea floor. Fluid composition and/or conditions in the sub-basin changed, and sulphides were deposited. Initial sulphide deposition over the vent area was rapid, as evidenced by lack of included clastic sedimentary rock. These features are felt to be consistent with deposition of sulphide particles which issued from the vent area. Waning stages of sulphide deposition were much less violent, and well-layered sulphides intercalated with intermittent clastic sediments became the dominant depositional style. In the upper part of both the eastern and western portions of the orebody, delicate sulphide lamellae consistent with chemical precipitation are widespread. Post-ore sodium-rich hydrothermal fluids altered tourmalinite, sulphide rocks, and hanging wall and footwall rocks over the vent area (Geological Association of Canada Special Paper 25).

Showings of sulphide mineralization were discovered in 1892. In 1909 the property was acquired by Consolidated Mining and Smelting Company of Canada (Cominco Ltd.). Beginning in 1900, the Sullivan mine has been a continuous producer until December 21, 2001, when the mine closed.

The mine is located on the southeast slope of Sullivan Hill, 3.2 kilometres northwest of the center of the city of Kimberley; the concentrator is located at Chapman Creek, 3.2 kilometres southeast of the center of the city. The North Star mine is located about 3.2 kilometres south of the Sullivan, on North Star Hill.

Prospectors Pat Sullivan, John Cleaver, E.C. "Ed." Smith, and Walter Burchett, of the Coeur d'Alene area of Idaho, were prospecting in the Kootenay Lake area in 1893 when they decided to band together for an overland trip to the Fort Steele area. On their arrival they heard stories of the impressive orebody of the North Star mine which had been discovered the previous year. On reaching North Star Hill, they found all of the hill had been staked but decided to prospect in the vicinity. They crossed Mark Creek to prospect the other slope and soon found the outcrop of the Sullivan orebody. They located 3 claims, the Shylock, Hamlet, and Hope (Lots 1385-1387 respectively). One of the partners, Sullivan, was killed in the Coeur d'Alene district in the winter of 1892 but the remaining three continued work on their claims at intervals when finances permitted until 1896.

The claims were bonded in 1896 to A. Hanson, of Leadville, but the bond was not taken up. Later that same year the property was bonded to Col. Ridpath, Judge Turner & associates, of Spokane. These interests organized the Sullivan Group Mining Company, which was registered in British Columbia in March 1897; the 3 original claims were Crown-granted to the company in 1898. From 1896 to 1899 some surface stripping was done and several small shafts sunk but transportation was a limiting factor and serious development was not begun until a branch line of the C.P. Railway was completed from Cranbrook in 1900. During the following years ore was shipped to the Hall Mines smelter at Nelson and the Canadian Smelting Works at Trail. In 1902 the company began the construction of a lead smelter at Marysville, 6.4 kilometres southeast of Kimberley. Due to the many metallurgical difficulties encountered, and also to the depressed condition of the lead market, the smelter was not put into operation until about 1905. The ore could not be treated profitably and both the smelter and mine closed late in 1907 after some 75,000

CAPSULE GEOLOGY

tons of ore had been smelted. At this stage the company had numerous-creditors and could not raise sufficient money to meet its debts. In 1909 the bond-holders and the creditors re-organized the company under the name of the Fort Steele Mining & Smelting Company, the control of the company being vested in the Federal Mining and Smelting Company, a subsidiary of the American Smelting and Refining Company.

The Consolidated Mining and Smelting Company of Canada (Limited) acquired a lease and bond on the property in December 1909. Subsequent exploration work indicated a large tonnage of complex ore which would become valuable if a satisfactory process of concentration could be developed. Also, these were high-grade ore zones which could be worked during the interval and smelted for lead. Late in 1910 the option on the stock of the Federal company and on that of some of the other shareholders was exercised; purchase of the property was completed in 1913. All of the adjoining claims considered necessary to the operation were purchased by the company in 1910. For the next few years mine development was directed to the discovery of ore sufficiently high in lead and silver, and low enough in zinc to be smelted with the facilities available at Trail. In 1914 the mine became the largest lead producer in Canada.

The future of the mine depended heavily on the improvement of the metallurgy of the ore, particularly the recovery of the contained zinc, and work on this problem began in 1910. Many tests on various processes of separation were carried out until, at last, satisfactory lead and zinc concentrates were produced at Trail by differential flotation in 1920. This new process made it possible to separate the run-of-mine ore into high-grade lead and zinc concentrates, and pyrrhotite concentrate for future use. A concentrator based on this process was built at the Sullivan mine and commenced operating in August 1923 with a capacity of 3,000 tons per day; the capacity was later increased in steps to 8,500 tons, and then to 11,000 tons in May 1949.

Development work on the orebody was initially from small pits and shallow shafts, and later from a main adit at the 1402 metre elevation. After it was proven that the ore went to depth an adit at the 1188.7 metre elevation was driven more than 1.6 kilometres north to the orebody; above it were 4 levels, including the old 1402 metre level. In subsequent operations an inclined shaft was sunk from 1188.7 metre level to the 807.7 metre elevation to establish 9 more levels. By the end of 1949 a new 1127.7 metre level haulageway was completed. Two new shafts, 609.6 metres apart, were put down in 1947 to service below the 1021 metre elevation. In 1960 the main shaft was extended 152.4 metres to provide two new levels. Mining was done initially in square-set stopes but in order to provide a shipping product low in zinc a kind of room and pillar system was introduced; this was modified somewhat when the concentrator was put into operation. Experimental work in backfilling began in 1936 and the practice has continued, utilizing development waste, cemented float fill, glacial till, and caving. Pillar extraction had become a major part of the operation by the 1950's.

An open pit mining operation began in 1951 to recover the remaining ore in the outcrop and nearby areas, and for several years provided about 20 per cent of total mine production. The pit operation was closed temporarily in May 1957 and not re-opened until 1964. During the latter year the remaining open pit ore was removed, providing about 7 per cent of total production for that year.

Tin was discovered in the ore in 1925. A plant for recovery of cassiterite from the flotation tailings was put into operation in March 1941 and an electric smelter for tin was added in April 1942. Traces of indium in the zinc concentrate had been known for many years and a recoverable accumulation was eventually found in slag from the complex lead-zinc smelting process at Trail. Indium was first recovered at Trail in 1941 and production on a commercial scale began in 1955. In 1954 an estimated 10,000,000 ounces of indium was available in by-product stockpiles built up over the years.

In 1960 the company estimated pyrrhotite flotation concentrate reserves at 15,000,000 tons and calculated an equivalent of 350,000 tons would be added to the total annually from production. Roasting of these concentrates to recover contained sulphur as sulphuric acid began on a limited scale in 1953. Facilities for converting the by-product iron oxide sinter to pig iron were installed in 1961.

The company name was changed in 1966 to Cominco Ltd. The property at that time included 678 Crown-granted claims and fractions and 30 recorded claims, and extended southerly to include the former Stenwinder and North Star mines (see 82 F/9 Zn I and Pb 2). In 1975 the company began a modernization program which will, over a number of years, convert the mine to trackless mining methods.

Measured and indicated reserves in the Sullivan mine, as of

CAPSULE GEOLOGY

December 31, 1979, were reported as 54,000,000 tons at 4.5 per cent lead, 5.9 per cent zinc, 37.7 grams per tonne silver (Cominco Ltd., 1979 Annual Report).

Reserves estimated by the company at September 30, 1994 were 13 million tonnes grading 7.91 per cent zinc, 4.53 per cent lead and 25.69 grams per tonne silver, sufficient for about another six years of operation (Information Circular 1995-9, page 8). In 1995, it was the first full year of operation of the new lead-regrind circuit in the mill, resulting in higher grade zinc concentrates, and improved lead and zinc recovery.

In 1995, with Explore B.C. Program support, Cominco Ltd. made substantial progress on a deep drillhole that had been started December 14, 1991 on the Hope 12 claim on Mark Creek to test for the downfaulted extension of the Sullivan horizon. The hole was resumed on August 15, 1995 at 182 metres depth and drilled by October 31, 1995 to 1937 metres, still 214 metres short of the originally planned 2150 metre length. The hole intersected a section of Middle Aldridge sediments and a gabbro considerably thickened by thrusting, and did not reach the Sullivan horizon target, now projected to be at 2500 metres depth (Explore B.C. Program 95/96 - A142). This hole ended at 2600 metres in 1996.

Reserves estimated by the company at January 31, 1996 were 11,435,200 tonnes grading 25.0 grams per tonne silver, 4.5 per cent lead and 8.0 per cent zinc (Information Circular 1997-1, page 10).

Reserves in 1997 are estimated at 6,349,700 tonnes grading 41.1 grams per tonne silver, 6.8 per cent lead and 12.1 per cent zinc; the mine is scheduled to close on December 31, 2001 (T. Schroeter, personal communication, 1997).

Reserves entrusted by the company at January 31, 1997 were 8,800,000 tonnes grading 8.0 per cent zinc, 4.4 per cent lead and 24.0 grams per tonne silver (Information Circular 1998-1, page 9).

Reserves as of December 31, 1997 were 7,100,000 tonnes grading 7.2 per cent zinc, 4.0 per cent lead and 23 grams per tonne silver (Cominco Ltd. Fact Book, October 26, 1998).

Proven and probable reserves as of December 31, 1998 are reported as 6.1 million tonnes averaging 6.6 per cent zinc, 3.7 per cent lead and 20 grams per tonne silver (Exploration in BC 1998, page 73).

Proven and probable reserves as of December 31, 1999 are reported as 4.6 million tonnes averaging 6.4 per cent zinc, 3.3 per cent lead and 18 grams per tonne silver (Information Circular 2001-1, page 6).

Proved reserves as of December 31, 2000 are reported as 1.8 million tonnes averaging 6.6 per cent zinc, 3.7 per cent lead and 17.00 grams per tonne silver.

The mine closed December 21, 2001.

CAPSULE GEOLOGY

The property is located at about the 1590 metre elevation on the northeast slope of North Star Hill, 3 kilometres west of Kimberley.

The host rocks are argillaceous quartzites of the Middle Proterozoic Aldridge Formation, Purcell Supergroup. The original orebody was a replacement deposit similar to the Sullivan mine (082FNE052). The ore was primarily a very clean and solid argentiferous galena with only a small amount of sphalerite. Wire silver and crystals of cerussite occur as well as iron sulphides.

The showings were discovered and staked in June 1892 by Messrs. Bourgeois and Langill, who bonded the claims to the Woods Brothers, of Quebec; the latter sold 4/5 of their interest to D.D. Mann & associates, of Montreal, in 1893. The initial development work, in a shaft and crosscut adit, exposed a large body of high-grade ore. In 1894, four claims, the North Star, O.K., Buckhorn, and Dreadnaught (Lots 657-660, respectively), were Crown-granted to the North Star Mining Company, Limited Liability, which was incorporated that same year. The initial production from the mine was hauled by wagon 32.1 kilometres to the Kootenay River for transport by boat to Jennings, Montana, and then by rail to the smelter at Great Falls. Shipments ceased in 1897 to await the construction of the railway and mine operations were confined to development work. In April 1899 a new company, The North Star Mining Company, Limited, was incorporated with D.D. Mann as president; the former company was dissolved in 1900. The property at that time included, in addition to the Crown-grants, 13 claims held by location, including the Stemwinder. The C.P.R. railway was completed to Cranbrook in 1899 and a branch line was completed to Kimberley in 1900. During 1903 the limits of the orebody were reached and efforts were directed towards further exploration by means of numerous shallow workings and a shaft. The orebody had been mined from surface workings and from an adit driven in the footwall 18.2 metres below the surface outcrop.

In 1904 the company accountant, Mr. N. Curran, was appointed manager of the property to salvage the few tons of known ore left and to wind up the operation. This "clean up" project revealed a surprising amount of ore at the edges of old stopes and also the existence of considerable carbonate ore underlying surface gravels and soils. Mining operations continued into 1910 when the mine finally closed.

CAPSULE GEOLOGY

The Federal Mining and Smelting Company, a subsidiary of the American Smelting and Refining Company, optioned the property in 1917 and for 2 or 3 months during 1918 carried out limited diamond drilling. Later that same year O.C. Thompson & associates leased the North Star and began shipping ore sorted from the old dumps.

In June 1924 Thompson and associates gave a 3-year sub-lease and option on the property to the Porcupine Goldfields Development and Finance Company, Limited, of London, England. Work on the property during 1924 and 1925 included 624 metres of diamond drilling in a few shallow holes, and electrical prospecting. The lease and option expired in 1927. The North Star Mining Company charter was surrendered in 1931.

The Consolidated Mining and Smelting Company of Canada Limited acquired the property prior to 1937.

CAPSULE GEOLOGY

The Cotnoir - Fors is underlain by siltstone and wacke of the Middle Proterozoic (lower) Aldridge Formation. A showing on the east side of Pitt Creek consists of a quartz-calcite vein hosting chalcopyrite, pyrrhotite and minor arsenopyrite and sphalerite. About 90 metres to the south, a quartz vein occurs hosting galena and sphalerite.

CAPSULE GEOLOGY

Portions of massive quartz occur in argillaceous quartzite of the Middle Proterozoic Creston Formation (Purcell Supergroup). The quartz vein is mineralized with pyrite, chalcopyrite, gold and silver.

In 1973 and 1974, 1,481 tonnes was mined from surface showings and shipped to Trail for smelting. From this 13,405 grams of silver, 14,945 grams of gold, 1,307 kilograms of copper, 3,286 kilograms of lead and 1,481 kilograms of zinc were recovered. It was also mined for its silica.

CAPSULE GEOLOGY

Quartz vein occurs in argillaceous quartzites of the Middle Proterozoic Creston Formation, Purcell Supergroup. Mineralization includes hematite and pyrite with gold, silver and lead values. From 381 tonnes of ore mined between 1937 and 1940, 5,194 grams of silver, 3,173 grams of gold and 200 kilograms of lead were produced.

CAPSULE GEOLOGY

Two or more large persistent quartz veins occur in fissures in a fault zone within argillaceous quartzites of the Helikian Creston Formation, Purcell Supergroup. These contain small amounts of pyrite and galena, and rare pyromorphite crystals (lead phosphate). A vein has been traced 470 metres and varies in width from 0.6 to 7.6 metres. It strikes 015 degrees and dips 35 to 50 degrees southeast.

CAPSULE GEOLOGY

A vein of white quartz occurs conformable with schistosity of phyllitic quartzites of the Middle Proterozoic Creston Formation, Purcell Supergroup. A Middle Proterozoic granitic stock occurs nearby. The ore consists of galena, pyrite, sphalerite, tetrahedrite, scheelite, hematite and stibnite.

This property is located on the Sawmill Creek Fault, 6 to 8 kilometres south of St. Mary's Lake, near Angus Creek. In 1932, the property was owned by J. Angus. Early exploration and development consisted of an adit, a shaft and open cuts, all caved. There was also a drift out 39 metres long and some surface exploration.

In 1950, road construction to the property commenced but work ceased in October.

Estella Mines, Ltd., took option on the property in the following year and carried out general exploration. In 1955 the company changed its name to United Estella Mines Ltd., but it is not known if this company still holds this property.

Assays from the gold and silver range from 0.7 to 164 grams per tonne gold and 10 to 1971 grams per tonne silver.

Middle Proterozoic	Purcell	Aldridge	

LITHOLOGY: Argillaceous Quartzite

GEOLOGICAL SETTING

TECTONIC BELT: Omineca
TERRANE: Ancestral North America

PHYSIOGRAPHIC AREA: Purcell Mountains

CAPSULE GEOLOGY

The property is located between elevations of 1219.2 metres and 1981 metres on the southeast side of Hellroaring Creek, 4.8 kilometres south of St. Mary Lake and 19 kilometres southwest of Kimberley.

The Warhorse is underlain by intensely sheared argillaceous quartzite of the Middle Proterozoic Aldridge Formation, Purcell Supergroup. Mineralization occurs in quartz veins and lenses up to 1 metre wide. The veins are well-mineralized with galena, sphalerite, pyrite and locally, arsenopyrite. Some siderite also occurs locally.

The showings were reportedly staked in about 1895 and development work prior to 1910 was done in two adits, one of which was on the Iron Duke claim. The property was owned in 915 by N.A. Wallinger and associates. In 1920 A.H. Mayland of Calgary acquired an interest in the property. Four claims were Crown-granted in 1925, the Warhorse (Lot 13077) to Messrs. Wallinger, Bennett, and Mayland, and the Hope, Granite, and Faith (Lots 13078-13080 respectively) to Mayland. The property was known from about 1926 as the Boy Scout group. Development work, financed by Mayland and associates, was begun in a new (No. 3) adit in 1926 and continued into 1930. Cranberra Mines, Limited was incorporated as a private company in January 1930 by Mayland and associates to develop the property. When work ceased in 1930 the No. 3 adit had been driven as a crosscut for 104 metres and drift for more than 152 metres, with crosscuts near the face driven 21 metres northeast and 15 metres southwest. The old No. 1 adit had been driven to a length of about 49 metres. The No. 2 adit was driven in the footwall of the vein for most of its 91 metre length, with four crosscuts extending into the hangingwall.

Staple Mines and Minerals Limited held an option on the property during the first half of 1949 but no work was reported. Lake Expanse Gold Mines, Limited optioned the property from R. Bennett of Cranbrook late in 1949. Surface diamond drilling was carried out on the Warhorse claim.

Thomas Consolidated Mines, Inc., of Spokane, optioned the property late in 1950. Development work began in 1951 in a new 1387 metre elevation adit, about 213 metres vertically below No. 1 adit. By 1956, a total of 1245 metres of drifting and crosscutting, and 500 metres of diamond drilling had been carried out in the new adit. Work ceased at the end of July 1956.

St. Mary's Silver Lead Ltd. was incorporated in September 1965

to acquire the property. The company name was changed to Hellroaring Silver Lead Ltd. in November 1965, and to St. Mary's Mines Ltd. in April 1968. Work by previous operators had indicated approximately 23,000 to 27,000 tonnes at 6 per cent lead, 8 per cent zinc, 171 grams per tonne silver (Northern Miner, Dec. 30, 1965). In 1969 the company carried out 610 metres of surface diamond drilling in 11 holes.

CAPSULE GEOLOGY

The Lower Jack zone (082FNE115) was discovered in 1999 during prospecting along a newly constructed logging road in a steep, overburden-covered area. A number of large, lead-zinc bearing, hydrothermally altered, angular tourmalinite and Aldridge Formation fragmental float boulders occur in a 300 by 300 metre area. The float boulders are well mineralized with galena, sphalerite, arsenopyrite and pyrrhotite. This discovery was staked in the summer of 1999 and is now part of what is called the Pakk property. The Upper Jack zone (082FNE115) was also discovered by prospecting in the area and is located 2500 metres northwest of the Lower Jack zone. A third discovery, the Sinclair zone (082FNE117), is 2000 metres north-northeast of the Upper Jack zone. The Polly Vent showing is located 4000 metres north-northeast of the Sinclair showing. The Pakk property includes the Horn, Burn, Pit and Pakk claim groups.

The original Dan Howe showing, now called the Polly Vent, was described as a lenticular quartz vein in sheared argillaceous quartzites of the Helikian Aldridge Formation (Purcell Supergroup) beneath a Proterozoic Moyie Intrusions diorite sill.

In 1999, Chapleau Resources Ltd. completed one diamond drill-hole which intersected a sulphide-rich fragmental complex 230 metres thick. The complex consists of fragmental rock units up to 50 metres thick interbedded with thin bedded pyrrhotiferous argillite. Massive sulphide, mainly pyrrhotite and arsenopyrite, form the matrix of the fragmental units. Bedding-parallel bands of disseminated sphalerite up to 30 centimetres thick occur within the interbedded argillite units.

Super Group Holdings Ltd. is directing the exploration and Chapleau Resources Ltd. is performing the work on the property.

CAPSULE GEOLOGY

Fractures occur in Aldridge Formation quartzite of the Middle Proterozoic Purcell Supergroup, above a Moyie diorite sill. Stringers and lenses of quartz in the fractures contain galena and a little chalcopyrite, sphalerite and scheelite. Garnet is a common gangue.

In 1998, Abitibi Mining Corp. drilled a 443-metre hole.

CAPSULE GEOLOGY

The Copper King property is located at elevations of 1830 to 2440 metres on White Grouse Mountain, at the headwaters of Goat River and Meachen Creek, some 39 kilometres southwest of Kimberley.

A zone, 30 to 120 centimetres wide, bearing irregular quartz stringers was exposed for 18 metres by a trench in buff-weathering dolomitic strata of the Middle Proterozoic Kitchener Formation, Purcell Supergroup. Tetrahedrite, pyrite, galena and a little chalcopyrite occur.

A number of claims were staked in this area in 1893 or earlier but due to the difficult access little was done other than assessment work. A 15 metre adit was driven on the Copper King claim, and also an adit on the Silver Tip claim. In 1900 the Delaware (Lot 2858) was Crown-granted to Messrs. Ray and Gosselin, the Lucy (Lot 2860) to J. Blanchard and A. Williams, and the Chapin (Lot 2862) to California and Clipper Silver-Lead Mines, Limited. In 1905 Crown-grants were issued to Hugh Sutherland for the Copper King, Big Four, Mammoth, Silver Tip, Duplex, and Colby (Lots 3835-3838, 3840, 3632, and 6340 respectively). Another group of claims, located about 800 metres to the south, including the Storm King, Robber King, Gem, Nowell, and Tamarack (Lots 3625, 3626, 3631, 3838, and 6338 respectively) were Crown-granted in 1905 to Messrs. Gibson, Sutherland, Nell, and Holmes. The Banner claim (Lot 3839) was Crown-granted to Hugh Sutherland in 1909.

CAPSULE GEOLOGY

This Faller property is located on the westerly side of Mount Evans, about 24 kilometres southwest of Kimberley.

The area is underlain by quartzite and siltstone of the Middle Proterozoic (Middle) Aldridge Formation (Purcell Supergroup), intruded by meta gabbro or meta diorite of the Proterozoic Moyie Intrusions. Three or more of these sills, from 60 to 180 metres thick, strike in a northwest direction through the area for an aggregate length of 3.5 kilometres.

Pyrite, pyrrhotite and chalcopyrite are disseminated in diorite. Prior to 1920 three properties, the Evans, Good Hope, and Whitefish, were located over a north-south distance of about 3.2 kilometres.

A fourth property (Faller group) was located about 1.6 kilometres to the northwest) on the north side of Meacham Creek. The locations of the Good Hope and Evans prospects, as shown on Map 15-1957, appear to be reversed in view of the location of the Good Hope claim on Map 92 F/9 W, and the description given in the Report of Minister of Mines, British Columbia for 1915.

The Faller group, of 6 claims, was first reported on in 1900 when some 91 metres of adit had been driven. The Selkirk Copper Mines, Limited, incorporated at Moyie in May 1903, is believed to be the company which carried out exploration work on the property until about 1905. The workings at that time included 2 adits totalling about 152 metres of crosscuts and drifts.

Work on the Good Hope group prior to 1901 consisted of a 15 metre adit. In 1912 the Good Hope, Rose, and Toolips claims (Lots 9820-9822, respectively) were Crown-granted to Mr. C.H. Pollen.

Messrs. C. and W. Evans, of Marysville, recorded assessment work on the Pacific, Curfew, Twilight, and Sunset claims on Fiddler Creek in 1904. Their holdings were expanded in about 1915 to include claims in Pollen Basin and Kelly Basin. Most of their exploration work to that time had been done at their main camp near the head of Fiddler Creek, where approximately 91 metres of adit was driven. Their combined holdings were known as the Evans or Achilles property. Assessment work by the Evans brothers was reported yearly until about 1926.

The only report on the Whitefish group (3 claims) was in 1920

when the workings consisted of 50 metres of adit and a 6 metre winze.
The JAG 1-58 claims, staked in March 1972 by A. Hopkins, of Toronto, covered the four old properties mentioned above. Mount Evans Copper Corp. Inc., incorporated in Ontario in May 1972, acquired 18 of the Jag claims.

CAPSULE GEOLOGY

This Whitefish property is located on the westerly side of Mount Evans, about 24 kilometres southwest of Kimberley.

The occurrence area is underlain by quartzite and siltstone of the Middle Proterozoic (Middle) Aldridge Formation (Purcell Supergroup), intruded by meta gabbro or meta diorite of the Proterozoic Moyie Intrusions. Three or more of these sills, from 60 to 180 metres thick, strike in a northwest direction through the area for an aggregate length of 3.5 kilometres.

A quartz vein occurs in diorite with pyrite, malachite and azurite. Ore shipped in 1920 was reported to run "6 per cent copper and 6 ounces silver" (presumably meaning per tonne, giving 205 grams of silver per tonne)(Annual Report 1920).

Prior to 1920 three properties, the Evans, Good Hope, and Whitefish, were located over a north-south distance of about 3.2 kilometres.

A fourth property (Faller group) was located about 1.6 kilometres to the northwest) on the north side of Meacham Creek. The locations of the Good Hope and Evans prospects, as shown on Map 15-1957, appear to be reversed in view of the location of the Good Hope claim on Map 92 F/9 W, and the description given in the Report of Minister of Mines, British Columbia for 1915.

The Faller group, of 6 claims, was first reported on in 1900

Messrs. C. and W. Evans, of Marysville, recorded assessment work on the Pacific, Curfew, Twilight, and Sunset claims on Fiddler Creek in 1904. Their holdings were expanded in about 1915 to include claims in Pollen Basin and Kelly Basin. Most of their exploration work to that time had been done at their main camp near the head of Fiddler Creek, where approximately 91 metres of adit was driven. Their combined holdings were known as the Evans or Achilles property. Assessment work by the Evans brothers was reported yearly until about 1926.

The only report on the Whitefish group (3 claims) was in 1920 when the workings consisted of 50 metres of adit and a 6 metre winze.

The JAG 1-58 claims, staked in March 1972 by A. Hopkins, of Toronto, covered the four old properties mentioned above. Mount Evans Copper Corp. Inc., incorporated in Ontario in May 1972, acquired 18 of the Jag claims.

CAPSULE GEOLOGY

This Evans property is located on the westerly side of Mount Evans, about 24 kilometres southwest of Kimberley.

The occurrence area is underlain by quartzite and siltstone of the Middle Proterozoic (Middle) Aldridge Formation (Purcell Supergroup), intruded by meta gabbro or meta diorite of the Proterozoic Moyie Intrusions. Three or more of these sills, from 60 to 180 metres thick, strike in a northwest direction through the area for an aggregate length of 3.5 kilometres.

Veins in diorite contain quartz and calcite, which in and adjacent to are found chalcopyrite, pyrrhotite, pyrite and sometimes galena.

Prior to 1920 three properties, the Evans, Good Hope, and Whitefish, were located over a north-south distance of about 3.2 kilometres.

A fourth property (Faller group) was located about 1.6 kilometres to the northwest) on the north side of Meacham Creek. The locations of the Good Hope and Evans prospects, as shown on Map 15-1957, appear to be reversed in view of the location of the Good Hope claim on Map 92 F/9 W, and the description given in the Report of Minister of Mines, British Columbia for 1915.

The Faller group, of 6 claims, was first reported on in 1900 when some 91 metres of adit had been driven. The Selkirk Copper Mines, Limited, incorporated at Moyie in May 1903, is believed to be the company which carried out exploration work on the property until about 1905. The workings at that time included 2 adits totalling about 152 metres of crosscuts and drifts.

Work on the Good Hope group prior to 1901 consisted of a 15 metre adit. In 1912 the Good Hope, Rose, and Toolips claims (Lots 9820-9822, respectively) were Crown-granted to Mr. C.H. Pollen.

Messrs. C. and W. Evans, of Marysville, recorded assessment work on the Pacific, Curfew, Twilight, and Sunset claims on Fiddler Creek in 1904. Their holdings were expanded in about 1915 to include claims in Pollen Basin and Kelly Basin. CAPSULE GEOLOGY

The Good Hope property is located on the west side of Mount Evans, about 24 kilometres southwest of Kimberley.
A faulted quartz-calcite vein(or two veins) hosting chalcopyrite occurs in diorite. The vein(s) are from 0.3 to 2 metres wide. Chalcopyrite also occurs in the host diorite. A 72 metre-long adit is reported.
Prior to 1920 three properties, the Evans, Good Hope, and Whitefish, were located over a north-south distance of about 3.2 kilometres.
A fourth property (Faller group) was located about 1.6 kilometres to the northwest) on the north side of Meacham Creek. The locations of the Good Hope and Evans prospects, as shown on Map 15-1957, appear to be reversed in view of the location of the Good Hope claim on Map 92 F/9 W, and the description given in the Report of Minister of Mines, British Columbia for 1915.
The Faller group, of 6 claims, was first reported on in 1900 when some 91 metres of adit had been driven. CAPSULE GEOLOGY

A skarn occurs in dolomitic marble and dolomitic siltstone of the Middle Proterozoic Kitchener Formation (Purcell Supergroup) between two lobes of granite of the White Creek Batholith. Calcsilicate alteration of the sediments to epidote, tremolite and calcite is common. Tungsten and molybdenum mineralization are reported to occur within the skarn.

CAPSULE GEOLOGY

A band of dolomite of the Lower Cambrian Badshot Formation outcrops on the east shore of Kootenay Lake, 3 kilometres northwest of Cape Horn (Pilot Point) and continues northeast for 3.5 kilometres across Crawford Peninsula to Crawford Bay. The band strikes 040 degrees and dips 70 degrees northwest on Kootenay Lake. The bed is 150 metres thick at this location.

The exposures on Kootenay Lake reveal white to yellowish-white, medium grained dolomite with quartz veins, golden mica grains and patches of various silicates. The dolomite becomes interbedded with schistose rocks near the northern edge of the band. Numerous dykes intrude the dolomite. A sample from the northern edge of the band contained 30.32 per cent CaO, 20.18 per cent MgO, 3.94 per cent SiO₂, 0.71 per cent Al₂O₃, 0.49 per cent Fe₂O₃ and 0.02 per cent sulphur (CANMET Report 811, p. 212, Sample 85A).

Diamond drilling on the northeast end of the band at Crawford Bay encountered mostly white to bluish-grey dolomite displaying some pink and rusty zones. A sample of cored dolomite contained 27.70 per cent CaO, 16.80 per cent MgO, 14.12 per cent SiO₂, trace of Al₂O₃,

0.52 per cent Fe₂O₃ and 39.94 per cent ignition loss (Assessment Report 4923).

The deposit was explored by diamond drilling, by International Marble & Stone Company, near the east shore of Crawford Bay during 1973 and 1976. The company drilled the Roy claims in 1981.

CAPSULE GEOLOGY

These claims lie directly west of Loon Lake at an elevation of about 1000 metres, The property may be reached by road from Ainsworth.

The Krao and Crow-Fledgling (082FNE080) Crown grants are underlain by hornblende schists, limestone and banded quartzite of the Mississippian to Lower Permian Milford Group. Calcite, siderite and quartz with galena and sphalerite occur in a fissure in the limestone. Wire silver occurs in solution cavities and joint planes within the mineralized zone.

The Krao was mined intermittently from 1889 until 1964. A total of 1,463 tonnes mined is recorded for the property. From this, 3,842,776 grams of silver, 179,928 kilograms of lead and 8,721 kilograms of zinc and 6 kilograms of cadmium were recovered.

The Krao and Crow-Fledgling claims were Crown granted to A.D. Wheeler in 1890. During the first period of major development work, which lasted through 1908, the deposit was stripped over a 18 by 46 metre area. A shaft, dipping west at 75 degrees, was sunk on the hanging wall to a depth of 30 metres. A tunnel on the Crow Fledgling claim was driven for 259 metres to intersect the Krao limestone at about 91 metres below the surface. Several hundred feet of drift along a limestone band at the end of the crosscut failed to turn up any ore. In 1906 the property was sold to the Krao Silver-Lead Mining Co. and a program of stripping and of stoping of small amounts of high-grade ore was carried out. The following year the shaft was deepened to 78 metres and 152 metres of drifting and crosscutting was completed. Water courses were encountered in sinking.

Active production ceased soon after 1908 and except for small amounts of very rich silver ore mined by leasers, there was little change up to 1952. In 1949 the Yale Lead & Zinc Mines Ltd. acquired these claims. The Krao dump, amounting to 173 tonnes, was milled in 1952. In 1953-54 stoping was done adjacent to the shaft at the 30 metres level. The following year stoping was carried out above the 61 metres level. Coin Explorations and David Minerals may have been involved with property in 1967 and 1980 respectively.

CAPSULE GEOLOGY

The United workings consist of a two-compartment shaft inclined at 60 degrees to the southwest, reported to be 72 metres deep, and three level workings from the shaft.

Most of the work on the United was done before 1910. Shipments of ore were made between 1918 and 1920. The property was drilled in 1950 and much of the old dump near the shaft was trucked to the Yale mill in 1952. At total of 776 tonnes of ore was mined and 95,455 grams of silver, 81,160 kilograms of lead and 93 grams of gold were recovered.

Mineralization exposed in a trench northwest of the shaft and at the collar of the shaft is along a vein in fine-grained hornblende schist of the Permo-Triassic Kaslo Group which strikes northwest and dips 60 degrees to the southwest. The vein contains quartz, galena, spalerite, pyrite and minor chalcopyrite and is about 60 centimetres thick. The trench is within 15 metres of the Jospephine fault, which separates the hornblende schist from grey knotted schist and intercalated minor limestones to the west. The vein is not found west of the Josephine fault, and probably it swings northward into the fault.

CAPSULE GEOLOGY

The Neosho property is located about 1.6 kilometres west of Kootenay Lake and about 1 kilometre north of Coffee creek at an elevation of about 1036 metres. A branch road 18 kilometres long was built to the property from the No. 1 mine road.

The country rocks are limestone, argillite and staurolite schist of the Mississippian to Lower Permian Milford Group. Granite of the Nelson Intrusions occurs immediately to the south. Intrusive sills or dikes of gneissic granite occur throughout the area north of the contact. The limestones strike approximately north and dip to the west. The Neosho vein, varying in width up to 0.76 metres, follows the bedding in the limestone. The vein is not presently exposed but is reported to have been in a zone of sheared and oxidized schist (with limestone layers) containing galena, sphalerite and locally wire silver.

Small amounts of high grade silver ore are reported to have been shipped from this property in 1889 and 1890. The Neosho claim was Crown granted to the Neosho Mining Co. in 1892. By 1895 the workings consisted of a shaft over 30 metres deep and 76 metres of tunnel. Neosho Mines Ltd. acquired the Neosho, Normandy and several other claims in 1928 but very little work was done and the property lay idle for the next 20 years.

S. Hallgran obtained the claim from the Crown in 1948. Leasers worked the property in 1949. Privateer Mines Ltd. obtained an option to purchase the property but after a preliminary investigation by the company engineer in May 1950, it was decided that the option should be dropped.

Ten tonnes were shipped in 1922 and a further 135 tonnes were shipped in 1949 and 1950. From this 104,785 grams of silver, 3,508 kilograms lead and 7,808 kilograms of zinc were recovered.

CAPSULE GEOLOGY

These claims lie directly west of Loon Lake at an elevation of about 1000 metres, The property may be reached by road from Ainsworth.

The Krao (082FNE076) and Crow-Fledgling Crown grants are underlain by hornblende schists, limestone and banded quartzite of the Mississippian to Lower Permian Milford Group. Calcite, siderite and quartz with galena and sphalerite occur in a fissure in the limestone. Wire silver occurs in solution cavities and joint planes within the mineralized zone.

The Crow-Fledgling has recorded production for 4 years from 1937 to 1960 when 169 tonnes was shipped. From this, 25,913 grams of silver, 13,394 kilograms of lead and 10,039 kilograms of zinc and 22 kilograms of cadmium were recovered.

The Krao and Crow-Fledgling claims were Crown granted to A.D. Wheeler in 1890. During the first period of major development work, which lasted through 1908, the deposit was stripped over a 18 by 46 metre area. A shaft, dipping west at 75 degrees, was sunk on the hanging wall to a depth of 30 metres. A tunnel on the Crow Fledgling claim was driven for 259 metres to intersect the Krao limestone at about 91 metres below the surface. Several hundred feet of drift along a limestone band at the end of the crosscut failed to turn up any ore. In 1906 the property was sold to the Krao Silver-Lead Mining Co. and a program of stripping and of stoping of small amounts of high-grade ore was carried out. The following year the shaft was deepened to 78 metres and 152 metres of drifting and crosscutting was completed. Water courses were encountered in sinking.

Active production ceased soon after 1908 and except for small amounts of very rich silver ore mined by leasers, there was little change up to 1952. In 1949 the Yale Lead & Zinc Mines Ltd. acquired these claims. The Krao dump, amounting to 173 tonnes, was milled in 1952. In 1953-54 stoping was done adjacent to the shaft at the 30 metres level. The following year stoping was carried out above the 61 metres level. Coin Explorations and David Minerals may have been involved with property in 1967 and 1980 respectively.

CAPSULE GEOLOGY

Although the Firebrand is an old property, there is no published account of the work done on it until 1955. Two shallow shafts and a number of open cuts and a short adit have been excavated.

The workings occur along a quartz vein that strikes 340 degrees and dips about 65 degrees west. The host rocks are micaceous quartzite and quartz-mica schist which lie west of a layer of hornblende schist, all of the Mississippian to Lower Permian Milford Group. The vein is found intermittently along strike for about 150 metres.

Recorded production of 15 tonnes for 1924 shows that 56,981 grams of silver and 1,569 kilograms of lead were recovered.

CAPSULE GEOLOGY

The Glengarry showing occurs in a hornblende schist and gneiss of the Permo-Triassic Kaslo Group and a quartz-mica schist with minor limestone unit of the Mississippian to Lower Permian Milford Group. Workings consist of a caved incline shaft, about 20 metre deep and made about 1900, and a shallow adit about 200 metre southeast of the shaft, made after 1917.

Several short narrow veins in quartzite and hornblende schist contain coarse, dark-coloured sphalerite, galena, pyrite and minor chalcopyrite. One vein exposed in and open cut less than 30 metres northwest of the adit contains galena in siderite and quartz.

The Noble 3 showings occur in hornblende schist of the Permo-Triassic Kaslo Group. A quartz vein striking 300 degrees and dipping steeply south contains coarse galena, sphalerite and pyrite locally in well-formed cavities between quartz crystals. The vein has been traced for "several hundred feet" and is less than 30 metres thick.

Middle Proterozoic	Purcell	Mount Nelson	

LITHOLOGY: Argillite

GEOLOGICAL SETTING

TECTONIC BELT: Omineca
TERRANE: Ancestral North America

PHYSIOGRAPHIC AREA: Purcell Mountains

CAPSULE GEOLOGY

This property is located at the 1800-metre elevation on the south side of Canyon Creek, a northwesterly flowing tributary of Crawford Creek, about 18 kilometres east of Kootenay Lake.

The Silver Hill deposit consists of one or more quartz veins, from 30 to 60 centimetres wide, that parallel the bedding in dark grey argillite of the Middle Proterozoic Mount Nelson Formation (Purcell Supergroup). The veins have been traced for at least 800 metres. The veins are well-mineralized with galena, sphalerite, tetrahedrite and pyrite.

A number of ore shipments occurred from 1901 to 1952. From a total of 2,204 tonnes mined, 2,184 kilograms of silver, 31 grams of gold, 26 kilograms of copper, 159,401 kilograms of lead and 16,122 kilograms of zinc were recovered.

The Silver Hill group, including the Silver Hill (Lot 2852), Green Crown, S & N Fraction, Norfolk, Simcoe, and Boy Crown-granted claims, was held by The London Consolidated Cold Fields Exploration and Mining Company Limited, incorporated March 1897, from 1898 until 1901. The Richelieu group, adjoining the Silver Hill group on the south, included the Indication (Lot 2863) and Jennie D, Crown-granted claims. The Richelieu Mining Company Limited, incorporated May 1899, carried out development work on the property until 1901. The London and Richelieu Mining and Smelting Company Limited, Incorporated June 1901, apparently acquired both groups of claims and work continued until late 1901. Development work to this date consisted of 1036 metres of underground workings in 4 adits and some 457 metres of open cutting and stripping. The X-ray claim (Lot 5089), located a short distance south of the Indication claim, was Crown-granted to H.M. Rumball in 1901, however, no development work has been reported.

Lessees reportedly shipped ore from the property in 1903. Silver Hill Mines Limited, incorporated in August 1916, is reported to have shipped ore from the property in 1917. In 1925, W.J. Williams and associates leased the property from the Bank of Montreal and the following year shipped 23 tonnes of ore.

No further work was reported until about 1935 when private capital began exploration work on the property. British Columbia Lead and Zinc Mines Limited, formed in March 1937, acquired the

CAPSULE GEOLOGY

property and expanded it to 17 claims. The four adits were cleaned out and the veins resampled, however, no further work was reported done by the company.

Mr. J.J. Gray of Toronto held a lease on the property and during 1949 and 1950 made several shipments of ore from the dump. The Abco Mining Corporation Limited, Nelson, B.C., made a shipment of 15 tonnes of ore from the property in 1952.

CAPSULE GEOLOGY

The Gold Ledge occurs in the Alki fault zone which cuts Middle Proterozoic argillaceous quartzite of the Aldridge Formation, Purcell Supergroup. The principal workings are a 41-metre drift and a 14 metre crosscut. The drift traverses sheared rock containing numerous quartz stringers. The crosscut exposes 2.4 metres of quartz-filled breccia and 7.6 metres of fractured quartz. Arsenopyrite, galena and pyrite are the sparse sulphide minerals present. Siderite is present in the gangue. A selected sample yielded more than 34 grams per tonne gold (GSC Memoir 228).

CAPSULE GEOLOGY

The Bulldog area is underlain by quartzite of the Middle Proterozoic Aldrige Formation, Purcell Supergroup. White quartz outcrops widely on the hillside but sulphides are sparse or lacking. A little to the west of these showings, a tunnel has been driven in a shear in diorite. The shear carries quartz stringers with a little galena and arsenopyrite. The diorite is probably related to the Proterozoic Moyie Intrusions.

CAPSULE GEOLOGY

Scheelite occurs in fracture stockwork zones in Middle Proterozoic Moyie metadiorite sills. The sills occur within quartzwacke, quartz arenites and siltstones of the Middle Proterozoic Aldridge Formation, Purcell Supergroup. Wolframite, chalcopyrite, pyrrhotite, quartz, garnet, epidote and calcite are also reported.

CAPSULE GEOLOGY

The Val occurs at or near the contact between rusty-weathering argillites, siltstone and quartzite of the Middle Proterozoic lower Aldridge Formation (Purcell Supergroup), and turbidite wackes and laminated siltstone of the middle Aldridge Formation.

Cassiterite, scheelite and wolframite bearing quartz-greissen veinlets occur in Moyie diorite sills within the Aldridge rocks.

The contact is a favourable horizon to Sullivan-type mineralization on the property.

CAPSULE GEOLOGY

The property is located on the south side of St. Mary River some 40 kilometres west-northwest of Kimberley. Four claims, the Surprise, Welcome, Enterprise and Shrewsbury extend southerly from the river up the northeast slope of Hungry Peak between elevations of 1,160 and 1,980 metres.

The Welcome & Enterprise showings occur in quartz-carbonate lenses containing chalcopyrite, pyrite and locally galena. The hostrocks are reported to be sheared limy argillites of the Middle Proterozoic Creston Formation, Purcell Supergroup.

The Enterprise claim (Lot 3559) was Crown-granted to H. McCool and Wm. Millican and the Welcome claim (Lot 1389) to Geo. Urquhart in 1900. The Surprise claim (Lot 3560) was Crown-granted in 1901 to Arthur Phillips and the Shrewsbury (Lot 5584) to H.R. Thomson and associates in 1902. Development work to about 1904 was done in open cuts and 3 adits. A 0.36-tonne sample of galena mineralization was packed out to the Marysville smelter in 1904.

Newmont Mining Corporation of Canada Limited held the property in 1961 as part of an optioned group of 88 claims. Work included stripping, geological mapping, and 485 metres of diamond drilling in 5 holes.

The Surprise Crown-grant, held as a mineral lease by D.C. Jackson, was under option to Meridian Resources Ltd. during 1977-78. The company also held a lease on the Welcome Crown-grant.

CAPSULE GEOLOGY

Sedimentary rocks of the Lower and Middle Aldridge Formations underlie the claim area. The sediments are Proterozoic in age and consist of quartzwackes, quartz arenites, and siltstones. The sediments in the area have been folded into a northwesterly striking anticline. Diorite sills and dikes of the Proterozoic Moyie intrusions intrude the strata. Disseminated fine-grained galena and chalcopyrite was seen in a diorite and quartzite contact area.

CAPSULE GEOLOGY

The iron showings were first mentioned in 1902. Claims were staked on the showings between 1952 and 1955. A band of specular hematite, up to 1 metre thick, occurs in schist which may be a schistose conglomerate. The band strikes north for about 75 metres and dips 70 degrees west. Dolomite underlies the schist to the east.

The hostrock may be part of the Upper Proterozoic Toby Formation, Windermere Supergroup.

CAPSULE GEOLOGY

The main workings are on the Florence M Crown grant near the boundary of the Fergus and R.F.G. Crown grants. The workings include an adit driven westward about 30 metres from which some stoping was done.

The workings on the Florence M follow a vein that strikes east and dips 60 degrees south. The vein is in fine-grained hornblende schist of the Permo-Triassic Kaslo Group, which near the portal contains a lens of grey crystalline limestone. The oreshoot that has been mined is in the hornblende schist near its footwall contact and also near the limestone. The ore dump shows a fine-grained aggregate of pyrite, pyrrhotite, galena and sphalerite, quartz and siderite. The vein is reported to have been up to 45 centimetres thick.

In 1907, 7 tonnes were mined from which 4,914 grams of silver and 3,094 kilograms of lead were recovered.

CAPSULE GEOLOGY

The Laurier and Tamrak claims lies along the south side of Lendrum Creek, and may be reached by about 3 kilometres of road from the Florence mine. This is one of a number of claims lying between the Florence and Silver Glance properties. The claim was Crown granted to The Laurier M. & M. Co. in 1899. Owner of the property in 1949 was E. Emilson. The last record of work was in 1951. The country rocks are argillite, cherts, limestone and schists of the Mississippian to Lower Permian Milford Group. From 1949 to 1951, 21 tonnes of ore were shipped. From this ore 13,654 grams of silver, 5,988 kilograms of lead and 1700 kilograms of zinc were recovered.

PHYSIOGRAPHIC AREA: Purcell Mountains

CAPSULE GEOLOGY

The property is located at about 182.8 metre elevation on Spring Creek, a tributary of Crawford Creek, some 51.4 kilometres west of Kimberley.

Early work on the showings, reportedly in the 1890's, was done in a short adit. Further prospecting on the showings was done in 1926 by J.W. Mulholland on behalf of Portland interests.

The showings were held as the Barefoot 1 and 2 claims by C. Derbyshire, of Crawford Bay and associates, and acquired by Rose Pass Mines Ltd. in about 1967. Work by the company in the period 1968-72 included bulldozer trenching and more than 396.2 metres of diamond drilling in 8 or more holes. The company name (Rose Pass) was changed in 1974 to Range Industries Ltd; the property at that time had been reduced to 22 claims.

Springpoint Resources Ltd, in 1980 acquired the Jackass group of 12 recorded claims covering the showings; an additional 24 claims (Barefoot group) was staked adjacent. Work in 1981 included 367 metres of diamond drilling in 6 holes.

Argentiferous galena occurs in dolomite-quartz veins in phyllite of the Upper Proterozoic Horsethief Creek Group (Windermere Supergroup). Silver values range from 82 to 219 grams per tonne; tungsten assayed 0.68 per cent across 0.6 metres; tin was found in all vein intersections with assays of 0.28 per cent over 1.2 metres (Northern Miner, January 14, 1982).

CAPSULE GEOLOGY

The United Copper showing occurs in an area underlain by siltstone, argillite, quartzite and dolomite of the Middle Proterozoic Dutch Creek Formation, Purcell Supergroup.

Quartz veins and inclusions containing chalcopyrite, sphalerite, galena, pyrite and pyrrhotite occur along a shear zone in foliated zones in chlorite schist or laminated argillite. Bornite with silver minerals occurs as replacements in limestone. The property was drilled in the early 1970s.

TERRANE: Ancestral North America
PHYSIOGRAPHIC AREA: Purcell Mountains

CAPSULE GEOLOGY

The property is located at elevations of approximately 1,219 to 1829 metres on the north side of St. Mary River, between Office and Morris Creeks, some 40.2 kilometres west-westnorthwest of Kimberley.

The Bracebridge group of 6 claims, the Bracebridge, Gracie, Denbigh, Regina, Snowden, and Brace Bridge Fr (Lots 5037, 5575-5579 respectively) was surveyed in 1901. Crown-grants were issued in 1903 for the Bracebridge, Regina and Denbigh claims to J.H. Wright, O.H. Burden & associates. The showing had originally been exposed by erosion. Work to 1904 included open cuts on the Bracebridge claim and apparently some underground work on the Regina claim.

The Joe and Goat groups comprising 22 recorded claims were under option to Cominco Ltd. in 1966. Diamond drilling totalled 200.5 metres in 6 holes. The option was relinquished later in the year.

Pharaoh Mines Ltd. optioned the Joe, Goat and Don groups comprising 12 recorded claims from D.C. Jackson late in 1967. Work during the year included bulldozer trenching, sampling, and percussion drilling in four 12.1 metre holes.

Meridian Resources Ltd. optioned the Joe 1 & 2 and Don 1 & 2 claims from D.C. Jackson and staked about 30 adjacent claims in the Joe, Winnie, Vera and Silvertip groups. A geochemical soil survey was carried out in 1977.

Minor chalcopyrite occurs in veins up to 1.5 metres wide. The hostrock is strongly contorted biotite schist. The area is underlain by rocks of the Middle Proterozoic Creston Formation, Purcell Supergroup. Trenches north of St. Mary River expose the showings. The hostrock is also described as a schistose dolomitic argillite.

Sedimentary rocks of the Lower and Middle Aldridge Formation underlie the occurrence area. The sediments are Proterozoic in age and consist of quartzwackes, quartz arenites, and siltstones. The sediments in the area have been folded into a northwesterly striking anticline. Diorite sills and dikes of the Proterozoic Moyie intrusions intrude the strata.

The Hilo 4 occurrence (called the "Old Workings") consist of mineralized veins and replacements in diorite. Mineralization consisted of massive concentrations of scheelite, pyrrhotite and chalcopyrite with lesser amounts of arsenopyrite, pyrite, galena and sphalerite. Tourmaline, garnet and actinolite are associated minerals.

Sedimentary rocks of the Lower and Middle Aldridge Formation underlie the occurrence area. The sediments are Proterozoic in age and consist of quartzwackes, quartz arenites, and siltstones. The sediments in the area have been folded into a northwesterly striking anticline. Diorite sills and dikes of the Proterozoic Moyie Intrusions intrude the strata.

The Hilo 3 or Main showing occurs about 35 metres southwest of a diorite contact in thinly interbedded quartzites and siltites. Minor amounts of fine-grained galena and pyrrhotite are disseminated along 6 millimetre thick planes which parallel bedding and occasionally transect it. This mineralization is limited to a 7.5 metre wide band of outcrop. Fine-grained chloritic material is associated with the sulphides. Most of the occurrence is hosted in quartzite with lesser amounts in the siltites.

CAPSULE GEOLOGY

Molybdenum occurs in fractures and veins along edge of the Cretaceous Fry Creek Batholith. The intrusive rocks range from granite to granodiorite to monzonite. A siltstone, argillite, quartzite and dolomite unit of the Middle Proterozoic Dutch Creek Formation (Purcell Supergroup) is in contact with the batholith at or near the mineralized locality.

CAPSULE GEOLOGY

The Alice showing occurs in an area underlain by Middle Cambrian to Middle Devonian Lardeau Group rocks of the Badshot and Mohican formations.

Galena, sphalerite, pyrite and pyrrhotite occur in crosscutting and layer-parallel veins or replacement bodies in limestone, calcareous schist and micaceous schist surrounded by Jurassic to Cretaceous quartz monzonite.

In 1915, 14.5 tonnes of ore containing 15 per cent lead and 2835 grams per tonne silver was produced (Bulletin 73).

CAPSULE GEOLOGY

The MC (Greenland Creek) showing is a sulphide breccia with scattered, rounded quartz fragments in a massive pyrrhotite matrix with broad, subtle sphalerite/galena bands. The texture resembles a 'durchbewegung texture' found in the massive portion of the Sullivan (082FNE052) orebody. The zone appears to be stratabound within thin-bedded siltstones of the Middle Proterozoic Lower Aldridge Formation (Purcell Supergroup). True thickness of the zone is about 0.5 metre and has been exposed for about 5 metres laterally. Five grab samples have been assayed and the richest yielded 130.3 grams per tonne silver, 9.17 per cent lead and 6.27 per cent zinc. Short drillholes in the immediate vicinity of the zone indicate it to be narrowing quickly but a longer hole intersected two thin sphalerite/galena layers which appear to be more than 100 metres downdip from the showing (P. Wilton, personal communication, 1997). Miner River Resources Ltd. and Eagle Plain Resources Ltd. drilled approximately 610 metres in 7 holes in 1997. In 1998, Eagle Plains conducted a soil geochemical survey over a portion of the property. The companies amalgamated in 1999 to form Eagle Plains Resources. In 1999, Kennecott Canada Exploration optioned the property and conducted a program of mapping and soil geochemistry. In 2000, Kennecott drilled a single 295-metre hole which was to test a prominent zinc in soil geochemical anomaly. The hole intersected a thick gabbro sill from 90 to 209 metres and then entered granitic pegmatite. Kennecott dropped its option in 2000.

CAPSULE GEOLOGY

The Snow King is underlain by intensely folded limestone, dolomite, argillaceous schist and chloritic schist of the Upper Proterozoic Horsethief Creek Group (Windermere Supergroup). Galena, sphalerite, pyrite and some tetrahedrite are present in quartz, calcite and minor barite veins in siliceous, limonite-stained limestone. Sulphides also occur as disseminations in brecciated dolomite and as disseminations and replacements in siliceous limestone. Small amounts of chalcopyrite are also reported. One sample assayed 0.69 grams per tonne gold, 1906 grams per tonne silver, 73.7 per cent lead and 1.8 per cent zinc (Annual Report 1926).

CAPSULE GEOLOGY

The Hellroaring Creek pegmatite stock is about 20 kilometres southwest of Kimberley and 31 kilometres west-northwest of Cranbrook. The stock has been explored for feldspar, quartz, mica and, in the 1960's, beryllium.

The area is underlain by quartzite and argillite of the Creston Formation and argillite, quartzite and mica schist of the Aldridge Formation, both of the Helikian Purcell Supergroup. These metasediments are intruded by sills and dykes of granodiorite of the Proterozoic Moyie Intrusions, which are in turn intruded by pegmatite of the Middle Proterozoic Hellroaring Creek stock. The east trending St. Mary fault separates this area from the area underlain by Creston Formation metasediments to the south. The Aldridge Formation is

CAPSULE GEOLOGY

folded into an open northwest plunging anticline with the Hellroaring Creek stock emplaced in the core.

The pegmatite stock trends north-northwest for 4 kilometres within the Aldrige Formation and is up to 1.5 kilometres wide. The stock appears to be a series of large dyke swarms. Most of the sampling and diamond drilling is concentrated in an area at the north end of the stock, where drilling encountered thicknesses of up to 150 metres.

The stock is comprised of medium to coarse grained white to light grey pegmatite typically containing 60 to 70 per cent feldspar, 20 to 30 per cent quartz, 0 to 10 per cent muscovite and 0 to 10 per cent tourmaline. Beryl, garnet, pyrite, pyrrhotite, galena and arsenopyrite occur in minor to trace amounts. The feldspar occurs in distinct microcline and albite rich zones. Quartz occurs in massive lenses several metres thick that are free of feldspar. Muscovite forms fine flakes along fractures and books, up to 13 centimetres across, in irregular patches. Thin needle-like tourmaline crystals (3 by 10 millimetres) and blades up to 3 centimetres long occur in patches. Beryl forms erratically scattered very pale bluish green and white crystals and irregular masses up to 7.5 centimetres in diameter and 15 centimetres in length that tend to be associated with plagioclase, quartz and muscovite. Garnet is present as pink to red grains 1 to 2 millimetres across in addition to occasional veinlets of pyrite, pyrrhotite, galena and arsenopyrite. Iron and manganese staining is common on outcrops and in drill core.

Work in 1965, by Richfield Oil Corporation, indicated the north end of the stock contains 450,000 tonnes of 0.1 per cent beryllium oxide (Assessment Report 13415, p. 21). Diamond drilling in 1985 and 1986 by Lumberton Mines Ltd. encountered zones containing in excess of 1 per cent tourmaline (Assessment Report 15760, p. 12). Nineteen samples of feldspathic pegmatite analyzed as follows in per cent (Exploration in B.C. 1987, p. B111):

SiO2	64.86 to 76.72
Al2O3	12.61 to 19.00
K2O	0.45 to 12.45
Na2O	1.95 to 6.44
CaO	0.05 to 0.64
Fe2O3	0.05 to 4.24

Tests carried out by CANMET indicate that the pegmatite can be processed to produce feldspar and mica concentrates that meet industry standards with full liberation at 50 mesh.

This stock was first staked in 1958 as a beryllium prospect. Subsequent exploration, by various operators in the 1960's and by Lumberton Mines Ltd., in 1984 and 1985 failed to discover beryllium reserves of sufficient grade to warrant further development as a beryllium prospect. However, this work combined with further sampling and diamond drilling by Lumberton Mines in 1986 indicates that the stock contains a considerable amount of glass and ceramic grade feldspar.

The property is located on the east side of Hellroaring Creek between the 1,219 and 1,524 metre elevations, 33.7 kilometres due south of the east end of St. Mary Lake.

In 1958 H. Bennett of Cranbrook located the Linda and Linda No. 1 claims on a pegmatite showing in which he found beryl crystals. International Beryllium Corporation was formed in 1961 to prospect the property, which had been expanded to 32 claims. Some 1,219 metres of trenching was done before the project was abandoned.

The property was acquired by Canuck Beryllium Corporation and a small amount of stripping and open-cutting was reported done by the company in 1963. An agreement between Canuck Beryllium, a subsidiary of Peace River Petroleum Ltd., and Richfield Oil Corporation of California for prospecting and development work on the property was announced in August 1, 1965. Under the terms of the agreement, Richfield Oil will have control over operations. Work in 1965 was limited to blasting and sampling some 365.7 metres of trench. This work is reported to indicate 500,000 tons averaging 0.1 per cent Beryllium oxide (Bearcat Explorations Ltd. News Release., 1/02/1984).

Some 4,550 acres of mineral claims covering these showings were acquired in early 1984 by Bearcat Explorations Ltd. (80 per cent) and Colt Exploration (Western) Ltd. (20 per cent). A joint venture agreement that same year with Fairholme Development Ltd. and Barnwell industries, Inc. provided financing for an initial stage of exploration. Work carried out in 1984 by Lumberton Mines Limited, Bearcats 100 per cent owned subsidiary, included trenching and 500 m of diamond drilling in 7 HQ drill holes; subsequent joint venture interests were: Colt (15 per cent), Fairholme (5 per cent), Barnwell (25 per cent), Bearcat (55 per cent). Further work in 1985-86 included 2584 metres of diamond drilling in 29 holes, and bulk sample

CAPSULE GEOLOGY

flotation tests.

This work delineated three surface areas with significant high-grade ceramic feldspar; potential by-products are high-grade mica, high-grade silica, and a minor amount of beryllium in the form of beryl.

Surface prospecting by Chapleau Resources Ltd. in 2000 revealed a number of new untested outcrops of beryl-rich pegmatite. The work is reported to have extended "the old Richfield zone south for 500 metres and 500 metres east". Values high in beryllium and rubidium are reported from grab samples taken by Chapleau (George Cross Newsletter, August 1, 2000 (No. 147)).

CAPSULE GEOLOGY

The property is located at approximately 1768 metres elevation, a short distance to the east of Rose Pass summit and some 45 kilometres west of Kimberley.

The showings were originally staked in the "nineties". The workings consisted of two shallow open cuts about 518 metres apart and a crosscut adit of unknown length.

The showings were restaked in 1936 but there is no report of work at that time. In about 1966, Rose Pass Mines Ltd acquired the Rose Pass property, comprising the Silver 5-10 claims, and staked the Vi 1-8 claims. An induced potential survey was apparently carried out over the property. The company name was changed in 1974 to Range Industries Ltd.

The showings were held in 1980 as the KJ claim (9 units) by Gerhardt Holdings Ltd, of Nelson. Geological mapping and a geochemical rock sample survey was carried out.

The ore occurs in quartz veins occupying fractures in black argillite of the Middle Proterozoic Mount Nelson Formation (Purcell Supergroup). A small dike or sill of granite porphyry intrudes the strata. The veins are well mineralized with galena, sphalerite, chalcopyrite, pyrite and a tin-bearing mineral, probably stannite. The vein strikes northeasterly and dips steeply west. It has an average width of about 30 centimetres. One sample yielded 312 grams per tonne silver and 1.15 per cent tin (National Mineral Inventory).

CAPSULE GEOLOGY

Beryl occurs in pegmatite dikes cutting quartzite of the Middle Proterozoic Aldridge Formation (Purcell Supergroup) and dioritic intrusions, probably related to the Proterozoic Moyie Intrusions. Very pale, glassy beryl crystals occur. Black tourmaline is abundant, as are muscovite and garnet but beryl is rare.

CAPSULE GEOLOGY

dip is much steeper.

The deposit is comprised of white, medium-grained dolomite containing scattered crystals of various metamorphic minerals, especially tremolite. The dolomite develops a brown staining on weathered surfaces. Numerous randomly oriented fractures occur with spacings of 10 to 15 centimetres. A sample of randomly collected chips from the quarry analysed 30.26 per cent CaO, 20.17 per cent MgO, 2.14 per cent insolubles, 0.77 per cent R2O3, 0.92 per cent Fe2O3, 0.021 per cent MnO, 0.012 per cent P2O5, 0.01 per cent sulphur and 46.37 per cent ignition loss (Minister of Mines Annual Report 1964, page 184).

Imasco initially quarried dolomite on the south side of Crawford Creek, 600 metres north of the current mine site during 1962 and 1963. In 1964 quarrying began at the current site. Underground mining began in 1969 in order to produce a cleaner product. Between 1962 and 1988 some 734,500 tonnes of dolomite have been mined. The dolomite is trucked to the company's plant in Sirdar where it is crushed and screened for a variety of products, mostly agricultural soil conditioner, as a component in stucco and roofing materials, and is white, ornamental aggregate rock.

Inferred reserves at Crawford Creek are 2 million tonnes of dolomite grading 20.17 per cent MgO (Mining in British Columbia 1988).

CAPSULE GEOLOGY

Quartzite is produced from two quarries, 1.6 kilometres apart, along the road that follows the north side of Crawford Creek, east of Kootenay Lake. The western quarry is located 5.5 kilometres north-northeast of the north end of Crawford Bay, 100 metres east of Preacher Creek.

This area, on the north side of Crawford Creek, is underlain by Lower Paleozoic metasediments of the Lardeau and Hamill groups and the Badshot and Mohican formations, which are locally warped into a series of northerly trending folds. The two quarries are developed in quartzite of the Lower Cambrian Hamill Group, comprised of some 3500 metres of quartzite, schist and meta-siltstone. Two varieties of stone are quarried; a pale, translucent beige quartzite and a darker brown quartzite.

The quarries have been operated since 1966 by International Marble and Stone Ltd. The company trucks the quartzite to its processing plant at Sirdar where it is crushed and screened to produce construction aggregate for architectural, decorative and landscaping purposes. Some of the stone is oxidized by roasting to produce pink and reddish material (D. Gunning, personal communication, 1991).

CAPSULE GEOLOGY

The Lower Jack zone was discovered in 1999 during prospecting along a newly constructed logging road in a steep, overburden-covered area. A number of large, lead-zinc bearing, hydrothermally altered, angular tourmalinite and Aldridge Formation fragmental float boulders occur in a 300 by 300 metre area. The float boulders are well mineralized with galena, sphalerite, arsenopyrite and pyrrhotite. This discovery was staked in the summer of 1999 and is now part of what is called the Pakk property. The Upper Jack zone was also discovered by prospecting in the area and is located 2500 metres northwest of the Lower Jack zone. A third discovery, the Sinclair zone (082FNE117), is 2000 metres north-northeast of the Upper Jack zone. The Pakk property includes the Horn, Burn, Pit and Pakk claim groups.

At surface, the Upper Jack vent zone consists of a fragmental structure with abundant galena, sphalerite, pyrrhotite and arsenopyrite in massive lenses, veins and disseminations. The structure is 30 metres wide and is traced in outcrop for 800 metres. Helikian Aldridge Formation (Purcell Supergroup) marker beds outcrop nearby.

In 1999, Chapleau Resources Ltd. conducted a diamond drilling program on the Upper Jack Vent zone where three short holes were completed to acquire preliminary geologic data. The holes outlined a near-vertical dipping structure consisting of discordant fragmental rocks about 10 metres thick. The crosscutting fragmental rock is bracketed by a 20-metre thick zone of intensely altered sediments. Sulphides form all or part of the fragmental matrix. Sphalerite and galena are dominant, with lesser pyrrhotite, arsenopyrite and chalcopyrite. The fragmental hostrock is intensely tourmalinitized along with garnet, albite and actinolite with abundant muscovite and biotite. Scheelite is widely scattered throughout the fragmental

CAPSULE GEOLOGY

rocks and in the adjacent sediments. The scheelite occurs as large disseminated crystals and as thin veinlets.

Super Group Holdings Ltd. is directing the exploration and Champleau Resources Ltd. is performing the work on the property.

PHYSIOGRAPHIC AREA: Purcell Mountains

CAPSULE GEOLOGY

The Stemwinder hostrock consists of argillaceous quartzites of the Middle Proterozoic Aldridge Formation, Purcell Supergroup. These are intruded by several sills of hornblende gabbro of the Proterozoic Moyie Intrusions. The mineralized zone is a lens of massive sulphides entirely enclosed by the quartzites. The lens consists largely of pyrrhotite, strikes nearly north, and dips about 75 degrees west. The thickness of the sulphide zone is about 60 metres. The occurrence is considered to be similar to the Sullivan mine (082FNE052).

The ore zone lies along the footwall side of the sulphide lens. It consists of a fine-grained mixture of galena and sphalerite passing into a fine-grained mixture of pyrrhotite, pyrite and sphalerite. The ore zone has width of about 6 metres. It is separated from the normal quartzite by a cherty layer. Underground work and diamond drilling indicates a that the ore zone is 80 metres long with a width of 4.5 to 9 metres.

The Stemwinder property is located on Mark Creek about 2.4 kilometres west-northwest of the center of Kimberley, and is adjoined on the north by the Sullivan mine and on the south by the North Star property.

In 1896, the Stemwinder was one of 13 recorded claims held by the Mann & McKenzie interests as part of the North Star property, under the name of the North Star Mining Company, Limited Liability. Exploration work began in an adit about 140 metres above the creek and by 1899 this had been driven 183 metres, intersecting a mineralized zone which appeared to be mainly iron sulphide. The Stemwinder claim (Lot 2998) was Crown granted to D.D. Mann and Wm. McKenzie in 1899. Further limited development work was reported in 1905.

The Federal Mining and Smelting Company, a subsidiary of the American Smelting and Refining Company, optioned the property in 1917 and for 2 or 3 months during 1917-1918 carried out diamond drilling. Results were not encouraging and the option was dropped. In 1921 the Federal Mining and Smelting Company again optioned the Stemwinder and Ontario claims from the Mann & McKenzie interests and further diamond drilling was carried out; the option was subsequently dropped. The property was reported held in 1923 by the Stemwinder Mining Company, Limited but details are lacking. In 1923 O.C. Thompson & associates

CAPSULE GEOLOGY

bonded the property and in June 1924 gave a 3 year lease and option to Porcupine Goldfields Development and Finance Company, Limited, of London, England. Exploration and development work included sinking a shaft to the 78-metre level and crosscutting drifting, and raising totalling 1638 metres was done on the 24, 38, and 76 metre levels. Diamond drilling on surface and underground totalled 3762 metres. An additional 40 metres of shaft sinking was reported but details are lacking. This work indicated, on the 38-metre level, an orebody 79 metres long by 6 metres wide of mainly zinc ore. Ore reserves to the 206-metre level were estimated at 90,700 tonnes. Exploration and development work was suspended in May 1926, at which time ore shipments began to Trail. Ore shipments continued to December 1926 when operations were suspended due to poor mill recoveries and markets. The lease and option expired in 1927. Reserves were reported at 66,410 tonnes, grade unstated (Porcupine Goldfields Development and Finance Company, Limited June 1927 Annual Report). The Consolidated Mining and Smelting Company of Canada Limited purchased the property in 1929 for \$115,000.

The recorded total ore mined came from 1926 when 25,620 tonnes of ore was shipped and 1,955,197 grams of silver, 1,306 grams of gold, 3,990,900 kilograms of zinc and 945,317 kilograms of lead were recovered.

CAPSULE GEOLOGY

The Lower Jack zone was discovered in 1999 during prospecting along a newly constructed logging road in a steep, overburden-covered area. A number of large, lead-zinc bearing, hydrothermally altered, angular tourmalinite and Aldridge Formation fragmental float boulders occur in a 300 by 300 metre area. The float boulders are well mineralized with galena, sphalerite, arsenopyrite and pyrrhotite. The Upper Jack zone (082FNE115) was also discovered by prospecting in the area and is located 2500 metres northwest of the Lower Jack zone. A third discovery, the Sinclair zone, is 2000 metres north-northeast of the Upper Jack zone. The Pakk property includes the Horn, Burn, Pit and Pakk claim groups.

At the Sinclair showing, thin bedded lead-zinc mineralization occurs in a mudstone unit 60 metres thick which has been traced on surface for 600 metres. Chappleau Resources Ltd. completed two short diamond drill-holes on the showing in 1999. The first hole intersected a fault zone and did not find the mineralized zone. The second hole intersected the stratiform sphalerite mineralization 90 metres downdip from the surface showing. The hole cut forty, thin, bedding-parallel bands of disseminated sphalerite and pyrrhotite ranging in thickness from 1 to 10 centimetres. The sulphide-rich bands are scattered throughout the 150-metre section of thin-bedded argillite and silty argillite of the Helikian Aldridge Formation (Purcell Supergroup).

Super Group Holdings Ltd. is directing the exploration and Chappleau Resources Ltd. is performing the work on the property.

CAPSULE GEOLOGY

Pyrrhotite and chalcopyrite are disseminated in a flay-lying dike or sill, probably 12 to 15 metres thick, intruded into Lardeau Group sediments. Platinum and palladium are associated with the sulphides. An 80-metre long adit was driven in 1930 to test the mineralization.

CAPSULE GEOLOGY

The Jackpot showing occurs in schist and gneiss of the Middle Cambrian to Middle Devonian Lardeau Group. Sill like intrusions of granite, possibly of Cretaceous age, intrude the schist near the showings. The veins are characterized by brecciated structure, cemented and partially replaced with quartz. Sulphide minerals are sparse and consist of galena, sphalerite and possibly some grey copper. The widths vary from several centimetres up to 60 centimetres. A tunnel was driven on the more northerly of two veins for about 45 to 60 metres. Other scattered mineralization is reported in the property area.

CAPSULE GEOLOGY

The property is located on the east shore of Kootenay Lake, at the north edge of the community of Riondel and adjacent to the Bluebell mine claims.

The Kirby group of 7 claims, and fractions (Lots 13007-13013) was staked by A.J. Curle, of Kaslo, in 1919. Work on the showings to 1921 included a 17-metre crosscut and about 30 metres of drifting on the footwall of the main vein. Where intersected by the crosscut, the vein consisted of 3 metres of sparsely mineralized quartz with a narrow band of ore on the hangingwall and small bunches and stringers of galena on the footwall. The claims were Crown-granted to A.J. Curle, W.T. Kirby and R.V. Guthrie in 1922. The owners incorporated The Shepherd Mining Company, Limited in December 1922. A new low level crosscut adit, driven from near the lake shore, reached bedrock at 227 metres and was continued to 305 metres, cutting a vein at 274 metres and a stronger vein at 305 metres; the latter was drifted on for about 229 metres, connecting with a shaft to surface. The last reported work by the Company was in 1926.

The area is underlain by Middle Cambrian quartzites and schists of the Index Formation, Lardeau Group.

Three principal veins occur as distinct bedding fissure veins, mainly in schist but also cutting granitic dikes and sills locally. The calcareous schists are sparingly impregnated with sulphides, mainly pyrite. A series of steep fissures connect the main veins, cutting across the strike of the sediments. The ore minerals, pyrite, arsenopyrite, sphalerite, galena, pyrrargyrite occur with quartz, rhodochrosite and other carbonates in bedded shear zones, along with fragments of country rock.

Eight tonnes of ore was reported mined in 1920 and 7,558 grams of silver and 1,778 kilograms of lead were recovered.

CAPSULE GEOLOGY

The area of the Burnt occurrence is underlain by siltstone and wacke of the Middle Proterozoic (lower) Aldridge Formation of the Purcell Supergroup. Cretaceous intrusions consisting of granite, granodiorite and monzonite intrude the strata. Pyrite, chalcopyrite and pyrrhotite occur in narrow discontinuous veins and lenses in a small shear zone in quartzite, near meta diorite. A 5-metre adit exposes the shear which strikes 080 degrees and dips 37 degrees south.

CAPSULE GEOLOGY

The Ben Derby showing occurs where Cretaceous granitic intrusions come into contact with argillites and quartzite of the Upper Proterozoic Horsethief Creek Group (Windermere Supergroup). Disseminated molybdenite was noted in the granite near the contact zone. Earlier exploration consisted of driving two adits on steeply dipping 1.2-metre-thick white quartz veins mineralized with molybdenite.

PHYSIOGRAPHIC AREA: Purcell Mountains

CAPSULE GEOLOGY

This Jag property is located on the westerly side of Mount Evans, about 24 kilometres southwest of Kimberley. The Jag occurrence is underlain by quartzite and siltstone of the Middle Proterozoic (Middle) Aldridge Formation (Purcell Supergroup), intruded by meta gabbro or meta diorite of the Proterozoic Moyie Intrusions. Three or more of these sills, from 60 to 180 metres thick, strike in a northwest direction through the area for an aggregate length of 3.5 kilometres. This occurrence consists of pyrite and iron staining in a shear and tension zone in diorite. Assays over 1.5 metre yielded 4.89 grams per tonne silver, 0.30 per cent copper and 0.1 per cent lead (Assessment Report 4235). Prior to 1920 three properties, the Evans, Good Hope, and Whitefish, were located over a north-south distance of about 3.2 kilometres. A fourth property (Faller group) was located about 1.6 kilometres to the northwest) on the north side of Meacham Creek. The locations of the Good Hope and Evans prospects, as shown on Map 15-1957, appear to be reversed in view of the location of the Good Hope claim on Map 92 F/9 W, and the description given in the Report of Minister of Mines, British Columbia for 1915. The Faller group, of 6 claims, was first reported on in 1900 when some 91 metres of adit had been driven. The Selkirk Copper Mines, Limited, incorporated at Moyie in May 1903, is believed to be the company which carried out exploration work on the property until about 1905. The workings at that time included 2 adits totalling about 152 metres of crosscuts and drifts. Work on the Good Hope group prior to 1901 consisted of a 15 metre adit. In 1912 the Good Hope, Rose, and Toolips claims (Lots 9820-9822, respectively) were Crown-granted to Mr. C.H. Pollen. Messrs. C. and W. Evans, of Marysville, recorded assessment work on the Pacific, Curfew, Twilight, and Sunset claims on Fiddler Creek in 1904. Their holdings were expanded in about 1915 to include claims in Pollen Basin and Kelly Basin. Most of their exploration work to that time had been done at their main camp near the head of

CAPSULE GEOLOGY

Fiddler Creek, where approximately 91 metres of adit was driven. Their combined holdings were known as the Evans or Achilles property. Assessment work by the Evans brothers was reported yearly until about 1926.

The only report on the Whitefish group (3 claims) was in 1920 when the workings consisted of 50 metres of adit and a 6 metre winze.

The JAG 1-58 claims, staked in March 1972 by A. Hopkins, of Toronto, covered the four old properties mentioned above. Mount Evans Copper Corp. Inc., incorporated in Ontario in May 1972, acquired 18 of the Jag claims.

GEOLOGICAL SETTING

TECTONIC BELT: Omineca PHYSIOGRAPHIC AREA: Purcell Trench
TERRANE: Ancestral North America

CAPSULE GEOLOGY

The Crystal Lake property was originally described as a vein occurrence of galena and sphalerite in limestone. In 1928, D. Broster, M. Johnson and associates staked the area and conducted tunnelling and trenching on two showings. Cominco Ltd. conducted surveys on the Craw claims from 1973 to 1979. Bruce Doyle prospected and sampled on the Sure Bet and Pup in 1991. Kokanee Explorations Ltd. surveyed and drilled the area in 1991 and 1992. Cominco surveyed and drilled in 1996, 1997 and 1998.

Cream Minerals Ltd. acquired the property in 1999. Previous exploration on the property has discovered two large airborne electromagnetic geophysical anomalies situated within a 1.3 km long silver-lead-zinc anomaly. Within this geochemical anomaly, massive sulfide boulders, some weighing up to 30 tonnes and containing more than 343 grams per ton silver have been found.

The area is underlain by schist and dolomite of the Cambrian to Devonian Index Formation (Lardeau Group). Cretaceous granite intrudes the rocks.

Silver	140.5700	Grams per tonne
Gold	2.0600	Grams per tonne
Lead	5.7300	Per cent
Zinc	6.1000	Per cent

COMMENTS: From a 6 centimetre chip sample.

REFERENCE: Minister of Mines Annual Report 1958, page 42.

CAPSULE GEOLOGY

The area of the Kootenay occurrence is underlain by hornblende gneiss, amphibolite and calcite marble of the Middle Cambrian to Lower Devonian Index Formation, Lardeau Group. The map accompanying Bulletin 73 shows the occurrence within a band of calcite marble.

The occurrence consists of four parallel narrow quartz veins striking 036 degrees and dipping 068 degrees southeast. Occasional transverse quartz stringers connect adjoining veins. The main vein is reported to range in width erratically from nil to 15 centimetres, and is mineralized with galena, sphalerite and pyrite in vuggy quartz.

An 8-centimetre wide sample yielded 0.7 gram per tonne gold, 456.0 grams per tonne silver, 24.65 per cent lead and 0.2 per cent zinc; a 6-centimetre sample yielded 2.06 grams per tonne gold, 140.57 grams per tonne silver, 5.73 per cent lead and 6.1 per cent zinc (Bulletin 73).

HOSTROCK COMMENTS: The formations and lithologies are general for the area. The hostrock is not known.

GEOLOGICAL SETTING

TECTONIC BELT: Omineca

TERRANE: Ancestral North America

PHYSIOGRAPHIC AREA: Purcell Mountains

CAPSULE GEOLOGY

The area is underlain by Middle Proterozoic rocks of the Purcell Supergroup and by Upper Paleozoic rocks of the Windermere Supergroup. Windermere rocks include conglomerate of the Toby Formation and quartzite, limestone, arkose and pebble conglomeration of the Horsethief Creek Group. Purcell rocks include laminated argillite, dolomite and quartzite of the Mount Nelson and Dutch Creek formations.

Iron ore with values in silver, lead and copper is reported to occur at the head of Houghton Creek. Except for the presence of a "lime dike" the host rocks are not described. One of the original claims was called "Speculate Hematite" which, along with the nearby Gray Creek specular hematite occurrences (082FNE094,095), indicates the probable nature of the ore. By 1905, over \$10,000 was spent in development by the Five Metals Company. At this time, men were still engaged in "running a deep level to tap the main ledge". This "ledge" was reported to be 30 metres wide. A furnace with 40 tonnes/day capacity was planned.

This occurrence has been created based on its given location at the head of Houghton Creek and on the north side of Sphinx Mountain (The Nelson Miner, 1905). Although in the same vicinity, the Gray Creek occurrences are well defined by J.T. Fyles in a 1956 report (Property File) as being to the south of Sphinx Mountain. Three Crown grants exist near the location at which the Five Metals should occur: Palouser (Lot 8797), Spokane (Lot 8796) and Tekoa (Lot 8798).

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The area of the General - Grant is underlain by the Mississippian to Lower Permian Milford Group. Upper Triassic to Middle Jurassic intrusions cut the strata. Grey-copper (tetrahedrite) carrying small amounts of galena and sphalerite and high amounts of silver within small shoots in quartz-filled fissure veins which cut siliceous limestone near a granite contact. The vein has been accessed by two tunnels with considerable development. A sample across a 20-centimetre pay-streak in one stope gave: 0.69 gram per tonne gold, 21,579 grams per tonne silver, 13.3 per cent lead and 4.8 per cent zinc (Annual Report 1921). A shipment of 5 tonnes in 1972 yielded 7589 grams of silver, 107 kilograms of lead and 146 kilograms of zinc. In 1889 and from 1916 to 1921, 22 tonnes of ore was shipped and 298,718 grams of silver and 2489 kilograms of lead were recovered.

CAPSULE GEOLOGY

The Fourth occurrence is situated near the contact of Mississippian to Lower Permian Milford Group strata, consisting of argillite, limestone and quartzite, and porphyritic granite, granodiorite and granite gneiss of the Middle Jurassic Nelson Batholith.

A vein, 0.9 metres wide, strikes southeast. A 150 metre long tunnel was reported in 1895. Assays indicated 686 to 2606 grams per tonne silver and 10 to 38 per cent lead. Galena is presumed. In 1968, approximately 5.5 tonnes of mud and high grade ore was stacked but not shipped. Some stripping and trenching were done in 1979.

CAPSULE GEOLOGY

The Dave area is underlain by the Middle Proterozoic Dutch Creek Formation (Purcell Supergroup) consisting of siltstone, argillite, quartzite and dolomite.

High geochemical readings in lead and zinc were obtained in the brecciated limestone and quartzite. Replacement type mineralization is found in the quartzite, near the contact with the argillite. Mineralized quartz-carbonate veins contain limited galena, sphalerite, chalcopyrite, barite and fluorite.

David Wiklund conducted geochemical soil surveys and diamond drilling from 1975 to 1979. Norcan Energy Resources Ltd. held an option on the property in 1980 and conducted geological mapping, an electromagnetic survey, geochemical surveys and trenching.

The Ormonde (Lot 7239) and Umpire (Lot 7240) Crown grants are located to the east. A 37-metre adit was driven on the Umpire claim in 1900.

Hunter Resources Ltd. conducted exploration for barite in 1995 on the Dave-Wall manto property.

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The Albion occurrence is hosted by micaceous and chlorite schists, quartzites, and limestones of the Mississippian to Lower Permian Milford Group intruded by sills of granite and quartz monzonite and lamprophyre dikes. The vein is parallel to bedding and schistosity and varies considerable in width and grade. The Albion was crown-granted in 1899 by the Albion Mining Co., and worked intermittently. The property was acquired by Yale Lead and Zinc Mines Ltd. in 1949 and worked as part of the Highlander (082FNE030) property until 1958. The Highlander vein outcrops on the Albion, Banker and Jackpot claims. See Highlander for further details. The average mining width is 2.3 metres made of about 0.6 metres of nearly barren hangingwall gouge, up to 1 metre of galena and sphalerite in a gangue of quartz and carbonates and up to 1 metre of footwall zone consisting of irregularly spaced veinlets of sphalerite in quartz. The ore is restricted to the vicinity of a shear and a lamprophyre in the vein.

CAPSULE GEOLOGY

The area is underlain by the Middle Cambrian to Middle Devonian Index Formation of the Lardeau Group.

The August Fraction (Lot 6287) is located on the west shore of Kootenay Lake, near the mouth of Woodbury Creek. The claim was Crown granted in 1904 to King Solomon Mining Co. Ltd. A vein on the shore cliff was worked between 1948 and 1951 by L.D. Besecker. In 1947, Besecker also worked the King Solomon, which is likely in this area.

A 30-metre adit explored the vein, which occurs in mica schist. The vein contains quartz and calcite, with bands of galena, pyrite, sphalerite and chalcopyrite.

In 1894, the King Solomon produced 4 tonnes of ore, yielding 24,882 grams of silver and 1814 kilograms of lead. This King Solomon might be confused with the one at the head of Woodbury Creek (see 082FNW242).

CAPSULE GEOLOGY

The Northwind (Old Timer) occurs in slates and schists. There are three veins of broken schistose material with some quartz. By 1899, a crosscut tunnel, 75 metres long, runs into the first of the three veins, on which a drift had been run to the right for 23 metres and to the left for 24 metres. There is in this tunnel a showing of galena. There is a second tunnel about 10 metre long on the same vein. A 1 tonne shipment made in 1899 yielded 2,239 grams of silver.

The Old Timer claim (as shown on Figure 3, Bulletin 53) is underlain by schist of the Mississippian to Lower Permian Milford Group and hornblende schist and gneiss of the Permian Kaslo Group.

CAPSULE GEOLOGY

Much of the Early Bird (082FNE017) and the Lakeshore (082FNE018) workings were reported to have taken place on the Carey claim. Galena and sphalerite occur in veins with associated silver. The zone is reported to 2.4 metres wide. The workings appear to be in limestone of the Mississippian to Lower Permian Milford Group (Bulletin 53, Figure 3).

There is some confusion between this occurrence and the Lakeshore which is reported to have existed on the Carey Crown grant. They were worked in the same years (see Annual Reports 1950 and 1953) but apparently at different locals.

CAPSULE GEOLOGY

A vein was traced from the Budweiser No.2 claim onto the Dixie Fraction . The ore was reported to consist of galena. A total of 234 tonnes of ore was shipped from the Dixie Fraction. Except for 1 tonne shipped in 1951 the remaining 233 tonnes was mined in 1954 and 1955. From all ores mined, 16,298 grams of silver, 14,127 kilograms of lead and 1,375 kilograms of zinc were recovered.

The area is underlain by calcareous mica schist and silicate marble of the Index Formation, Lardeau Group.

Showings on the Lady of the Lake property consist of rusty siderite and quartz containing galena and sphalerite along a poorly defined vein in a limestone. The vein trends northward parallel to the formations. The area is underlain by the Mississippian to Lower Permian Milford Group. A total of 9 tonnes were recorded mined in 1895 and 1937 from which 25,500 grams of silver and 4564 kilograms of lead were recovered.

CAPSULE GEOLOGY

The area of the Laura M is underlain by limestone, schist and greenstone of the Mississippian to Lower Permian Milford Group. The property was part of the Kootenay Florence mine (082FNE016) and was developed in conjunction with that property.

Production from the Kootenay Florence group consisted of silver, lead, zinc, cadmium and gold. Replacement ore in limestone consists of galena and sphalerite with some pyrite and chalcopyrite. Gangue minerals include quartz, calcite and fluorite.

CAPSULE GEOLOGY

The Lulu property shipped 5 tonnes of ore in 1954 and 3515 grams of silver, 3249 kilograms of lead and 200 kilograms of zinc were recovered. The extension of the Vigilant vein (082FNE005) was traced along strike onto the Lulu claim. Many steep fractures, containing narrow widths of quartz cross Woodbury Creek in this area. The Vigilant veins contains lenses of galena with some sphalerite. Replacement ore typically extends 60 to 100 centimetres from the quartz veins. The most favourable replacement rock is a soft brownish biotitic calcareous schist. Vein widths vary up to 1.3 metres.

The country rocks are micaceous and chloritic schists, quartzites and limestone of the Cambrian to Devonian Index Formation, Lardeau Group.

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The hostrocks of the mineralized features are mapped as brown micaceous quartzite, fine-grained mica schist and minor limestone of the Mississippian to Lower Permian Milford Group (Bulletin 53, Figure 3). Minor amounts of disseminated galena and sphalerite are found in some limestone and quartz veins. Gouge and breccia from the main shear zone varies in thickness from 0.6 to 6 metres.

These claims are located about 1 kilometres southwest of Ainsworth and may be reached by about 6.4 kilometres of road that winds up the mountain side. They adjoin the Highlander and Albion claims on the west.

In 1892 the Black Diamond and Little Donald claims were owned by J.F. Stevens of St. Paul, Minnesota. A joint 4001 crosscut tunnel was driven on the dividing line between the Black Diamond and Little Phil claims. Two veins were reached. The first one was driven on for 61 metres, the second for 14 metres.

The Highlander Mining and Milling Co. took over the Black Diamond and Little Donald claims in 1899. The Highlander tunnel, driven from the Eagle claim at the foot of a high bluff, cut the two Black Diamond veins, the first at 760 metres, the second, at 795 metres. The dip of the veins at this horizon is about 260. The Highlander mine closed in 1911 and the property lay idle until 1949.

Yale Lead and Zinc Mines Ltd. obtained the property in 1949. Leasers shipped the old dump and did about 30 metres of drifting during 1949 and 1950. The company mined the Black Diamond in 1951 and early 1952 and the Little Phil for the balance of 1952.

Intermittent mining occurred from 1895 to 1964. A total of 985 tonnes were mined. From this, 701,872 grams of silver, 31 grams of gold, 335,273 kilograms of lead, 13,935 kilograms of zinc and 26 kilograms of cadmium were recovered.

CAPSULE GEOLOGY

The Little Mamie consists of a thin cavernous quartz vein along the footwall of a lamprophyre sheet. Ore mineralization is lean at surface, but intersections of as much as 60 centimetres of 30 per cent galena and sphalerite were obtained in drill core. The rocks are described as mica schist, micaceous quartzites and limestone of the Mississippian to Lower Permian Milford Group.

A shipment of 10 tonnes of ore was made in 1921 from which 17,107 grams of silver and 4989 kilograms of lead were recovered.

CAPSULE GEOLOGY

The property is located at 850 metres elevation on the east side of Kaslo River, 7 kilometres northwest of Kaslo.

The showings were discovered by A.J. Curle, of Kaslo, in 1907 but not being of economic value lay dormant until July 1917 when he staked 6 claims, the Manganese, Manganese 1-4, and Cantan. Two claims Manganese (Lot 10673) and Manganese No. 1 (Lot 10674) were Crown-granted to Mr. Curle in 1925. The No. 1 deposit, on the Manganese claim, was evaluated by some 85 test pits and trenches. On the No. 2 deposit (Manganese No. 1 claim) Mr. Curle sank a large number of test pits. A trial shipment of 27 tonnes (490 sacks) of ore was made in 1917 by Mr. Curle and A.G. Larson, of Spokane. In 1918 the property was under lease to Col. F.B. Millard, of Spokane, and 15 car-loads of ore were shipped by the Kaslo Nakusp Railway which bordered the lower edge of the property. The high water content of the first shipment necessitated the installation of a dryer but results were not entirely satisfactory and work ceased in October of that year. Mr. Curle made further shipments in late 1918 and 1919. The analysis of samples sent by Mr. Curle to the Mines Branch, Ottawa, in 1940 indicated the sample material was of low quality and didn't warrant further testing. Curle estimated from 700 to 800 tons averaging 30 per cent manganese remained on the Manganese claim following the 1918-19 production. On the Manganese No. 1 claim, Hanson, 1932, estimated 2270 tons; and analysis of this material gave 31.57 per cent manganese, 12.03 per cent silica, 3.75 per cent limonite.

The area is underlain by greenstone (mafic volcanics), chlorite and hornblende schist and gneiss of the Permian Kaslo Group. Three manganese deposits have been located: a lower deposit located just above the old railway bed is exposed for 21 metres along the slope; two deposits occur on a single terrace or bench some 90 metres above the railway bed and consist of the No.1 deposit covering about 20,000 square metres and the No.2, located about 350 metres to the north of the No.1, and covering about 10,000 square metres. Within these areas, the bog manganese varies from less than 2 centimetres to 1 metre in thickness. The deposits consist of different forms of wad

MINFILE NUMBER: **082FNE151**

CAPSULE GEOLOGY

or bog manganese interstratified with, but generally distinct from, various amounts of hydrous iron oxides, calcareous tuffa or sinter and layers of clay-rich subsoil.

CAPSULE GEOLOGY

The showings are reported to be at 820 metres elevation, east of Zwicky. The Harp, Collingwood, and Black Diamond claims comprising this property were owned in 1918 by W.J. Murphy, of Kaslo. The workings at that time included trenches and a 10-metre drift adit.

A series of quartz veins occur in sedimentary rocks or along the contact of sediments with greenstone schist of the Lower Permian Kaslo Group. The footwall rock of one vein was explored by a short adit. It consists of a greenish schist carrying abundant rhodonite in lens-like masses from 5 to 45 centimetres wide, adjacent to the quartz vein. The hangingwall is a quartzitic argillite containing manganeseiferous garnet, partly altered to manganese oxide.

The veins consist of vitreous to smoky quartz mineralized with pyrrhotite, pyrite and chalcopyrite.

CAPSULE GEOLOGY

The initial claims on the Bootleg property were staked in 1996 by Eagle Plains Resources Ltd. and Miner River Resources Ltd. A two-day geological reconnaissance program consisting of stream sediment sampling and prospecting was undertaken on the Bootleg Claims in August 1996.

Field work on the Bootleg Claims during the 1997 and 1998 consisted of prospecting, soil sampling, silt sampling and minor geological mapping. A total of 62 were samples collected. Geochemical results confirmed the presence of elevated base metal levels within prospective Aldridge Formation stratigraphy.

The south and central part of the Bootleg claims cover a shallow dipping package of siltites, quartzites and wackes assigned to the Middle Proterozoic Lower Aldridge Formation which are conformably overlain by Middle Proterozoic Middle Aldridge Formation sediments in the northern part of the property. Within this sedimentary package are a number of intrusive Middle Proterozoic Moyie sills. A fragmental unit has been mapped near the northern boundary of the Boot 2 Claims. This unit appears to occur stratigraphically near the Lower-Middle Aldridge Contact (LMC), similar to the LMC-fragmental relationship at the Sullivan Mine.

Bedding throughout the property area is generally shallow in the 10 to 30 degree west dip range, with strikes roughly orientated south-east/north-west.

Samples of silicified sediments assayed 8 grams per tonne silver and 0.51 per cent lead (Eagle Plains website, February 1999). Rio Algom signed an agreement to option the property in January, 2000 and drilled a single 675 metre drillhole in the same year, which failed to intersect the target horizon. Rio Algom elected to withdraw from the project following the drillhole results.

CAPSULE GEOLOGY

Limestone was once mined underground by Cominco Ltd. as a source of flux beside the C.P. Railway, 2.4 kilometres east of Proctor on the west shore of Kootenay Lake.

A 9 to 15 metre thick bed of limestone in schist of the Mississippian Milford Group outcrops along the railway track and continues up the steep mountain side west of the lake. The bed strikes 0.25 degrees and dips 30 degrees northwest.

The limestone is coarse to fine grained and white to bluish white in colour. The rock is comprised largely of calcium limestone with some thin beds of dolomite. The limestone is cut by some veins of white quartz. A sample comprised of chips taken at various places in underground workings contained 44.18 per cent CaO, 7.34 per cent MgO, 5.61 per cent SiO₂, 0.20 per cent Al₂O₃, 0.26 per cent Fe₂O₃ and 0.02 per cent sulphur (Canada Bureau of Mines Report 811, p. 202, Sample 68)

The deposit was explored underground by 490 metres of drifting by Cominco between 1935 and 1938. 6896 tonnes of limestone were mined during this development work. In 1960 the property was leased to B & P Lime Development, which mined 318 tonnes.

CAPSULE GEOLOGY

Limestone of the Lower Cambrian Badshot Formation outcrops along the west shore of Galena Bay on the east side of Kootenay Lake and continues northward across a small promontory jutting into the lake for 1600 metres. The bed strikes 000 degrees and dips 35 degrees west. Thicknesses vary up to 60 metres. The unit is overlain by mica schist of the Index Formation (Lardeau Group) and underlain by hornblende schist of the Hamill Group.

The bed is comprised predominantly of calcium limestone interbedded with dolomite. In the vicinity of the Bluebell Mine (82F 043) the limestone contains sulphides with silicates and graphite. Tremolite and quartz become abundant near the top and bottom of the bed. A sample taken south of the Bluebell Mine across a 15 metre section contained 48.71 per cent CaO, 3.93 per cent MgO, 4.96 per cent SiO₂, 0.22 per cent Al₂O₃, 0.16 per cent Fe₂O₃ and 0.02 per cent sulphur (Canada Bureau of Mines Report 811, p. 212, Sample 84).

A small amount of limestone was once quarried to produce lime.

CAPSULE GEOLOGY

Marble from a small quarry located on the east shore of Kootenay Lake opposite Kaslo, was used to construct the Nelson City Hall, courthouse and Government building and the Kaslo and Grand Forks Government buildings. The stone varies in colour from white to blue-grey, is coarse-grained (greater than 5 and up to 16 millimetres) and contains tremolite which has a tendency to turn yellow with time.

The quarry is 13 metres long by 14 metres across by 8.5 metres high. Joints are irregular, striking between 0 and 90 degrees with dips varying from 60 to 90 degrees northwest. Remnant bedding strikes 320 degrees and dips 35 to 40 degrees southwest. Eighty-five per cent of the joints and fractures measured are spaced wider than 50 centimetres apart. Potential reserves of marble, similar to the stone in the quarry extend north parallel to the lakeshore. No production figures are available.

CAPSULE GEOLOGY

Sedimentary rocks of the Aldridge Formations underlie the area. The sediments are Proterozoic in age and consist of quartzwackes, quartz arenites, and siltstones. Diorite of the Proterozoic Moyie Intrusion occurs as dikes and sills.

A drill hole on the Vulcan 5 intersected fine-grained wackes to quartz wackes of the Aldridge Formation with gabbro sills. Bedding varies from finely laminated argillaceous rocks to medium bedded, more quartzitic units. Metamorphism is greenschist level with local development of intense biotite and or silicification. There are very minor occurrences of graphite along fractures and as narrow 'bedded' seams. The sulphides, most commonly pyrrhotite and pyrite, occur sporadically as fine laminations or as cross-cutting veins and fracture fillings. Minor associated sphalerite and galena were noted locally.

CAPSULE GEOLOGY

This occurrence is reported from several sources as being located along the ridge east of Mallandaine Pass and Mount McKay and within the main body of the Lower Cambrian Cranbrook Formation quartzites to the west of Hellroaring Creek.

An exact location and detailed description of the magnesite is unavailable other than it is hosted by quartzites and is of good grade.

CAPSULE GEOLOGY

A band of grey limestone of the Hadrynian Horsethief Creek Group trends northward along the east side of Kootenay Lake. The band is exposed over a width of 1000 metres, where it crosses La France Creek. The unit strikes 006 to 016 degrees and dips 45 to 55 degrees west, just north of the creek.

Limestone was quarried on La France Creek during 1923 and 1927 by Thomas Wall for agricultural purposes. A total of 83 tonnes were quarried.

CAPSULE GEOLOGY

The Pilot Bay smelter and concentrator was erected from 1891 to 1895 at a cost of 250,000 dollars. It was built with the intention of treating ore from the Bluebell mine (082FNE043) but financial difficulties caused the mine to cease operation in 1895 and the smelter the following year.

Besides the Bluebell mine which apparently did ship 47,000 tonnes to Pilot Bay in 1895, several other nearby mines are known to have shipped ore to Pilot Bay in the same year. These include the Ruth (082FNW052) (91 tonnes), Howard (082FNW136) (6.3 tonnes), Skyline (082FNE048) (1360 tonnes), Number One (1380 tonnes) (082FNW203), Lady of the Lake (6.3 tonnes) (082FNE145), Dellie (082FNE024) (11 tonnes), Mile Point (50 tonnes), Highlander (082FNE030) (4.5 tonnes) and Canadian Pacific Mg. Co. (68 tonnes). The Rambler (16.3 tonnes), Howard (11 tonnes), Fern (082FSW183) (22.7 tonnes), Skyline and California (082FNW005) (2.7 tonnes) shipped ore to Pilot Bay in 1886.

The Pilot Bay plant and Blue Bell mine were idle until 1905 when new owners took down the smelter and used part of the plant to construct a new concentrating mill at the mine. The Pilot Bay locality was purchased from Cominco by a private concern in 1947 and in the following two years shipped crude ore that had been recovered from the old ore dumps that remained from before the turn of the century. A small mill was established near the old smelter site in 1950 and the concern commenced the dredging and processing of old tailings that had been dumped off shore. It was estimated in 1952 that about 32,000 tonnes remained available for processing.

Records indicate that between 1948 and 1952 and between 1978 and 1980 and again in 1989 a total of at least 2686 tonnes of ore were shipped and 628 grams of gold, 994,686 grams of silver, 164,611 kilograms of lead and 733,545 kilograms of zinc were recovered.

The majority of the of the tailings and dump rock are likely to have been originally extracted from the Bluebell mine where Lower Cambrian Badshot Formation (Lardeau Group) limestone/marble host galena, sphalerite, pyrrhotite, pyrite, arsenopyrite and chalcopyrite.

CAPSULE GEOLOGY

The area is underlain by Hadrynian Horsethief Creek and Middle Proterozoic Mount Nelson Formation (Purcell) rocks. Sulphide mineralization occurs over a 100-metre strike length in two dolomitic limestone zones, separated by 100 meters of phyllite and argillite. A sample assayed 7.73 per cent lead, 1.59 per cent zinc and 119 grams per tonne silver (Assessment Report 24287).

The stratabound zinc was discovered by G. Johnstone while prospecting with a Prospector Assistance grant. Subsequent investigations focused on molybdenite mineralization to the north, associated with the old Baker occurrence (082FNE004).

CAPSULE GEOLOGY

The Apex occurrence, a past producer, is located 2 kilometres east of New Denver, British Columbia and 250 metres west of the former Mountain Chief mine (082FNW177).

Work on the Apex claim was confined to a quartz vein striking 070 degrees and dipping 40 degrees to the south. The vein was intersected at 148 metres from the portal of a 172-metre long crosscut. The vein was worked at this level and a second level, 26 metres vertically above the crosscut. Historically, the Apex occurrence has been under lease to the same operators as those of the Mountain Chief.

The Apex occurrence is underlain by argillaceous and calcareous sediments, slate and limestone of the Triassic Slocan Group. These strata have a general strike of 040 degrees and dip 45 degrees southwest and are intruded by large porphyry dikes and a porphyritic granite stock.

Mineralization consisted of blebs and disseminations of argentiferous galena and sphalerite, and lesser chalcocite hosted in a quartz vein and brecciated wallrock. Galena contains blebs of native silver and tetrahedrite visible with the naked eye. The maximum width of the vein is 60 to 90 centimetres.

Production records for the Apex occurrence show 520,446 grams of silver, 466 grams of gold and 4403 kilograms of lead recovered from 154 tonnes of ore, mined intermittently between 1912 and 1925.

CAPSULE GEOLOGY

The Bosun mine is situated on the east side of Slocan Lake, between Silverton and New Denver at 615 metres elevation above sea level in the Slocan Mining Division. The mine is located on the Boatswain Fraction Crown grant (Lot 3112).

The showings, discovered in 1898 were staked as the Fidelity and Fidelity Fr. claims; the Fidelity (Lot 2411) was Crown-granted to F.L. Byron and associates in 1898. Development work in several adits and a shaft was carried out under the name Fidelity Mining Company. Adjacent showings, staked as the Tyro, Botswain Fr. and Tyro Fr. (Lots 3111-3113, respectively), were Crown-granted to the North-West Mining Syndicate in 1899. The Bosun Mines, Limited, incorporated in England to consolidate the above companies, was registered in B. C. in 1899. The Fidelity Fr., Cracker Jack and Broken Lock (Lots 3748, 3747 and 3735) were Crown-granted to Bosun mines in 1900. Operations continued into 1903 when development work totalled some 1095 metres of drifts, crosscuts and raises in 5 adits and a 23-metre shaft.

Roseberry Surprise Mining Company, Limited was incorporated in November 1917 to acquire the Bosun property and others in the same

CAPSULE GEOLOGY

area. The company owned a mill at Rosebery, about 6.5 kilometres up the lake, and Bosun ore was milled there in 1918-19. Development work continued into 1928 and included the No. 6 (Main) level driven 915 metres from the lake shore, and a 43-metre inclined winze sunk at 832 metres from the portal to establish No. 7 level.

The property was purchased by Colin Campbell, of New Denver, in 1928. Lessees continued intermittent operations in various areas of the mine until 1943. Santiago Mines, Limited acquired the property in 1945. Development work in the lower levels included a winze from No. 7 level to establish No. 8 level. New Santiago Mines Limited was incorporated in January 1951 and development work continued from November to mid 1953. Lessees continued to explore and mine ore remnants in various areas of the mine into 1959 and in 1963. In 1970 the company name (New Santiago) was changed to Santico Mining and Exploration Ltd. In 1982 the company amalgamated with Heather Resources Inc. under the latter name.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slokan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slokan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slokan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The Bosun mine is hosted by impure quartzite, slate and limestone of the Slokan Group that generally strike 115 degrees and dip 45 to 75 degrees southwest. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slokan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Dikes and sills of biotite quartz monzonite, one to 25 metres thick, cut the sedimentary rock and several fault structures are evident and host vein mineralization in the area. Later stage normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Horizontal displacement can be several metres to over 90 metres. Drag features are also present.

The occurrence consists of a vein within a fracture striking 060 degrees and dipping 35 to 65 degrees southeast. The vein has been developed by six main adits and several intermediate levels and raises. The No. 6 or main level is about 1130 metres long and explores three separate orebodies known as, from west to east, the West, the Central and the Third orebody. The West orebody plunges at low angles to the west but the Central and Third do not show this trend. Within the workings, the vein is discontinuous, varying from a few centimetres up to 1.5 metres. For the most part, it follows an altered quartz monzonite dike. The ore consists of galena and sphalerite associated with minor pyrite, tetrahedrite, pyrargyrite, native silver and chalcopyrite in a gangue of quartz, siderite and calcite. Minor cassiterite also occurs within the high grade sphalerite ore. The wallrock immediate to the vein contains disseminated pyrite.

As followed northeast along the levels, the vein is offset to the southeast by bedding plane shears that strike 125 degrees. These shears appear to lie along narrow altered sills of quartz monzonite. The structure is further complicated in the vicinity of the Central orebody by a split commencing below the No. 4 level. The ore follows mainly the hangingwall section of this split which has provided most of the production from the mine. The Central or main orebody was mined almost continuously from surface down to the No. 7 level, about 150 metres below surface. The ore was stoped from large blocks about 150 metres long generally bound by bedding plane shears. The fracture hosting the deposit appears to pinch out below the No. 8 level where it contains only siderite and minor sulphide mineralization.

Production from the Bosun mine between 1898 and 1976 yielded about 60 tonnes of silver, 4906 tonnes of lead, 3145 tonnes of zinc, 814 kilograms of cadmium, 37 kilograms of copper and 3 kilograms of gold from 63,222 tonnes mined.

CAPSULE GEOLOGY

Santiago Mines Limited in 1946. The two lowest adits were reopened and sampled. In 1951, the New Santiago Mines Limited was incorporated and acquired the Hartney claim group.

Hostrocks of the Hartney occurrence are massive argillite and pyritic, carbonaceous slate of the Triassic Slocan Group.

Galena and sphalerite mineralization are hosted in a quartz-calcite-siderite vein. Cassiterite is reported associated with the sphalerite. Minor pyrite was found coating vugs in the ore. The vein ranges from 2 centimetres to 122 centimetres width and contains brecciated wallrock.

The best ore pitched with the slope of the hillside. Three samples were taken in 1946. The best of these samples, a 15-centimetre chip sample, yielded 285 grams per tonne silver, 3.1 per cent lead, 33.7 per cent zinc, 0.49 per cent cadmium and 0.08 per cent tin (Canadian Mining and Metallurgical Bulletin, October 1946, page 593).

Production records indicate 256 tonnes of ore were mined sporadically between 1900 and 1917. A total of 522,810 grams of silver, 81,876 kilograms of lead and 7900 kilograms of zinc were recovered.

CAPSULE GEOLOGY

The California occurrence is located at 1600 metres elevation on the northwestern flank of Idaho Peak. New Denver, British Columbia lies 3.5 kilometres to the northwest.

The California (Lot 918) and Clipper (Lot 3997) Crown grants were worked intermittently from 1897 to 1907. There has been no record of further development on this occurrence although it was owned by California Clipper S.L. Mines Limited in 1935. Workings consisted of two crosscut adits from which drifts extend.

The California occurrence is composed of a quartz fissure vein with argentiferous galena. The vein width varies from 5 centimetres to over 30 centimetres width, crosscutting siliceous argillites and quartzites of the Triassic Slocan Group. The vein has a general strike of 075 degrees and dip of 75 degrees to the southeast.

A total of 308 tonnes of ore are recorded produced from the California occurrence. This ore yielded 906,839 grams of silver and 151,784 kilograms of lead.

CAPSULE GEOLOGY

The lode has a variable strike from 355 to 066 degrees and dips from 55 to 70 degrees east and southeast. The mineralized zone consists of breccia hostrock in a matrix of calcite, quartz and ankerite? carrying streaks and blebs of galena and sphalerite. Galena occurs as bands with sphalerite or lenses of massive and sheared to coarse-grained galena up to 0.3 metre thick. In general, the lode appears to be closely associated with the hangingwall of a subparallel, quartz feldspar porphyry dike.

Near the face of the main adit the lode has been stoped to about 41 metres height. The ore was hand sorted and roughly jigged before shipment. Production records are incomplete but indicate 303 tonnes have been mined. From this 303 tonnes, 1,379,294 grams of silver, 684 grams of gold and 153,936 kilograms of lead were recovered.

CAPSULE GEOLOGY

associates. The Idaho occurrence was developed by six adits over 244 vertical metres. The No. 5 adit also explores the adjacent Cumberland lode and two lodges on the St. John claim.

The Idaho occurrence is hosted by massive, banded argillites and quartzites of the Triassic Slocan Group. Two quartz diorite stocks lie north and west of the occurrence.

The deposit consists of three lodges, the Idaho, Cumberland and St. John, all continuations of the Standard lode (082FNW180). The Idaho lode strikes 045 degrees and dips about 55 degrees to the southeast. The lode forms a strong shear or fracture zone varying in width from less than 30 centimetres to 7.6 metres. Evidence indicates downward and eastward motion along the faulted hangingwall. It has been explored over 762 metres length. The lodges carry lenses of galena, sphalerite, tetrahedrite and pyrargyrite in a gangue of principally calcite but also quartz and siderite which are locally dominant. The vein is commonly brecciated. The main shoot was up to 3 metres thick and included up to 61 centimetres of clean galena on the hangingwall side. Ore from lower levels contained abundant calcite gangue. Hostrocks are locally silicified.

The St. John and Cumberland lodges are branches of the Idaho lode on the footwall or north side. The St. John is nearly parallel with the Idaho and diverges to the west. It was explored by two adits and little is known about the lode. It is located 46 to 61 metres northwest of the Idaho lode. It is reported to have consisted of a vein carrying galena, sphalerite and pyrargyrite in a gangue of siderite, calcite and quartz. The Cumberland lode merges with the Idaho lode near the No. 5 adit and diverges to the northeast. It was explored by two adits and in the No. 5 adit over 442 metres length. It is a steep, well-defined fissure with little or no fault displacement, cutting argillite and quartzites at low to moderate northeastern dips. The best section was composed of 30 centimetres of siderite with seams of sphalerite and a little galena.

The majority of ore was mined from the upper two levels and on surface above the No. 1 and 2 adits of the Idaho. Production records for the Idaho occurrence show 26,866 tonnes of ore was mined intermittently between 1893 and 1984. Recovery from this ore included 50,643,149 grams of silver, 715 grams of gold, 2,316,299 kilograms of lead and 225,235 kilograms of zinc.

CAPSULE GEOLOGY

Queen Bess (082FNW010) properties were amalgamated. Hemsworth and associates obtained the property in 1947, after the death of Mr. Cunningham. Work was reported on the No. 5 adit by Alamo Silver-Lead Mining Company Ltd. in 1948. An agreement was reached between Cunningham Mines Ltd., Bralorne Mines Limited and Kelowna Exploration Company Limited to incorporate Bess Mines Limited in the following year. An option was acquired on the Idaho, Alamo and Queen Bess properties with development work confined to the latter.

The Alamo occurrence is hosted by massive, banded argillites and quartzites of the Triassic Slocan Group. These metasediments have a gentle dip with minor folding and faulting and are intruded by two quartz diorite stocks. On the north or footwall side of the Alamo occurrence, strata are overturned while those on the hangingwall are right-side-up. These represent displaced limbs of a large-scale dragfold with a near horizontal axial plane. The lode is deflected from its west-southwest strike to a northwest strike following bedding in this vicinity.

The lode consists of a curving vein of steep to shallow dip where hostrocks have been brecciated and cemented by quartz. The strike changes from 250 to 290 degrees. The dip averages about 60 degrees south but varies considerably. The lode varies in width from a few centimetres up to 3 metres thick with ore shoots composed of massive galena, tetrahedrite and minor sphalerite in a gangue of quartz, siderite, calcite and brecciated hostrock. A small amount of pyrrargyrite was associated with galena and tetrahedrite was prominent in the higher grade ore. Pyrite and chalcopyrite were also present with chalcopyrite locally forming unusually high proportions for ores from this area. Quartz was the dominant gangue mineral and higher grade silver values were reported associated with finely crystalline vuggy quartz.

The main ore shoot extends from surface to 15 metres below the No. 4 level and plunges to the east and formed in the upper part of the steep buckle of the lode. The maximum length is about 152 metres, between the Nos. 1 and 2 levels and decreases on lower levels to less than 61 metres on the No. 4 level. The lower workings are reported to contain ore richer in sphalerite. It is important to note that the hangingwall of the more productive sections of the workings were hosted by porphyry dikes.

A total of 538 tonnes of ore is recorded as mined from the Alamo occurrence periodically between 1920 and 1969. From this ore 976,199 grams of silver, 155 grams of gold, 55,563 kilograms of lead, 47,240 kilograms of zinc and 38 kilograms of cadmium are reported recovered.

CAPSULE GEOLOGY

The Conductor property is situated near the headwaters of Howson Creek at 1800 metres elevation above sea level, in the Slocan Mining Division. The underground workings are on Reverted Crown grant Lot 1251. The claim was staked about 1898 and developed then and in 1903.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted by predominantly interbedded black argillite, quartzite and limestone of the Slocan Group. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slocan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Several fault structures are evident and host vein mineralization. Later stage normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Drag features are also present.

On the Conductor property, the sedimentary rocks strike 145 degrees and dip 50 degrees northeast. The occurrence consists of a fissure vein striking 068 degrees. The vein has been explored with at

CAPSULE GEOLOGY

least one 45 metre long adit and about 20 metres of drifting. The vein is 2 to 15 centimetres wide and contains disseminated coarse galena and calcite. Surface exposures of the vein are strongly oxidized. The vein is probably an extension of the Idaho-Alamo vein system exposed on the Idaho (082FNW007) and Alamo (082FNW008) properties to the west. There is no record of production from this property.

CAPSULE GEOLOGY

2 were in poor condition. Two short adits Nos. 6 and 7, now caved, did not encounter the lode. B vein adit was driven from near the lower road, on the supposed course of the B vein is in the hanging wall of the lode. Only the lowest of the C vein adits, about 122 metres northwest of the main lode, is accessible.

The last work recorded, was in 1957, when Bess Mines Limited carried out some underground development.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slokan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slokan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slokan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The Queen Bess occurrence is hosted by massive argillite and quartzite of the Slokan Group. The sedimentary rocks are intruded by quartz porphyry dikes probably related to the Nelson intrusions. The rocks generally strike 125 degrees and are folded in a tight synclinal structure. The upper strata are mostly deformed and slaty whereas the lower beds are mainly massive, argillaceous and quartzitic. The sedimentary rocks are cut by several pre-mineral faults with variable displacements.

At least three fissure veins have been mined on the Queen Bess property. From south to north, these are the A, B and C veins. Of these, the A vein has produced the bulk of the ore. A small tonnage has been shipped from the C vein and little or no production is attributed to the B vein which is believed to be a faulted segment of the A vein.

The A vein correlates with the Palmita (082FNW012) to the northeast and the Idaho (082FNW007) to the southwest. It has been developed by nine main levels over a vertical range of about 150 metres. The vein strikes 045 to 050 degrees, dips 40 degrees southeast and has been explored for 500 metres of strike length. It is within a fault zone that displaces a quartz porphyry dike about 33 metres to the left. Within the fault zone, the vein is up to 8 metres thick with orebodies of massive, sheared galena up to 5 metres wide. The ore is located in flexures of the vein where there is less gouge and more brecciation. The largest orebody was developed on the No. 5 level and was about 90 metres long, 3 metres thick and extended for about 90 metres downdip.

Mineralization consists of argentiferous galena and sphalerite with minor amounts of pyrargyrite, pyrite, chalcocite, native silver, and chalcopyrite in a quartz gangue. The vein is broadly zoned with sphalerite being more abundant in the lower workings and galena being more concentrated in the upper levels of the mine.

Production from the Queen Bess between 1893 and 1978 yielded about 42 tonnes of silver, 8558 tonnes of lead, 19 tonnes of zinc and 849 grams of gold from 16,573 tonnes mined. Production in 1961 was likely attributed to a property called Bess, operated by M. Tarnowski.

CAPSULE GEOLOGY

The Silverite property is situated on Shea Creek in the Slocan Mining Division. The underground workings are on Reverted Crown grant Lot 14624 at 1433 metres elevation above sea level.

This property consists of the Silver Ridge, Silver Ridge Fraction, Speculator, Consolidated Virginia, Elk and G. Fraction claims, adjacent to the Violamac (082FNW204) and Queen Bess (082FNW010) groups. The claims were prospected in the early years of the district's history and in 1929 an adit was driven on the Silver Ridge Fraction in search of the downward extension of the Black Colt (082FNW223) ore zone. In 1938 the property was operated under lease by Clarence Cunningham and by others during the next 3 years.

Excelda Mines Limited rehabilitated the camp in 1945 and in 1946 Sylverite Mines Limited was formed to take over the property. In 1950 Slocan Base Metal Mines took over the claims and in 1951 and 1952 did considerable stripping and drove an adit in a westerly direction 88 metres to the Violamac boundary. This adit was collared at an elevation of 1350 metres in the northeast corner of the Silver Ridge claim. At 46 metres from the portal a fracture was followed 38 metres to the southwest, and at 27 metres from the commencement of the drift another fracture was followed to the west for 36.5 metres. All work ceased in 1952, and in 1960 the property was optioned to Violamac Mines Limited.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in

CAPSULE GEOLOGY

the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted by predominantly interbedded black argillite and quartzite of the Slocan Group. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slocan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Several fault structures are evident and host vein mineralization. Later stage normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Drag features are also present.

On the property, the Slocan Group rocks strike southeast and dip 30 degrees southwest. The occurrence consists of a fissure vein striking about 055 degrees. The vein has been explored with an adit driven for about 135 metres in a westerly direction from the Silver Ridge Fractional Reverted Crown grant (Lot 14625). A northerly crosscut extends 53 metres into the Black Colt (Lot 1721) (082FNW223) and a raise connects the crosscut to the No. 2 level of the Black Colt workings. An adit located on the main road, 122 metres northwest of the Black Colt No. 1 portal, extends 61 metres to the west in broken ground.

The occurrence is developed on the downdip extension of the Black Colt vein exposed on Lot 1721 to the south. The mineralized vein is within a fault zone that is about 20 metres wide. The wider portions of the fault zone are brecciated and contain fragments of argentiferous galena, pyrite and sphalerite mixed in a quartz matrix. The fissure zone is mostly filled with crushed wallrock.

Production from the Silverite occurrence between 1919 and 1949 yielded 254,143 grams of silver, 57,920 kilograms of lead, 4189 kilograms of zinc and 31 grams of gold from 103 tonnes mined.

CAPSULE GEOLOGY

The Palmita property is situated west of Shea Creek in the Slocan Mining Division. The underground workings are on Reverted Crown grant Lot 4880 at 1610 metres elevation above sea level.

The Palmita was owned in 1952 by G.W. Robinson. The earliest development on the claim was on the eastward extension of the Queen Bess lode (082FNW010), and several adits were driven on the general lode zone. Later development, starting about 1928, was from the upper Black Colt adit (082FNW223), and mining was later carried out by Clarence Cunningham when the Palmita was part of the Consolidated Queen Bess holdings. In 1949 a discovery was made on the main road crossing the claim. An option was taken by Kelowna Exploration, but the option was later dropped.

Workings consist of 4 short adits on the steep hillside between 2 branches of the main road, driven many years ago. One adit was cleaned out by Kelowna Exploration but the other 3 are caved. The workings on the Palmita, driven from the Black Colt No. 1 adit were in poor condition when examined by Hedley in 1949. A raise almost on the boundary line reaches a level 10 metres above Black Colt No. 1 level. A crosscut 32 metres long leads to a northeasterly drift section 73 metres long. A second raise reaches a level 14 metres higher on the same zone and a level 9 metres still higher, 15 metres long. The ore, mined locally to widths of 3 metres, has all been taken out to fault boundaries.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and

CAPSULE GEOLOGY

compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted by predominantly black and locally calcareous argillite and quartzite of the Slocan Group. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slocan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Several fault structures are evident and host vein mineralization. Later stage normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Drag features are also present.

The occurrence consists of four short adits driven on a vein that correlates with the "A vein" on the Queen Bess property (082FNW010). The vein strikes east and dips 40 degrees south. It is within a 2 metre wide shear zone and consists mostly of galena and sphalerite in a gangue of quartz and calcite. The ore is concentrated in pockets and lenses that pinch and swell from 0.1 to 3 metres along the vein.

Production from the Palmita property between 1930 and 1951 yielded about 1612 kilograms of silver, 371,011 kilograms of lead and 34,939 kilograms of zinc from 711 tonnes mined.

COMMENTS: Reserves at the Silvana (082FNW050) and Hinckley mines as of April 1993.

REFERENCE: Information Circular 1995-1, pages 8,11.

CAPSULE GEOLOGY

The Hinckley property is situated on Shea Creek in the Slocan Mining Division. The underground workings are on Crown grant Lot 1720 at 1220 metres elevation above sea level. See also Silvana (082FNW050).

In 1898 the property, owned by the Hinckley-Black Colt Mining Company, was developed by R.A. Grimes in 1923, and by the Standard Silver-Lead Mining Company in 1924 and 1925. In 1936 and 1937 it was worked under lease and a small amount of ore produced. Some additional work was done in 1941 but remained dormant until 1954.

Workings consist of 5 adits and a shaft. A fifth adit on the Bear Paw Mineral Claim passes into the Hinckley from the north. Three short adits, one of which is caved, are located at an elevation of nearly 1160 metres, at the edge of the creek. A short access road was made in 1954 to one of these adits, located on the east side of the stream, and between 1954 and 1957 mining operations were carried on intermittently by the owners, and the adit extended. About 76 metres northeast of this adit a series of small pits exposes an irregular mineralized fracture, and an adit a little lower in

CAPSULE GEOLOGY

elevation explores what is presumably the same zone. The shaft is at an elevation of 1128 metres near the north boundary of the claim and is inaccessible. A small caved adit is located close to the collar of the shaft. The adit from the Bear Paw claim is located 46 metres lower and 107 metres to the northeast, and has a length of 79 metres. This adit was driven in argillites for 55 metres where it encountered a 24 metre porphyry sill. A crosscut 24 metres to the west encountered a fissure zone, perhaps the same as that on which the shaft was sunk, which was drifted on for 60 metres. In the property the zone is gougy, but in the argillite it is a quartz vein about 15 centimetres wide.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The property is underlain by quartzite and argillaceous quartzite of the Slocan Group. A prominent sill or dike of porphyritic quartz diorite about 45 metres wide is exposed along Shea Creek. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. On the Hinckley property, the strata generally strike east and dip steeply south.

Mineralization occurs in a vein up to 1 metre thick. The vein follows a near vertical, northeast-trending fissure which is parallel to a joint set within the quartzite. The fissure vein has been explored with at least six short adits and a vertical shaft. It consists of lenses of massive, coarse grained, commonly cubic pyrite containing irregular to wispy bands of coarse-grained sphalerite, fine to coarse grained, sheared galena, and a discontinuous band of siderite at the footwall. Quartz forms irregular lenses and bands in the vein.

Moskogee Minerals Inc. conducted diamond drilling in 1985 and underground development in 1988.

The Silvana mine closed indefinitely in April, 1993. In October, 1994, Amcorp Industries Ltd. signed an agreement to buy the Silvana mine and mill at Sandon from Treminco Resources Ltd. A review of the Silvana (082FNW050) and Hinckley mines' ore reserves by Amcorp indicated that about 54,400 tonnes of ore grading 290 grams per tonne silver, 3.4 per cent lead and 4.7 per cent zinc, remain in the developed areas of the mines with potential to develop additional reserves. Amcorp expected to resume production in early 1995 (Information Circular 1995-1, page 8). Amcorp changed their name in May 1996 to Molycor Gold Corporation, part of the Verdstone Group of companies.

Past production from the Hinckley mine, between 1936 and 1988, yielded 265,512 grams of silver, 113,309 kilograms of zinc, 54,840 kilograms of lead, 59 kilograms of cadmium and 481 grams of gold from 106 tonnes mined.

During the end of 1997, underground access to the Hinckley and Silvana lodes was re-established. Mining started on the Hinckley lode and the Silvana mill was re-commissioned. In 1997, Treminco Resources extracted and processed 1905 tonnes, averaging 285 grams per tonne silver, 5.29 per cent zinc and 5.15 per cent lead from the eastern extension of the Hinckley lode (GCNL #10, 1998). In 1998, Treminco signed a Letter of Intent with Regeena Resources Inc. to purchase the Silvana and Hinckley operations. Treminco changed their name to Elkhorn Gold Mining Corporation in February 1999. In June 1999, Klondike Gold Corp. plans to acquire the Silvana and Hinckley mines. Selective mining on the 4625 level, surface drilling and trenching are planned in July 1999.

CAPSULE GEOLOGY

The Cinderella property is situated west of Shea Creek in the Slocan Mining Division. It is located on the steep slope above Carpenter Creek, adjacent to the Victor group (082FNW040). The underground workings are on Crown grant Lot 3621 at 1210 metres elevation above sea level.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted by massive and carbonaceous argillite and quartzite of the Slocan Group. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. On the property, the Slocan Group rocks strike southeast and dip at shallow angles to the northeast or southwest. The rocks are intruded by dikes and a stock of biotite quartz diorite.

The old workings include 6 adits and one short incline adit and range in elevation from about 30.4 to 243.8 metres above Carpenter Creek. Two adits between 122 and 152.4 metres north of the Lone Bachelor adits (082FNW205) are driven on steep joints in thick bedded argillite that dips southwestward into the hill. The upper adit is caved and the other, 18.2 metres lower, is about 61 metres long. Two other adits are located at the old camp. The upper adit is reported to be 198 metres long. The other adit, 30.4 metres lower, is nearly

CAPSULE GEOLOGY

244 metres in length. The adits explore fissure veins that follow a joint system striking 042 degrees and dipping 70 degrees southeast. The veins vary from a mere fracture to about a metre in width. They consist mainly of crushed wallrock with stringers of galena, pyrite and oxidized sulphides in a matrix of quartz. Within the underground workings, several mineralized fractures were intersected, some striking parallel but most striking across the bedding planes of the enclosing rocks. In the lower parts of the mine, the veins contained mainly sphalerite and siderite with only minor galena and quartz.

In November 1948 the property was acquired by Violamac Mines Limited. In 1953 the No. 9 adit of the Victor mine (082FNW040) was collared on the Cinderella claim and in the next few years was advanced to a point 1280 metres from the portal; most of the workings being on the Victor property. A vein was exposed near the portal of this level in 1953, and in 1955 a similar vein, possibly the same one, was exposed 30.4 metres lower and 91.4 metres to the northeast. In 1956 No. 10 adit was started on this vein, and in 1957 had a length of over 247.3 metres. A raise was put up from this level to the surface near No. 9 portal. Some short sections of ore were encountered in the raise and some stoping was done. In 1956 some of the old workings, consisting of 2 connected adits and approximately 609.6 metres of workings, were reopened, mapped and surveyed. In 1957 a new No. 11 adit was started near the old workings at a point 45.7 metres northeast and 30.4 metres lower than No. 10 portal. The adit was driven southwestward to intersect the old shaft workings at 45.7 metres from the portal. By the end of 1957 this adit was 170.6 metres long but little ore was encountered. In January 1958 work on both No. 10 and No. 11 adits was suspended and there has not been any record of work on the property since.

Production from the Cinderella mine between 1904 and 1936 yielded 574,317 grams of silver, 149,814 kilograms of lead and 11 kilograms of zinc from 226 tonnes mined.

CAPSULE GEOLOGY

claims (Lots 1918, 1919 and 1920, respectively).

Sandon Mining & Milling Company, Limited Liability held the property from about 1898. Underground work in 4 adits totalled about 460 metres. The company charter was surrendered in 1912 and the claims eventually reverted to the Crown for taxes.

The Altoona claim was re-Crown-granted to A.J. Murphy, of Sandon, in 1926. Altoona Mines, Limited was incorporated in August 1929 to acquire the Altoona and Bowknot Crown-grants and the Commander located claim. Work during 1930 included trenching and a short crosscut driven from No. 1 adit; the claims were subsequently abandoned.

The claims were acquired by E. Doney in 1949 and optioned the following year to Kootenay Belle Gold Mines, Limited, operator of several properties in the Sandon area. Ore from stopes in No. 1 and 2 adits was shipped to the Whitewater mill during 1950-51.

During 1965-66 Sven Hallgren and associates carried out mining in No. 1 adit under the name Hallmac Mining Syndicate. The Altoona and Bowknot claims were optioned from E. Doney by A. Hewitson in November 1968 and assigned to Hallmac Mines Limited in January 1969. In addition the company acquired the Tawanada Crown-grant, the Hall 1-3 located claims, and the adjoining Majestic property (082FNW017). Intermittent work to 1980 included geological mapping, crosscutting on No. 2 level, diamond drilling, and a geochemical soil survey. In 1981-83 development and mining operations were carried out in two adits vertically apart on a new showing discovered in 1980. A third adit was begun in 1983 on a newly discovered adjacent structure. Operations were suspended in 1984 due to the low silver price. The company name (Hallmac) was changed in February 1986 to Royal Oak Resources Ltd. The mineral inventory at closure in 1984, including stockpiled high-grade and mill feed and ore in place is estimated to contain 7,651,500 grams of silver, 726 tonnes of lead and 193 tonnes of zinc (Royal Oak Resources Ltd. June 30, 1986 Annual Report).

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Hallmac mine area is underlain by a sequence of siltstone, argillite, carbonaceous graphitic and pyritic slate, phyllite and quartzite of the Slocan Group. The sedimentary rocks have been intruded by porphyritic and aplitic dikes and sills apparently related to the emplacement of the Nelson intrusions.

The sedimentary rocks strike 310 to 320 degrees and dip steeply east and west. Within individual beds, crenulations related to soft sediment deformation are evident. A penetrative axial plane cleavage occurs subparallel to the bedding. This is best developed in the more phyllitic units. A more pronounced fracture cleavage, generally normal to bedding, is characteristic of the slates.

Sedimentary rocks and dikes are cut by fractures, joints and faults along several diverse directions. Two fault orientations, one striking 070 degrees and dipping 58 degrees southeast, and the second striking 068 degrees and dipping 39 degrees southeast, appear to be favourable for economic mineralization.

Very low rank regional metamorphism has converted former shales and mudstones to slates and phyllites. Minor biotite occurs along narrow (25 millimetre) "bake" zones adjacent to intrusive contacts.

Argentiferous galena with variable amounts of sphalerite and minor tetrahedrite and arsenopyrite occurs in a siderite-quartz-calcite gangue in brecciated vein structures crosscutting argillite-slate-quartzite host strata. The silver-bearing galena varies from coarse, massive aggregates to fine, foliated or lined "steel" galena. Similarly, sphalerite in the zinc-rich veins varies from clusters of coarse subhedral brown crystals to very fine, dark brown to nearly black (iron-rich) massive aggregates.

The brecciated fault controlled vein structures strike in a general 070 to 085 degree direction and dip from 50 to 65 degrees

CAPSULE GEOLOGY

southeast. Pinching and swelling is common and vein structures can vary in width from 0.25 to over 2 metres. Average mining width is about 1 metre. Galena can occur in aggregates, pods, lenses and sinuous bands along the footwall, hangingwall and within the fissure structures. This, together with the friable nature of the oxidized breccia host, has made control difficult. Extensive timbering and rock-bolting was required for ground stabilization in stoping areas (Assessment Report 18551).

Work done to date suggests there is a vertical transition from galena to sphalerite between the 1735 and 1690 levels. Silver grades appear to decrease somewhat in the high zinc zone.

Extensive surface oxidation has penetrated the vein structure and oxide contamination is prevalent throughout the galena-bearing lodes. However, mineralization intersected in the 1988 underground program comprises clean, unoxidized sulphides indicating the limit of surface oxide contamination has been passed in this area of the mine.

Just above the 1735-metre elevation west of section 83740E (mine grid), the main Hallmac zone bifurcates downward into two separate vein lodes termed the Footwall (FW) and Hangingwall (HW) zones, respectively. Exploration to date suggests that the HW zone pinches out at about the 1725-metre elevation east of 83740E; this is conjectural, however, due to lack of drilling data. Though apparently locally offset by sinistral north-northeast striking faults, the main FW zone of the Hallmac system is more or less continuous on strike for at least 250 metres (Assessment Report 18551).

In late 1984, a 1-metre wide section of zinc-silver mineralization was exposed in a crosscut which crossed the FW zone at the east end of the 1690 level. This discovery suggested that the limits of the effects of surface oxidation had been reached (on the 1690 level at least) and that uncontaminated commercial ore might be intersected east to the crosscut exposure (Assessment Report 18551).

Based on a diamond drilling and underground exploration program in 1988, the mineral inventory (indicated/probable/possible reserves) of the Hallmac mine was 11,398 tonnes of ore grading 778.1 grams per tonne silver, 7.75 per cent lead and 2.84 per cent zinc (Assessment Report 18551).

Past production from the Hallmac between 1951 and 1990 yielded about 7754 kilograms of silver, 874,298 kilograms of lead, 172,704 kilograms of zinc, 382 kilograms of cadmium and 703 grams of gold from a minimum of 8041 tonnes mined.

CAPSULE GEOLOGY

The Mercury occurrence consists of two subparallel fissure veins striking 035 degrees and dipping 55 degrees southeast. The veins vary in thickness from a few millimetres to 1.5 metres. The main vein is exposed in the No. 1 adit near the boundary between the Mercury and Redress Fraction No. 2 claims. The vein has been developed on both properties from the same adit. It consists of tetrahedrite, galena, sphalerite, pyrite and chalcopyrite in a gangue of quartz and siderite. Gypsum occurs with limonite in the weathered surface exposures. A second vein is exposed 25 metres north of the No. 1 adit. This vein has been explored with the No. 2 adit on the Mercury Reverted Crown grant and the Mercury No. 3 adit on the Redress Fraction No. 2 property to the northeast.

Production from the Mercury and Redress Fraction No. 2 properties yielded about 1056 kilograms of silver, 70,966 kilograms of lead and 1635 kilograms of zinc from 201 tonnes mined between 1901 and 1980. Although most of the production came from the No. 1 adit on the Mercury property, 4 tonnes were mined from the Mercury No. 3 adit on the Redress Fraction No. 2 property in 1921 to produce 29,548 grams of silver and 2182 kilograms of lead.

Golden Slipper Mines Ltd. held the property in the early 1950s. Yukon Minerals Corporation investigated the property in 1986.

CAPSULE GEOLOGY

The Majestic occurrence is situated on the north slope of Carpenter Creek at 1645 metres elevation above sea level, in the Slocan Mining Division. The property includes underground workings on the Majestic and Unexpected Crown grants (Lots 1405 and 2231 respectively).

The claims were Crown-granted to F.H. Bourne and C. French in 1899. Lessees work the property during the 1904-07 period and again in 1910. The owners did some work in 1912 and 1916. Small shipments of ore were reported in most of the above years and again in 1922. Development work to date included 3 adits, the lowest (No. 3) consisting of about 180 metres of drifting. The vein above No. 3 was locally stoped through No. 2 and No. 1 levels to the surface. In 1929 H.A. Turner optioned the property from Bourne and French for Coast interests. The No. 4 adit was begun and driven to 76 metres at last report.

Hallmac Mines Limited, owner of the adjacent Altoona property (082FNW015) acquired a 3 year lease on the Majestic and Unexpected from A.R. Bourne in 1980. The company name (Hallmac) was changed in February 1986 to Royal Oak Resources Ltd.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six

CAPSULE GEOLOGY

texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The property is underlain by massive to slaty argillite of the Slocan Group. The sedimentary rocks generally strike 115 degrees and dip 35 degrees northeast. The occurrence consists of a fissure vein striking 055 to 075 degrees and dipping 50 degrees southeast. The vein varies from a few centimetres up to a metre in width. An ore shoot was stoped between the No. 1 and No. 3 adits for an updip distance of 18 metres. The ore consisted of massive galena with pyrite and minor sphalerite in a quartz matrix. A total of 300 metres of drifting has been carried out on this fissure vein from at least three separate adits.

A second subparallel vein is exposed some 150 metres northwest and 15 metres below the portal of the No. 3 adit. This vein strikes 075 degrees, dips 62 degrees southeast and includes 10 to 15 centimetres of oxidized vein material carrying little sulphide mineralization.

Production from the Majestic occurrence between 1904 and 1922 yielded 452,425 grams of silver and 148,838 kilograms of lead from 221 tonnes mined.

CAPSULE GEOLOGY

The Sapphire occurrence is situated on the northwest face of Mount Payne at 1980 metres elevation above sea level, in the Slocan Mining Division. The property includes underground workings on the Sapphire, Minneapolis and Gem Crown grants (Lots 1857, 578 and 1858, respectively).

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The property is underlain by quartzite, calcareous quartzite and limestone of the Slocan Group. The sedimentary rocks generally strike 130 degrees and dip 55 degrees southwest. The occurrence consists of a fissure vein striking 050 degrees and dipping steeply southeast. The vein varies from a few centimetres up to 20 centimetres in width and carries argentiferous galena and quartz. The vein is exposed on the southwest portion of the Sapphire Crown grant and on the northeast slope on the Gem Crown grant. It has been explored with several short adits, raises and shafts. A similar, narrow, subparallel fissure vein is exposed about 200 metres southeast on the Minneapolis Crown grant. This vein has been exposed in three short adits, but there is no recorded production.

CAPSULE GEOLOGY

The Ajax occurrence is situated on Crown grant Lot 585, on the north side of Carpenter Creek east of Mount Payne. The property consists of the Ajax Crown grant and the Crown Point and Random Shot Reverted Crown grants (Lots 586 and 1726, respectively).

The claims were worked in the early 1890's until the close of that decade. Since 1900 the property has lain idle and the workings inaccessible. During the first few years the property was controlled by Matthews and Braden, representing the Ontario Gold Fields Mining and Development Company of Toronto.

In 1898 the claims were acquired by The Ajax Mining and Development Company, Limited; they were struck off the Companies Register in 1942.

Most production has come from the "West vein" of the West lode. This vein has been explored by 4 adits which, together with stopes extending for 24.3 metres above the highest adit, give a vertical depth of about 152 metres. The "Main vein" of the West lode was explored by an adit 38.4 metres feet vertically lower than the lowest adit on the "West vein". This adit is a crosscut for about 70 metres to where it meets a strongly sheared zone striking 030, for about 46 metres southwest and 137 metres northeast. On a possible continuation of this lode on the Crown Point claim, an adit 7.6 metres lower than the lowest on the West vein has been driven 20 metres along the lode to its termination in a broad slate belt and another adit, 30.4 metres below was also driven. Work on the East lode comprises 3 short adits aggregating about 122 metres of crosscut and drift.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been

CAPSULE GEOLOGY

regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Ajax occurrence is hosted by quartzite and argillaceous quartzite of the Slocan Group. The sedimentary sequence generally strikes 120 degrees and dips 58 degrees southwest. For the most part, the sedimentary rocks are well bedded and banded. South of the Ajax Crown grant, the quartzite and argillite that host the occurrence are overlain by black slate.

Two veins have been exploited on the Ajax property, an East and West vein. Most of the production came from the West vein which has been explored with at least four adits. The West vein strikes 020 degrees, dips 70 degrees southeast and parallels a prominent set of joint planes in the host rock. It consists mainly of crushed wallrock and small veinlets of galena with tetrahedrite.

The East vein is similar and parallel to the West vein. It is a millimetre to a few centimetres wide fracture that locally carries galena and tetrahedrite. The vein has been explored with at least three short adits.

Production from the Ajax property in 1899 and 1900 yielded 81,303 grams of silver and 10,456 kilograms of lead from 27 tonnes mined. Production from the Treasure Vault in 1898 and 1899 yielded 31 grams of gold, 239,928 grams of silver and 42,490 kilograms of lead from 135 tonnes.

CAPSULE GEOLOGY

The Last Chance occurrence is situated on Crown grant Lot 717 at 2165 metres elevation above sea level, in the Slocan Mining Division. The property is on the north side of Carpenter Creek northeast of Mount Payne.

The Last Chance and American Boy (082FNW081) adjoin and the mine workings are on the same lode system. The principal claims making up the properties were located in 1891 and were among the first to be staked in Slocan.

Development commenced on both properties in the early 1890's and continued at a fairly steady pace until 1908 when activity ceased. Work on the American Boy was carried out by Tom McGuigan and by the American Boy Mining and Milling Company, formed in 1897, later (1918) reorganized and renamed American Boy Mining Company. Work on the Last Chance was carried out by the Last Chance Mining and Milling Company.

In 1920 work recommenced on the Last Chance property and in 1922 on the American Boy. Activity was intermittent and lasted until about 1927. From that time until 1953 nothing was done on either property. In 1951 Cody-Reco Mines Limited bought up several properties in the Slocan area including the American Boy and Last Chance. A new road system was put in connecting the workings with a new mill built at Cody in 1952.

Workings on the main vein lode comprise 11 adits and several intermediate levels aggregating about 4.8 kilometres of drift and crosscut. These workings are connected by raises and explore the

CAPSULE GEOLOGY

lode over a vertical depth of about 350 or 396 metres measured down dip. Most of the work was done on the main lode and only short crosscuts were required in any distance. Certain workings are continuous on the 2 properties and have developed the main lode a length of 823 metres.

In 1953 No. 9 adit of the American Boy was reopened and some drifting done. In 1954 about 106.6 metres of drifting to get around a cave on No. 9 adit level and raises were rehabilitated down to No. 10 and No. 11 levels. In 1960 Cody-Reco Mines Limited was reorganized and its name changed to Vespar Mines Limited.

Reco Silver Mines Limited in October 1968 acquired a lease, renewable every 4 years, on 21 claims in the Last Chance and Noble Five (082NW037) groups. Vespar amalgamated with Lakehead Mines Limited in January 1979 under the name Parlake Resources Limited. In May 1980 Reco Silver Mines changed its name to Silvex Resources Corporation.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slokan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slokan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slokan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Last Chance occurrence is hosted by quartzite, argillaceous quartzite and calcareous argillite of the Slokan Group intruded by various dikes of quartz porphyry probably related to the Nelson intrusions. The sedimentary sequence generally strikes 120 degrees and dips 58 degrees southwest. For the most part, the sedimentary rocks are well bedded and banded. The quartz porphyritic dikes, in general, tend to follow the strike of the sedimentary rocks, and are 3 to 10 metres thick.

The occurrence consists of two or more fissure veins that cut across the sedimentary and intrusive rocks. The veins strike 045 degrees on the American Boy Crown grant and 060 degrees on the Last Chance Crown grant; dips are 60 to 65 degrees southeast. The veins have been explored for about 825 metres along strike and 400 metres down dip on both the American Boy and Last Chance Crown grants. The veins pinch-out to the southwest on the Chicago Crown grant where they cut fissile slate of the Slokan Group. The strike and dip of each fissure varies from point to point so that fissures meet and separate at irregular intervals developing a braided structure varying from a few millimetres to over 6 metres in width. The fissures are mostly filled with crushed wallrock. Argentiferous galena, sphalerite, pyrite, tetrahedrite and pyrargyrite occur with quartz and siderite concentrated in narrow veinlets near the walls of the fissures. The sulphide material is usually less than 10 centimetres wide except where crossfaults cut the fissure veins and pockets of massive sulphide up to 75 centimetres wide are developed. In general, sphalerite increases with depth.

Production from the Last Chance portion of the fissure vein structures between 1895 and 1922 amounts to about 33 tonnes of silver and 3493 tonnes of lead from 8448 tonnes mined.

CAPSULE GEOLOGY

The Surprise deposit consists of two fissure veins, the Main or Surprise vein and the Little vein. The Main vein strikes 065 degrees and dips 65 degrees southeast. It is a well-defined zone varying from a few centimetres up to 5 metres in width. The zone tends to steepen where it crosses massive quartzite or quartz porphyry dikes. The vein consists mainly of crushed wallrock, quartz and siderite. The ore, which consists of massive galena, is mostly hosted by quartzite and the quartz porphyry dikes. Sphalerite is usually restricted to the edges of the massive galena bodies. Galena contains inclusions of tetrahedrite whereas pyrargyrite is reported to occur in veinlets cutting across both galena and sphalerite. Pyrite and chalcopyrite are common accessory minerals. Where the vein crosses more argillaceous sedimentary rocks, the ore is restricted to narrow bands concentrated along the walls of the fissure which is mostly filled with crushed wallrock. The widest ore shoot, which has been stoped for about 130 metres downdip, appears to be associated with a series of pre-mineral shears that strike between 015 and 020 degrees and dip 50 degrees southwest. The Main vein is believed to be an extension of the Last Chance vein (082FNW020) exposed on Lot 717 about one kilometre southeast.

The Little vein is subparallel to the Main vein and about 30 metres to the northwest. The vein is only a few centimetres wide and consists mostly of sphalerite and quartz. Although the Little vein has been explored with a shaft and several adits, no production figures are available for this vein.

Production from the Surprise occurrence between 1893 and 1929 yielded about 59 tonnes of silver, 5606 tonnes of lead, 3537 tonnes of zinc and 124 grams of gold from 44,475 tonnes mined.

CAPSULE GEOLOGY

The Fourth of July occurrence is situated on Crown grant Lot 2052 in the Slocan Mining Division. The property is at 1875 metres elevation above sea level, between Robb and Stenson creeks. The Texas (Lot 4889) (082KSW016) has been intermittently developed in conjunction with the Fourth of July occurrence in the past.

This property comprises the Fourth of July, Texas Cowboy, San Antonio, Minnie, Toronto, Garland Fraction, and Lucky Ed. Crown-granted claims and 4 others held by location.

The Fourth of July claim was one of the first staked in the region and by 1890, 90 metres of tunnelling had been done. In 1898 it was Crown-granted to Columbia Mining Company Limited and an initial shipment of ore made. In 1918 the property was bonded and some 45 tonnes of ore was said to have been mined. In 1926 the workings on both the Texas and Fourth of July groups were examined and sampled by A.G. Langley. Intermittent development work continued on the Texas until 1933.

On the Texas claim the workings consist of a shaft and 3 adits. The shaft was driven southwest in fine-grained granodiorite for 20 metres where it passed into argillite and quartzite and, 6 metres further, into limestone in which it continued to the face 33.5 metres from the portal. From this point a narrow fissure vein has been drifted on 7.6 metres southeast and 50.2 metres northwest. The lower 2 tunnels are caved, but the upper adit is partly open. It starts in limestone in a direction 65 degrees west, but is caved at a raise 30.4 metres from the portal.

In 1959 the property was optioned by Lucky Edd Mines Limited. July Silver Mines Ltd. acquired the property in 1960. Just over three kilometres of road was constructed to complete the road to the Fourth of July and Texas claims. The property can now be reached by 9.6 kilometres of road which leaves the Kaslo-New Denver highway at a

CAPSULE GEOLOGY

point 25.7 kilometres from Kaslo. Operations during 1961 were confined to the Texas vein; No. 2 tunnel was reopened and No. 3 tunnel was extended to pick up the downward extension of the vein from No. 2 tunnel.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

On the Fourth of July property, the sedimentary rocks of the Slocan Group strike northwest and dip steeply southwest. The sedimentary sequence is intruded by a medium grained, biotite granodiorite dike up to 200 metres wide. The occurrence consists of a quartz vein developed within a northwest trending fissure zone which conforms closely to the bedding of the enclosing calcareous argillite. The vein, which consists of white quartz and siderite with bands of pyrite, galena and sphalerite, is less than a metre wide at surface. Ore shoots up to 1.2 metres wide are developed where the vein changes strike slightly and is intersected by crossfaults (Assessment Report 9240). The vein has been explored with a crosscut and some 60 metres of drifting.

Limited production from the occurrence in 1898, 1937 and 1979 yielded 16,174 grams of silver, 2446 kilograms of lead and 503 kilograms of zinc.

CAPSULE GEOLOGY

The Boadicea occurrence is situated on forfeited Crown grant Lot 1961 in the Slocan Mining Division. The property is at 1735 metres elevation above sea level near the headwaters of Robb Creek.

This claim was Crown-granted in 1911. Three adits were driven in a southerly direction near the northeasterly claim line, in a direction parallel with, and within a few metres of the northern edge of the body of granodiorite. The uppermost and lowermost are about 76 metres apart vertically and over 91 metres horizontally. The lowermost adit is about 91 metres long, but the length of the other two is not known. A fourth adit is located about 114 metres west of, and nearly 122 metres below the lowest of the 3 adits referred to. This adit is not accessible, but has been driven under an outcrop oxidized vein matter about 3 metres wide. The relationship of this lode to the easterly lode is not known, but they are probably different lodes.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson

CAPSULE GEOLOGY

intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

On the Boadicea property, the sedimentary rocks of the Slocan Group strike northwest and dip steeply southwest. The sedimentary sequence is intruded by a lenticular, medium grained, biotite granodiorite dike up to 200 metres wide. The dike underlies most of the central part of the Crown grant and the Slocan Group rocks are only exposed near the northern and southern contacts of the dike. The occurrence consists of a breccia zone within a band of limestone, slate and andalusite schist developed near the northern contact of the granodiorite dike. The breccia zone strikes 120 degrees, dips 85 degrees southwest and follows the contact between limestone and andalusite schist. It is 60 to 90 centimetres wide and contains coarse-grained galena, pyrite and minor sphalerite in discontinuous streaks 5 to 10 centimetres wide and disseminated in a gangue of quartz and siderite. The zone has been developed with at least four adits totalling 115 metres.

Limited production in 1937 yielded 12,472 grams of silver and 2407 kilograms of lead from 8 tonnes.

CAPSULE GEOLOGY

The Carbenet No. 2 occurrence is situated on Crown grant Lot 6811 in the Slocan Mining Division. The property is at 1675 metres elevation above sea level near the headwaters of Robb Creek. Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies. South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5). On the Carbenet No. 2 property, the sedimentary rocks of the Slocan Group strike northwest and dip steeply southwest. The sedimentary sequence is intruded by a lenticular, medium grained, biotite granodiorite dike up to 200 metres wide. The dike underlies most of the northern part of the Crown grant; the sedimentary-igneous contact strikes southeast. A 15-centimetre wide shear is developed within the granodiorite near the sedimentary contact. The shear, which strikes 060 degrees

CAPSULE GEOLOGY

The Lucky Boy (Lot 632) is situated on the south slope of Goat Mtn. which is at the head of Jackson (Stenson) Creek, a tributary of Kaslo Creek. It is accessible by road and trail up Jackson Creek from Retallack station.

Work on the claim was begun in 1893 and continued intermittently up to 1910. Thereafter the property lay idle for many years and the workings, including two, perhaps more, adits, became inaccessible. In 1946 the claim was acquired by L. Garland of Retallack and he in turn sold it to Silverite Mines Ltd. later in the year. There is no record of this company having done any work on the property. Leasers did some work on the claim in 1949, however the extent of the underground workings at this time are not known.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The occurrence consists of a quartz vein within well-banded argillite and limestone of the Slocan Group. The vein changes strike from 070 to 030 degrees and back to 070 degrees. Argentiferous galena, sphalerite and oxidized pyrite are developed in the vein where it strikes 030 degrees and follows a series of closely-spaced joints

CAPSULE GEOLOGY

and fractures.

The property has been explored with at least two adits and 18 tonnes of high-grade ore were mined in 1893 but recoveries are unknown. Other small shipments are reported to have been made in 1903 and 1910. Of these one of 1.8 tonnes carried an average of 4285.7 grams per tonne silver and 70 per cent lead (GSC Memoir 184, page 230).

A total of 11,353 grams of silver, 1942 kilograms of lead and 94 kilograms of zinc were recovered from 2 tonnes mined in 1976.

CAPSULE GEOLOGY

The U.S. occurrence is located at 2125 metres elevation above sea level on Crown grant Lot 1055, in the Slocan Mining Division.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

On the U.S. Crown grant, the Slocan Group rocks consist of interbedded pyritic slate and argillite. The strata strike north, dip 55 degrees east and are intruded by mafic and felsic dikes. The occurrence consists of three separate brecciated fissure veins that have been exposed in four adits. The main vein is conformable to bedding, 1 to 5 centimetres wide, and consists of bands of pyrite associated with sparsely disseminated sphalerite. The fissure is marked by several centimetres of gouge and crushed siliceous argillite. A second fissure vein, 200 metres northeast of the main vein, strikes northeast and dips 50 degrees southeast. This vein consists mainly of 10 to 20 centimetres of gouge and crushed argillite carrying disseminated pyrite and veinlets of galena and sphalerite along joints and fractures within the argillite. A third vein, 100 metres south of the main vein, strikes 050 degrees and dips southeast.

CAPSULE GEOLOGY

This vein is at the contact between argillite and a mafic dike. It consists of broken quartz mineralized with disseminated pyrite.

Records indicate that 163 tonnes of ore were mined from the property between 1913 and 1914 to produce 8528 kilograms of zinc (Geological Survey of Canada Memoir 173, page 81).

CAPSULE GEOLOGY

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

On the Almeda Crown grant, the Slocan Group rocks consist of interbedded slate and fractured argillite. The strata strike north, dip 55 degrees east and are intruded by mafic and felsic dikes. The occurrence consists of at least two separate veins. The main Almeda vein strikes 020 degrees and dips 55 degrees southeast. It underlies and partly cuts across a sill-like quartz porphyritic intrusion and is cut off to the south by a northwest-trending fault. The vein has been explored for 45 metres along strike and 55 metres downdip, in at least five adits and a shallow shaft.

Approximately 60 metres west of the main vein, the Old Original Echo vein strikes southeast and dips 45 degrees southwest. This vein consists of a 10-centimetre wide seam of sphalerite, galena, pyrite and siderite within fractured argillite. The vein has been exposed in at least one 120-metre long adit. A short distance east of the shaft, a series of stopes break through to the surface. These are aligned southeast, dip 45 degrees southwest and may represent the faulted extension of the Old Original vein (Geological Survey of Canada Memoir 184).

Production from the Almeda and Old Original Echo veins in 1903 yielded 52,129 grams of silver and 7815 kilograms of lead from 13 tonnes mined.

CAPSULE GEOLOGY

The Bell mine occurrence is located at 1920 metres elevation above sea level on Crown grant Lot 1165, in the Slocan Mining Division. The property has been developed in conjunction with the Sunset-Trade Dollar occurrence (082FNW227).

The principal producing years on the Bell claims were 1916, 1917 and 1918. After 1918 little work was done on any of the claims until the autumn and winter of 1926-27, when lessees shipped over 100 tons from old workings on the Trade Dollar.

Workings on the Bell claim include 3 short adits over a vertical range of 27.4 metres. In 1927 those workings in the vicinity of the productive sections, were mostly inaccessible. Two bodies of nearly pure zinc ore were encountered in the No. 1 adit, but these did not continue far below this level. On No. 2 level a stope 12 metres long extends 4.5 metres above the level. This stoped area contained small lenses and streaks of galena, and in places as much as 0.9 metres of good zinc ore. The same zone continues to No. 3 level, 9 metres below, but at this level mineralization is only narrow streaks of vein matter containing some sphalerite.

On the Bell claim, several hundred tonnes of high-grade zinc ore were recovered from old dumps, and pillar and stope remains in the underground workings during 1943, 1944 and 1945.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been

CAPSULE GEOLOGY

regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Bell Crown grant is underlain by quartzite, calcareous argillite and slate of the Slocan Group. The strata generally strike northwest, dip 43 to 58 degrees southwest and are folded in a northwest-trending syncline. The central portion of the syncline is underlain by quartzite and calcareous argillite which host most of the ore. Beneath the core of the syncline are slate and thinly banded argillite which are cut by numerous felsic porphyritic intrusions. The Bell mine occurrence consists of a vein of nearly pure sphalerite within carbonaceous and calcareous argillite. The main body has an average thickness of 75 centimetres, strikes 110 degrees and dips 65 degrees southwest. It occurs near the lower contact of a porphyritic sill and is cut by numerous faults and fractures which complicate its geometry. Some north-trending fractures appear to be pre-mineral and the vein is thickest where it intersects these fractures, locally attaining up to 3 metres in width. The ore consists of massive sphalerite brecciated and cemented by yellow siderite and cut by veinlets of pyrite with minor galena. The vein has been exploited in three separate adits.

Production from the Bell mine between 1916 and 1944 yielded 158,408 grams of silver, 248 grams of gold, 761,892 kilograms of zinc and 14,594 kilograms of lead from 2189 tonnes mined. A small amount of ore was recovered from the Sunset-Trade Dollar occurrence between 1916 and 1918 and is included with the Bell mine production.

CAPSULE GEOLOGY

The Caroline property consisted of 9 claims and is located on the south side of Gwillim Creek, 9 kilometres northwest of the town of Slocan. An old upgraded wagon road connects the property to the town.

In 1948, Antimony Mines & Metals (Slocan), Limited, purchased the group from J.N. Russell. This company traced the vein for about 762 metres and did some sampling which showed good stibnite values, as well as traces of gold and other metals. It was planned to drive an adit into the vein, but the following year three holes were drilled on the vein exposures revealed no antimony. This company surrendered its charter in 1951.

The showing consists of a quartz vein in the bed of a northerly flowing tributary of Gwillim Creek. The country rock is a granite gneiss. The hillside is quite steep, and the vein is exposed along the creek bed for a vertical height of about 460 metres. The vein ranges in width from 0.6 to 1.5 metres and appears to be nearly vertical. Two lenses of stibnite, up to 7.6 centimetres in width, occur in the vein.

CAPSULE GEOLOGY

(Paper 1989-5).

The Green Horn and Home Rule Reverted Crown grants are underlain by quartzite, calcareous argillite and slate of the Slocan Group. The strata are folded in a northwest-trending syncline with limbs dipping at low angles to the north and south. The occurrence consists of two or more well-defined fissure veins striking 080 degrees and dipping steeply to the south. The main vein is 25 centimetres wide and consists mostly of fragments of galena enclosed in quartz which cements blocks of wallrock. Small pockets of more massive galena also occur along the vein. Siderite, pyrite and chalcopyrite occur in minor amounts with the galena. The vein has been explored in at least two adits on the Home Rule claim and several trenches on the Green Horn property.

Production in 1915 and again in 1965 yielded 10,544 grams of silver, 31 grams of gold, 2329 kilograms of lead and 1076 kilograms of zinc from a total of 14 tonnes mined.

CAPSULE GEOLOGY

The Oro occurrence is located on Crown grant Lot 2434 at 1448 metres elevation above sea level, in the Slocan Mining Division. The claim is on the north side of Carpenter Creek, just east of Cody Creek.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Oro property is underlain by argillite of the Slocan Group and a large quartz porphyritic dike probably related to the Nelson intrusions. An adit has been driven on a northwest-trending shear that dips 55 degrees southwest. The shear varies from a few centimetres up to 0.6 metre in width. It is filled with crushed rock, gouge and quartz which is sparingly mineralized with sulphide minerals (probably galena and sphalerite).

In 1927, seven tonnes of ore were mined from the adit to produce 7278 grams of silver, 527 kilograms of lead and 113 kilograms of zinc.

CAPSULE GEOLOGY

The Chambers occurrence is located on Crown grant Lot 1752 at 1555 metres elevation above sea level, in the Slocan Mining Division. The claim is on the north side of Carpenter Creek, just east of Cody Creek. The property consisted of the Chambers (Lot 1752), Wellington (Lot 1755), Eureka and Jay Gould Crown (Lot 1754) grants located in 1891.

The workings include 5 adits at elevations that range from 1280 to 1560 metres. In 1951, a small crew of men reopened the workings; the property was owned at that time by J.M. Harris.

Reco Silver Mines Limited, incorporated June 1964, optioned the Chambers (Lot 1752) and adjacent claims from Mrs. Harris. Geochemical surveys were carried out in 1965 and 1968. The Chambers 4785 level adit, which had been driven about 37 metres in the 1890's, was advanced 46 metres in 1969; diamond drilling totalling 150 metres was done at that time. Rayrock Mines Limited obtained a working agreement with Reco Silver in March 1973. Silvex Resources Corporation held the property in 1980 and, in 1981, constructed a raise into a massive zinc horizon. Knie Resources Inc. optioned the property from Silvex Resources in 1983 and produced in 1984.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar

CAPSULE GEOLOGY

porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Chambers property is underlain by massive to slaty argillite of the Slocan Group and several small quartz porphyritic dikes probably related to the Nelson intrusions. At least four adits have been driven on a fissure vein that generally strikes northeast and dips 50 to 80 degrees south. The vein is within a 1.5 to 3 metres wide shear zone which is partly filled with quartz and crushed wallrock. Small ore shoots carrying argentiferous galena with minor sphalerite and pyrite are developed along the vein structure which has been followed for about 340 metres of strike length.

Production from the Chambers vein between 1896 and 1984 yielded 490,392 grams of silver, 236,055 kilograms of zinc, 96,425 kilograms of lead, 1611 kilograms of cadmium and 155 grams of gold from 2321 tonnes mined.

CAPSULE GEOLOGY

The Grey Copper property is situated at 1830 metres elevation above sea level on the north slope of Carpenter Creek, on Reverted Crown grant Lot 580, in the Slocan Mining Division.

Development commenced in 1891 on the Grey Copper (Lot 580), Goodenough - Reucau (Lot 581, Lot 624) and Idaho No. 2 (Lot 1013) veins. The Grey Copper claim, staked in 1891, was owned in 1893 by Jack Thompson, Ed. Becker, and C. Rent; the claim was Crown-granted in 1896 to J.A. Whittier. Ore was reported shipped by Mr. Whittier in 1917, and by lessee Joe Miciewicz in 1931-33. The claim was owned in the 1930's by W.V. Papworth, R.S. Lennie, and S.J. Towgood, of Kaslo. The workings to that period comprised 5 adits; the upper four are closely spaced within a vertical range of only 30.4 metres.

Although the Purcell (Lot 849) and the Idaho No. 2 were staked in 1892, there is little record of development on the Idaho No. 2 prior to 1928. Following 1928 some drifting was done on the zinc-rich Idaho No. 2 Vein system but low metal prices resulted in a suspension of operations in 1931. Work began again on the Idaho No. 2 in 1951 but was redirected to the Grey Copper No. 3 Level in 1953.

Bluebird Slocan Mines Limited held the claim in 1953. No. 3 adit, which had been driven for 198 metres in a northeasterly direction, was extended an additional 45.7 metres before work ceased in April 1953.

Silver Mountain Mines Ltd. held the Grey Copper and adjacent claims from about 1958. Reco Silver Mines Limited in November 1966 acquired from Silver Mountain Mines a 50 per cent interest in a mineral lease covering nine Crown-grants including the Grey Copper and Goodenough (082FNW035). The lease was subsequently abandoned and the Silver Mountain Mines charter was surrendered in 1977.

In 1975, George Sipos acquired control of the Goodenough, Grey Copper, Purcell, Idaho No. 2, Rawdon, Bluebird (082FNW034) and Stranger reverted Crown-granted claims as the Bluebird Group. The Grey Copper No. 5A Level was worked in 1978. Some ore was shipped from the Grey Copper claim in 1978-79. In 1979 Sipos incorporated Sipald Resources Ltd. and acquired control of the present Purcell property. Sipald Resources did considerable rehabilitation work and reported modest production in 1980 from the Grey Copper No. 3 Level. In 1981, work included surface mapping, trenching, examination of mine dumps at the Goodenough No. 6 and No. 8 Levels, and the Idaho No. 2 dump; the Purcell adit was reopened and a diamond drill hole was directed northward towards the vein below the Big Stope on the Grey Copper No. 3 Level. In 1983, work was done on the road to the Purcell adit and the Idaho No. 2 was rehabilitated. Sipald Resources leased the Goodenough mine dumps to Modern Metal Recovery Systems Ltd., in 1983. Wavecrest Resources Ltd., optioned the property later in 1983 and Knie Resources Inc., optioned the property in 1984. Sipald Resources Ltd. was reorganized and renamed Rawson Resources Ltd. in 1986; they carried out a program of geochemical soil sampling during 1987. In 1988, Advanced Ecology Group (later the Consolidated Advanced Ecology Corp.) acquired the property and optioned it to General Tunnel Co. Ltd. in 1989. The property was sold to Avril Explorations Inc. in 1990; they conducted geochemical sampling, trenching, drilling and mapping.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse

CAPSULE GEOLOGY

grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Grey Copper Reverted Crown grant is mostly underlain by a large northwest trending quartz porphyritic dike related to the Nelson intrusions. Argillite and slate of the Slocan Group are exposed on the northern part of the Grey Copper claim and in the northeast part of the Purcell Reverted Crown grant (Lot 849).

Two veins are exposed on the Grey copper claim, the Grey Copper vein and the East vein. The Grey Copper vein occupies a shear plane with an average strike of 059 degrees and dip of 80 degrees southeast. The vein has been followed with underground workings the entire length of the Grey Copper claim and onto the Purcell claim. It has an average width of 20 centimetres but can locally be as wide as 40 centimetres. It comprises quartz, siderite, iron oxides and pyrite with residual galena and sphalerite. During 1990, 11 channel samples were taken from the Grey Copper vein in the No. 3 drift; these averaged 990 grams per tonne silver, 13.35 per cent lead and 29.24 per cent zinc (Tulley, D.W. (1991): Geological Evaluation Report on the Purcell Property).

The Grey Copper vein is estimated to contain 8145 tonnes grading 1131.43 grams per tonne silver, 18.8 per cent lead and 42.6 per cent zinc above and below the No. 3 drift, and 19,700 tonnes grading 226.34 grams per tonne silver, 0.06 per cent lead and 41.21 per cent zinc between the No. 5 and No. 3 drifts (Tulley, D.W. (1991): Geological Evaluation Report on the Purcell Property).

The East vein is a narrow, high-grade vein exposed 75 metres south of the Grey Copper No. 3 portal. The vein has been followed from the northeast corner of the Grey Copper claim onto the Idaho No. 2 Reverted Crown grant (Lot 1013). It is 1 to 6 centimetres thick and consists of argentiferous galena carrying as much as 5000 grams per tonne silver (Tulley, D.W. (1991): Geological Evaluation Report on the Purcell Property). The vein has been exposed in several adits and surface trenches.

Production from the Grey Copper veins between 1917 and 1983 yielded 143,144 grams of silver, 7854 kilograms of lead, 25,230 kilograms of zinc, 114 kilograms of cadmium and 31 grams of gold from a total of 772 tonnes mined.

CAPSULE GEOLOGY

branch drift, at 122 metres from the portal, was driven northwest for about 24 metres, 15 metres of which followed a lode 0.6 to 0.9 metres wide mineralized with sphalerite. At 183 metres from the portal a crosscut was driven 6 metres northwest to intersect a lode also containing sphalerite.

The Blue Bird and adjacent claims, owned by Mrs. J.M. Harris, of Sandon, were optioned to Reco Silver Mines Limited in about 1965. Geochemical surveys were carried out in 1965, 1968, and 1969. Rayrock Mines Limited obtained a working agreement with Reco Silver in 1973.

In 1975, George Sipos acquired control of the Goodenough (082FNW035), Grey Copper (082FNW033), Purcell, Idaho No. 2, Rawdon, Bluebird and Stranger claims as the Bluebird Group.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

Rocks on the Blue Bird property include a band of slate and thinly banded argillite of the Slocan Group which are surrounded on either side by quartzite and more massive argillaceous beds. Several narrow limestone beds are also present throughout the section. The strata generally strike between 125 and 155 degrees and dip 40 to 45 degrees southwest.

Three northeast striking fissure veins have been exploited on the Blue Bird claim. These are from north to south, the West vein, the Big or Idaho vein and the Little vein. All veins strike between 055 and 070 degrees and dip 60 to 65 degrees southeast.

The West vein is 45 to 60 centimetres wide and has been traced for about 60 metres along strike by a series of short adits and trenches. It consists of sphalerite with some galena and pyrite in a gangue of quartz and siderite. The Big or Idaho vein is 30 metres southeast of the West vein. It is a brecciated zone cemented by quartz in which little mineralization is present. The Little vein strikes 070 degrees and dips 60 to 65 degrees southeast and appears to join the Big vein near the portal of the No. 2 adit. Most of the production from the Blue Bird property probably came from this vein. It varies from 0.3 to 1.5 metres in width and contains bands of massive argentiferous galena with sphalerite up to 30 centimetres wide. Siderite, quartz and calcite cement blocks of crushed wallrock. The vein is intersected by two faults, one striking 147 degrees and the other due north; both faults dip 60 degrees east. The more westerly fault has offset the vein 6 metres to the north. Displacement of the other fault is unknown.

The Blue Bird veins may correlate with the veins on the Grey Copper (Lot 580) occurrence (082FNW033), 600 metres southeast.

Production from the Blue Bird vein system between 1892 and 1982 yielded 3,728,341 grams of silver, 574,181 kilograms of lead and 898 kilograms of zinc from 898 tonnes mined. This included 54 tonnes mined in 1898 but recoveries are unknown (Geological Survey of Canada Memoir 173).

CAPSULE GEOLOGY

The Reco occurrence is situated at 2043 metres elevation above sea level on the north slope of Carpenter Creek, on Crown grant Lot 624, in the Slocan Mining Division. The occurrence consists of two main vein systems. The southern vein extends from the Reucan Crown grant (Lot 624) through the Goodenough (Lot 581), and the northern vein extends from the Reucan Crown grant on to the Texas Crown grant (Lot 589).

The Reco No. 2 lode strikes northeasterly through the Texas, Ephraim Fraction, Ruecau, and New Denver claims. The Ruecau, early in its history, became known as the Reco for convenience. The history of the property dates from the location of the Texas claim in June 1892. Development work on No. 2 lode began at that time and ore shipments began in 1894. The owners, J.M. Harris and F.T. Kelly, incorporated The Reco Mining and Milling Company, Limited Liability, in 1896. The Ruecau (Lot 624), New Denver (Lot 612), and Texas (Lot 589) claims were Crown-granted to the company in 1896; the Ephraim Fraction (Lot 600) was Crown-granted to the company in 1897. The Omega claim (Lot 618), on the southerly extension of the lode, was Crown-granted to the company in 1900. Production from No. 2 lode covered the periods 1894-1896, 1904-1913, and 1915-1918. The lode was developed from 4 adits over a vertical range of more than 106 metres. The main workings are Nos. 1, 3, and 5 adits, along which an aggregate of almost 1524 metres of work has been done. No. 5, the longest adit, is about 366 metres long. These levels are connected

CAPSULE GEOLOGY

by raises and stopes. Three adits, Nos. 9, 11, and 15 on the Texas claim, and No. 19 adit, started on the Omega claim but passing into Texas ground, were driven to explore the downward continuation of No. 2 lode. These adits are 69.4, 96.9, 163, and 245.6 metres respectively below No. 5 adit.

Production began from No. 1 lode in 1900. The lode was explored on both sides of the Texas-Deadman boundary; most of the workings, however, lie within the Texas claim. The workings include Nos. 1, 2, and 3 adits, and an intermediate level above No. 3, over a vertical range of 30.4 metres. Only about a metre of work has been done on this lode.

Silver Mountain Mines Ltd. held an option on 26 Crown-granted claims during 1958-1960. Work was apparently confined to claims adjacent to those mentioned above.

Reco Silver Mines Limited, incorporated in June 1964, acquired an option to purchase the property from Mrs. A.L. Parris and Reco Mining and Milling. A geochemical survey in the fall of 1964 was conducted over the general area of the No. 2 and 3 lodes, and the area to the northwest. Detailed geological mapping of surface and accessible underground workings was done in 1965.

The Reco No. 3 lode (Reco-Goodenough lode) strikes northeasterly through the Goodenough, and Reco claims; its southwesterly extension, Reco No. 4 zone, occurs on the Slocan Sovereign (082FNW036) and Number One (082FNW203) claims. The No. 3 lode was developed initially under a joint venture between The Goodenough Mines, Limited Liability, and The Reco Mining and Milling Company, Limited Liability. A series of crosscut adits were run in on Goodenough ground to intersect the lode at the Reco-Goodenough boundary. From these crosscuts the respective companies run drifts on their own portions of the lode.

No. 3 lode was in production from 1895 to 1903, inclusive; further production was reported in 1909, 1913, and 1915-1919. Further development work was done in the 1920's, and a few tons of ore were shipped in 1935. The Goodenough claim (Lot 581) was owned and under development by J.A. Whittier, J. Thompson, and J. Martin from 1895. The claim was Crown-granted in 1896. The owners incorporated The Goodenough Mines, Limited Liability, in March 1897. Operations continued into 1907. The company charter was surrendered in 1923.

The Purcell Fraction claim (Lot 849), adjoining the Goodenough on the east, was Crown-granted in 1897 to Purcell Mining Corporation, Limited, of Spokane, Washington; no work was reported.

The Reco-Goodenough lode was explored by Nos. A, 2, 4, 6, and 8 adits and by No. 7 intermediate level over a vertical range of 161.2 metres. Altogether about 1524 metres of drifts and crosscuts were run. All levels were connected by raises and stopes. Most of the development work was done on the Ruecau claim, across which the longest or No. 4 adit extends for almost its entire length of 304.8 metres.

Silver Mountain Mines Ltd. held the property from about 1958; work was confined to a narrow quartz vein at the 1615.4 metre level.

Reco Silver Mines Limited acquired a number of adjacent claims in 1964 and carried out a geochemical survey in the vicinity of the Goodenough claim. By an agreement of November 1966 the company acquired from Silver Mountain Mines a 50 per cent interest in a mineral lease covering nine Crown-grants, the Goodenough, Grey Copper (082FNW033), Idaho No. 2, Bluebird (082FNW034), Rawdon, Stranger, Purcell, Dunedin, and Egalite. Some work was reported on the Purcell vein in 1971. The lease was subsequently abandoned and the Silver Mountain Mines charter was surrendered in 1977.

G. Sipos and associates incorporated Sipald Resources Ltd. in June 1979 to acquire five reverted Crown-grants, the Goodenough, Purcell, Rawdon, Grey Copper, and Idaho No. 2. An adit on the Idaho No. 2 was re-opened in 1980 and crosscutting and drifting carried out on several parallel veins. In 1981 work on the Idaho No. 2 and Purcell claims included an electromagnetic survey, trenching, sampling of vein and dump material.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by

CAPSULE GEOLOGY

the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The claims are underlain by calcareous sandstone, quartzite, argillite and a few narrow limestone beds of the Slocan Group. The major structure is a northwest-trending anticline with limbs dipping about 45 degrees northeast and southwest. Two large northwest trending quartz porphyritic dikes cut the sedimentary sequence in the southeast portions of the Reucan and Texas Crown grants.

At least four subparallel veins are known but most of the past production came from the No. 2 and No. 3 veins. The Reco No. 2 or northern vein cuts across the northwest end of the Reucan Crown grant, extends on to the Texas Crown grant and may correlate with the Slocan Sovereign vein on Lot 1927 (082FNW036), one kilometre southwest. The vein strikes 050 degrees and dips 65 to 70 degrees southeast. It has been exploited in at least four separate adits for a vertical distance of 100 metres. The vein, in the underground workings, had an average width of 75 centimetres but narrowed considerably where it crossed the porphyritic dikes. Galena, sphalerite and pyrite with siderite and quartz occurred in bands rarely exceeding 45 centimetres in width, but in one place was 2.4 metres thick. Crushed rock and gouge filled the remainder of the fissure vein.

The Reco No. 3-Goodenough or southern vein extends from the southern part of the Reucan Crown grant, through the northwestern part of the Goodenough Crown grant and may correlate with the vein on the Number One Crown grant Lot 4560 (082FNW203), one kilometre southwest. The Reco No. 3-Goodenough vein is 225 metres south of the No. 2 vein. It is a 15 to 20 centimetre wide fissure vein that includes a 6 centimetre wide band of massive sulphide. Ore minerals include galena, sphalerite, tetrahedrite, pyrargyrite, argentite and native silver. Pyrite with quartz and calcite are also present. The vein has been exposed in at least 5 adits.

Production from the two main veins between 1893 and 1966 yielded about 36 tonnes of silver, 2858 tonnes of lead, 168 tonnes of zinc, 604 kilograms of cadmium and 62 grams of gold from 7089 tonnes mined. Production records for the Reco No. 3-Goodenough vein were separated from the No. 2 vein in the late 1800s but exact production figures are not available for each year of production during that period. From the 4206 tonnes mined between 1895 and 1905, 393 tonnes are believed to have been mined from the Reco No. 3-Goodenough vein (Minister of Mines Annual Report Index 3, page 198). Although most of the production from the Deadman claim is included with the Noble Five property (082FNW037), some 81 tonnes of lead concentrate recovered from the Deadman Crown grant (Lot 618) in 1965 was included with the Reco production records.

CAPSULE GEOLOGY

was done in the Slocan Sovereign adits in 1951; ore from the dumps was milled at the company's 175 ton per day mill which was built at Cody in 1952. In 1954 some exploratory drifting and crosscutting was done. The company name was changed in 1960 to Vespar Mines Limited. Lessees worked the property in 1965 and 1966.

The Slocan Sovereign claim, owned in 1968 by Wayne Turley, of Kaslo, was sold late in the year to Liberty Mines Ltd. Diamond drilling was done in 2 short holes to test the continuity of the lode. Some stoping was done. A small test mill was installed, but not operated, on the Mollie claim by Cody Milling & Smelting Ltd.; through a lawsuit in 1970 the company was forbidden further use of the Mollie claim. Liberty Mines Ltd. was dissolved in 1972.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Crown grant is underlain by argillite of the Slocan Group and felsic to mafic dikes related to the Nelson intrusions. The felsic dikes are conformable to bedding and sill-like in nature while the mafic dikes appear to be parallel to the mineralized veins. The mafic dikes are 0.3 to 15 metres wide and in places cut the felsic dikes. The southwestern portion of the claim is mostly underlain by black slate.

Two veins are exposed on the Slocan Sovereign Crown grant. Both veins strike 040 degrees and dip 50 to 55 degrees southeast. The northern vein may correlate with the Reco No. 2 vein on the Reco property and the southern vein may correlate with the Reco No.3-Goodenough vein, also on the Reco property (082FNW035), one kilometre northeast.

The northern vein is within a fissure zone that varies from a few centimetres up to one metre in width. Galena, sphalerite and pyrite are usually concentrated in narrow bands, less than 10 centimetres wide, along the vein walls. The bands of massive sulphides are separated by crushed wallrock cemented by quartz, siderite and calcite. Crossfractures cutting the vein at high angles seem to have played a role in localizing the ore and a number of postmineral faults have caused small displacement of the vein.

The southern vein is exposed near the southern claim boundary with the Number One Crown grant (Lot 4560) (082FNW203). The vein extends to the south on the Number One Crown grant and was mostly worked from that claim. For description and production figures see Number One occurrence.

Production from the Slocan Sovereign property between 1898 and 1968 yielded about 3 tonnes of silver, 708 tonnes of lead, 140 tonnes of zinc, 47 kilograms of copper and 124 grams of gold from 4539 tonnes mined.

CAPSULE GEOLOGY

The Noble Five occurrence is situated on Crown grant Lot 467 at 1630 metres elevation above sea level, in the Slocan Mining Division. The property is on the north side of Carpenter Creek southeast of Mount Payne.

The original claims covering part of the property were located in 1891, covering 1500 metres along the strike of the Noble Five lode. Later 2 adjoining claims were staked along the Deadman lode. Operations in the early years were conducted by the Noble Five Consolidated Mining and Milling Company. In 1905 the property was acquired by the Hon. James Dunsuir who formed the Noble Five Mining and Milling Company. The mine remained inactive until 1927 when a lease was obtained by Paul Lincoln. In 1928 Noble Five Mines Limited was incorporated and work resumed until 1930. From that time until 1940, except for a brief period, the property remained dormant. In 1942 Reco Mountain Base Metals Mines, a consolidation of the Noble Five and Surprise Mining companies acquired the claims; the mill, power plant, office, and warehouse were destroyed by fire. Between 1944 and 1950 the property was worked by leasees. In 1950 C.F. Johnston obtained control of both the Noble Five and Deadman groups. Buildings were rehabilitated and underground exploration carried out. The following year the property was purchased by Cody-Reco Mines Limited who carried on an extensive development program until 1957.

In 1960, Cody-Reco Mines Limited was reorganized and its name changed to Vespar Mines Limited. Reco Silver Mines Limited acquired the Noble Five (Lot 467) and adjacent claims (Last Chance (082FNW020) and American Boy (082FNW181)) from Vespar Mines Limited by a lease agreement of October 1968; the lease expired in 1976. Rayrock Mines Limited obtained a working agreement on the Reco Silver properties in March 1973. Silvex Resources Corporation held the property in 1980 and opened the main 4000-foot access on No. 18 level. In 1981 they rehabilitated the mine and diamond drilled about 1500 metres. Knie Resources Inc. optioned the property from Silvex Resources in 1983.

CAPSULE GEOLOGY

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slovan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slovan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east-plunging, southeast-inclined axial planes and younger folds are open, southwest-plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slovan Group has been intruded by the Middle Jurassic Nelson Intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium-feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson Intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Noble Five occurrence is hosted by argillite, quartzite and limestone of the Slovan Group intruded by various dikes of quartz porphyry and small, dark green, mafic dikes probably related to the Nelson intrusions. The sedimentary sequence generally strikes 040 degrees and dips 57 degrees southwest.

Two veins have been exploited on the Noble Five claim; the Noble Five and the Deadman. The Noble Five vein has been developed by eleven adits, Nos. 1 to 8, A and C and 18. Adit No. 18 is about 300 metres below adit No. 8. A raise with sublevels developed every 60 metres connects adits 8 and 18. The underground workings are connected to the American Boy (082FNW181) and the Last Chance (082FNW020) workings.

Within the underground workings, the Noble Five vein strikes 055 degrees and dips 55 to 70 degrees southeast down to the No. 8 adit. It is regular and varies in thickness from a few centimetres up to 3 metres. Below the No. 8 adit, the vein is complicated by fracturing and faulting and in the No. 18 adit three separate veins are recognized. The vein also appears to pinch out at its northeast extremity.

The vein contains mainly galena, sphalerite and pyrite in a gangue of quartz and siderite commonly with some brecciated hostrocks. The vein is vertically zoned, with galena being more abundant towards the upper levels and sphalerite being more abundant in the lower levels of the mine.

The Deadman vein is exposed on the Deadman Crown grant Lot 613, about 100 metres southeast of the Noble Five workings. The vein has been exposed in at least four short adits. The vein is subparallel to the Noble Five and ranges from a mere crack up to 1.5 metres. It consists of crushed rock cemented with quartz and siderite and bands of galena and sphalerite up to 30 centimetres wide. Some 81 tonnes of ore were mined from the Deadman vein in 1965 and credited to the Reco property (082FNW035).

Production from the Noble Five between 1893 and 1982 yielded about 15 tonnes of silver, 2173 tonnes of lead, 1588 tonnes of zinc, 1961 kilograms of cadmium and 279 grams of gold from a minimum of 40,134 tonnes mined. The production figures are incomplete and include some ore mined from the Deadman vein. Production data for 1982 is from the Wild Goose, which for lack of evidence has been attached to this occurrence.

CAPSULE GEOLOGY

The Madison-Argenta occurrence consists of two fissure veins some 120 metres apart located on Reverted Crown grant Lots 1411 and 1412 at 1525 metres elevation, on the south slope of Mount Payne, about 0.8 kilometre northeast of Sandon and some 11 kilometres east-southeast of New Denver.

The Madison claim (Lot 1411) was Crown-granted to W.C. Price in 1897. The Argenta claim (Lot 1412) was Crown-granted that same year to P.A. Hanneberg and W.C. Price. The Great Eastern claim (Lot 2289) was Crown-granted to Joseph Eaton in 1898. The Legal Tender claim (Lot 1749) was Crown-granted in 1900 to Messrs. Freeman, Toms, and Wilson. The Madison Extension claim (Lot 5192) was Crown-granted to A. Simons in 1916; this claim was subsequently restaked in part as the Argenta Nos. 1 and 2 claims.

During the initial period of activity each of the veins was opened up by three adits. Development work to the end of 1899 was reported to total 233 metres of tunnel, 29 metres of raising, and 15.8 metres of winze.

The claims were reported to have been held by Slocan Sovereign

CAPSULE GEOLOGY

lines Company, Limited, in the 1920's but no work was reported at that time.

Black Cricket Mines Limited in July 1968 optioned 8 claims from Lorenzo Blondeau, of New Denver, including the four original Crown-grants which comprise Mineral Lease 204.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The claims are predominantly underlain by shale, argillite and graphitic phyllite of the Slocan Group. Several small quartz and feldspar porphyritic dikes cut the sedimentary sequence. Two distinct fault systems are evident on the property. These strike approximately north-northeast and dip nearly vertical.

Mineralization on the property consists of two quartz veins carrying galena and sphalerite. The veins follow fracture zones striking 035 degrees and dipping nearly vertical. Each vein has been explored with three small adits. The Southern or Madison vein is one metre wide at the surface near one of the adits' portal. A grab sample collected from the vein assayed 1.31 per cent zinc, 387 grams per tonne silver and 12 grams per tonne gold (Property File - Report on Madison Claims, Prospectus, Module Resources Inc.). Both veins are exposed near the northwest corner of the Argenta Reverted Crown grant (Lot 1412) and have been traced northeast on to the southwestern part of the Madison Reverted Crown grant (Lot 1411).

Production records are incomplete for the property but 41 tonnes were mined from the Northern or Argenta vein in 1900 to produce 124,941 grams of silver and 3616 kilograms of lead. An additional 18 tonnes were mined in 1898 and 2.7 tonnes were shipped to the Trail smelter in 1911 but recoveries are not known.

CAPSULE GEOLOGY

The Argo showing is located on the Belt Reverted Crown grant (Lot 2139) just north of Sandon, at 1310 metres elevation above sea level in the Slocan Mining Division.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The occurrence is hosted within argillaceous quartzite of the Slocan Group which are cut by three small quartz porphyritic dikes probably related to the Nelson intrusions. The sedimentary rocks strike 125 degrees and dip southwest. The occurrence consists of a quartz vein within a fissure zone that strikes 065 degrees and dips 45 degrees southeast. The vein is 30 to 60 centimetres wide at surface and mostly composed of crushed rock and quartz with minor galena and sphalerite. It has been explored with three short adits but all failed to identify significant mineralization.

CAPSULE GEOLOGY

The Victoria occurrence is situated on the Victoria No. 6 Reverted Crown grant (Lot 3154) at 1265 metres elevation, about 800 metres north of Sandon. The property also includes the Galt Reverted Crown grant (Lot 5194).

The claims were granted in 1903 and 1902 respectively but nothing is known of early work on the claims. Between 1917 and 1925 John Worgan, then owner of the property, carried out intermittent development and mined a small amount of ore. In 1925 the Sandon Silver-Lead Mining Company, Limited, acquired the claims but did only a small amount of development work.

Workings include 3 adits over a vertical range of 47.2 metres. The uppermost is about 64 metres long and is driven in blocky granite porphyry and black argillites along a mineralized fault fissure striking about north 35 degrees east and dipping from 70 degrees southeast to vertical. No. 2 adit, 29 metres below No. 1, has been driven for 12 metres along a mineralized fault separating argillites and quartz porphyry. The fissure strikes N 30 degrees E, and dips 60 degrees to the southeast. No. 3 adit, 18 metres below No. 2, is 97 metres long. For the first 48.7 metres it follows a mineralized fault fissure striking about north 45 degrees east and dipping 45 degrees to 75 degrees southeast. At 49 metres from the portal the adit meets a cross fault striking north 50 degrees west. From this point the adit was continued as a crosscut for 12.8 metres to where it meets the hanging wall of a quartz porphyry dyke; it follows this for a about a metre to where another fault striking north 25 degrees west was encountered. The adit follows this fault to the face, but no significant mineralization was encountered.

CAPSULE GEOLOGY

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slokan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slokan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slokan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The property is underlain by banded, grey quartzite and black argillite of the Slokan Group. The sedimentary rocks strike northwest and form part of an anticline with limbs dipping 40 to 45 degrees southwest. The rocks are cut by quartz porphyritic and medium grained granite dikes and sills.

Three adits were driven over a vertical range of 50 metres. The adits explore a fissure vein developed at the contact between the Slokan sedimentary rocks and a quartz porphyritic sill. The vein strikes 035 degrees and dips 70 to 80 degrees southeast. The fissure vein varies from a few centimetres up to 90 centimetres in width. It is mostly filled with crushed rock and gouge. Galena, sphalerite and pyrite occur with quartz in small pockets and narrow shoots along the vein. The largest ore shoot, in the upper adit, was 3 metres long and 2.5 metres high.

Production between 1917 and 1918 yielded 4448 grams of silver and 1207 kilograms of lead from 3 tonnes mined.

CAPSULE GEOLOGY

The Daniel occurrence is situated on the north side of Carpenter Creek, approximately 1.5 kilometres northwest of Sandon, in the Slocan Mining Division. The underground workings are at 1158 metres elevation above sea level.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The property is underlain by banded, grey quartzite and black argillite of the Slocan Group. The sedimentary rocks strike northwest and form part of an anticline with limbs dipping 40 to 45 degrees southwest. The rocks are cut by quartz porphyritic dikes and sills.

The occurrence includes three adits totalling about 300 metres of tunnelling. The adits follow a fissure vein lying at the contact between argillite and a large porphyritic granite dike. The dike strikes northwest and dips steeply southwest. Within the underground workings the fissure vein consisted mainly of quartz which locally

CAPSULE GEOLOGY

contains appreciable amounts of galena, sphalerite and pyrite. The vein, which was in part hosted by the porphyritic dike, pinched out against a fault zone and was not located beyond the fault.

A total of 16 tonnes were mined from the adits in 1917 to produce 4914 grams of silver and 6290 kilograms of zinc.

Yukon Minerals Corporation investigated the property in 1986.

CAPSULE GEOLOGY

The Elkhorn occurrence is situated west of Miller Creek on Crown Grant Lot 859 at 1143 metres elevation above sea level, in the Slocan Mining Division.

The Elkhorn claim in 1952 was held under lease from the Crown, by Neil Tattrie, New Denver. The workings are all caved, and the early history is incomplete. First recorded work was in 1895, when a shaft was sunk to a depth of 14 metres, and a tunnel driven 88 metres. In 1907 the property was worked by George Gormley and associates who owned the claim for many years.

Workings, according to Cairnes (1935), consist of 5 adits in addition to a shallow shaft. These adits are referred to by Cairnes, from uppermost to lowest, as Nos. A, B, 1, 2, and 3 respectively. The adits are spaced over a vertical distance of over 61 metres and altogether include about 610 metres of lineal work. Most of the work was done on adits Nos. 2 and 3. In No. 2 adit a strong shear zone was followed for over 61 metres and raises and stopes connect with surface workings 21.3 metres above. The lowest, or No. 3 adit, is a crosscut for about 140 metres to where it is reported to have intersected a fissure, perhaps corresponding to one of the mineralized cross-fissures encountered in the upper workings. The fissure at this depth carries abundant pyrite and considerable sphalerite. In the upper levels the principal ore mineral was galena. The workings in the other 3 adits are not described by either Cairnes (1935) or Hedley (1952).

In 1950 the Elkhorn claim was held under option by Kootenay Belle Gold Mines Limited. During this time the portal of No. 3 adit was reopened and the adit retimbered for about 15 metres before work was abandoned. Some 2750 tonnes from No. 2 dump were trucked to the Whitewater mill at Retallack in 1951, but all work ceased in September, when it was found that excessive soluble silica made the zinc concentrate unacceptable at the Trail smelter.

MINFILE NUMBER: **082FNW042**

CAPSULE GEOLOGY

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Elkhorn occurrence consists of a fissure vein hosted by argillite cut by a large sill of quartz porphyry. The strata generally strike north and dip 40 to 60 degrees east. The vein strikes 125 degrees, dips 75 degrees southwest and has been explored with at least five adits and a vertical shaft. Within the workings the vein averaged about 60 centimetres and was continuous for about 60 metres. The productive parts of the shear are at points where it is intersected by mineralized crossfissures striking 065 degrees and dipping 40 to 70 degrees southeast. The vein is vertically zoned. In the upper levels it consists mainly of galena with minor sphalerite, pyrite and chalcopyrite while in the lower level it contains abundant sphalerite and pyrite with lesser chalcopyrite in a gangue of siderite. Galena is argentiferous and gold appears associated with pyrite.

Production from the Elkhorn between 1907 and 1951 yielded 209,883 grams of silver, 55,441 kilograms of lead, 45,032 kilograms of zinc and 93 grams of gold from 2900 tonnes mined. See also New Springfield (082FNW199).

CAPSULE GEOLOGY

avoid bad ground.

Where first encountered the lode contained some sphalerite and galena. In 1951 a nearly vertical fissure was encountered 10.6 metres in the footwall at a point 79.2 metres west of the crosscut. In the first 30.4 metres of drift this fissure is mineralized erratically and contains as much as 0.9 metre of sphalerite, as well as local masses of galena.

The Lookout adit was started in 1946 at an elevation of 1300 metres, on the Lookout No. 2 claim. This adit was begun as a general exploratory tunnel, and was driven as a crosscut 686.4 metres at south 78 degrees west. At a point 365.7 metres from the portal a branch extends for 696.4 metres bearing about N 24 degrees W; the inner 91.4 metres of this branch is deflected nearly 200 degrees westerly. A zone consisting of 2 sub-parallel fissures 6 metres apart containing calcite and siderite was encountered about 495 metres northwest of the main crosscut.

An old adit on the Early Bird claim (082FNW229) at an elevation of about 1128 metres is entirely in quartz diorite. Workings here total about 122 metres.

A mineralized lode discovered in No. 2 ("A" adit?) was explored in 1952 by a new, No. 3 adit and a raise driven to connect the 2 levels. In the same year No. 4 adit was started and continued in 1953. About 305 metres from the portal a lode was intersected in the approximate projected position of the lode intersected in No. 3 adit. In the period from 1953 to 1956 the property was idle except for exploratory work on a small scale. In 1956 a narrow vein was exposed by stripping close to 100 metres from the Pearson adit, and a new adit started on the showing. In 1958 this adit had reached a total length of 7.6 metres. In December of that year an agreement was entered into with Violamac Mines Limited for the development of the Silver Ridge properties. The only work recorded on this property since was the extending of the adit started in 1956, for an additional 17 metres. In 1979, G. Sipos shipped 120 tonnes from the property.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slokan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slokan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slokan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Wonderful occurrence is hosted by argillite and slate of the Slokan Group. The rocks strike 165 degrees and dip 35 to 50 degrees northeast. The strata are believed to lie on the west limb of a syncline because the dip changes to southwest just east of the underground workings (Geological Survey of Canada Memoir 184). The sedimentary rocks are cut by joints that strike 060 degrees and dip steeply to the southeast. This orientation is similar to some mineralized veins exposed on the property. Several granodiorite and quartz monzonite dikes up to 15 metres wide cut the sedimentary sequence. The hostrocks are heavily pyritized close to the mineralized veins.

The Wonderful deposit occurs in a reverse sinistral (40 degrees east) fault zone that is cut and displaced by faults, subparallel to bedding, with generally sinistral but also dextral movements of up to 50 metres. The main orebody is developed by five main and three intermediate levels. The workings have a vertical range of about 180 metres below the surface. The main orebody strikes east and dips 50 to 90 degrees south. The ore occurs in a sheared and mineralized fracture that shows evidence of pre and postmineral displacement. The fissure vein is about 2 metres wide and consists of crushed wallrock cemented by quartz, calcite and siderite. The ore is brecciated and consists of fragments of galena, sphalerite and country rock with siderite. Pyrite and pyrhotite are common and oxidation is pervasive. Minor tetrahedrite may also be present.

Past production between 1896 and 1979 yielded about 13 tonnes of silver, 1619 tonnes of lead, 1214 tonnes of zinc and 6 kilograms of gold from 28,806 tonnes mined.

CAPSULE GEOLOGY

The Oregon property is situated on the north side of the ridge that separates Miller and Shea creeks, in the Slocan Mining Division. The underground workings are on Crown grant Lot 3098 at 1677 metres elevation above sea level.

In 1896 the Oregon claim was owned by the Sunshine Mining Co. Ltd. but there is no report of any work done on the property at this time.

In December 1935 the Sunshine Silver Lead Co. Ltd. was organized to develop a number of claims in the area. In 1936 the name was changed to the Silver Ridge Mining Co. Ltd. Extensive bulldozer stripping was done on this property in 1937 and several leads uncovered.

The Silver Ridge Mining Co. Ltd. started an adit on the Oregon claim in 1938 and then operations ceased and work was not resumed until 1945. The project was abandoned in 1946 due to excessively wet ground and bad air. The adit, an exploratory crosscut, was driven 3703.3 metres in a general south 22-degree west direction. Total linear work in the adit is about 838 metres. Two faults cut the Oregon tunnel, one 282 metres and the other 536 metres from the portal. The one farthest from the portal is full of gouge and a little quartz; the strike is north 70 degrees east and dips 55 degrees northwest. It was followed for 33.5 metres westward where it was intersected by a second major southwestward dipping fault. The hanging wall side was followed for 85.3 metres to the northwest and a diamond drill hole driven ahead an unknown distance but no mineralization was found. This exploratory work was based on the assumption that the faults of this locality are all right hand, however, this has not been proven.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are

CAPSULE GEOLOGY

intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted by predominantly interbedded black argillite and quartzite of the Slocan Group. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slocan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Several fault structures are evident and host vein mineralization. Later stage normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Drag features are also present.

The occurrence consists of three separate veins intersected in a 655 metre long adit. The adit is driven in a southerly direction through mostly flat-lying argillite for the first 90 metres. It then passes through the core of an anticlinal structure occupied by massive quartzite for about 180 metres. The next 190 metres are through a zone of fractured and sheared quartzite and argillite. Beyond the fractured and sheared zone the beds dip mostly 30 degrees northeast. The last 195 metres of the adit are through thinly bedded argillite cut by four lamprophyric dikes.

The first vein structure is 67 metres from the portal. The vein has been mined for about 25 metres and had a general 080 degree strike. The vein contained massive galena concentrated in narrow lenses along the vein. A few tonnes of lead may have been recovered from this vein but no definitive records could be located (Bulletin 29). The second vein is 274 metres from the portal. This vein was drifted on for about 10 metres to the west. It consists of a breccia zone containing quartz, siderite and sphalerite. The vein is next to a major southwest dipping fault zone.

The third vein is 503 metres from the portal. This vein is within a shear zone that strikes 070 degrees and dips 55 degrees southeast. The vein contains quartz but no apparent sulphides. It has been drifted on for about 33 metres in a westerly direction where it intersected a major southwest dipping fault zone.

There are no production records for this property.

CAPSULE GEOLOGY

raise west of the crosscut on this fissure extends at about 50 degrees to sublevels at 24 and 40 metres.

On the surface near No. 3 adit a trench has been dug on broken, mineral-bearing ground. This and old open cuts to the west indicate an east-west fissure or lode zone almost at right angles to the prevailing local strike of the strata. Just below the main road, about 137 metres east of the creek, there are 2 old shallow workings, on one of which there has been some underhand stoping.

The claim was owned in 1958 by S.J. Chin and prospecting was carried out under the name Kachin Explorations Ltd. In 1983 the property was held by Wavecrest Resources Ltd. and Springpoint Resources Ltd. under a joint venture agreement. Canada Development Corporation, approximately 85 per cent owned by the Government of Canada, optioned the property through a subsidiary, Ventures in Applied Science and Engineering ("Vase").

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slokan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slokan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slokan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted by predominantly interbedded black argillite, quartzite and limestone of the Slokan Group. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slokan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Several fault structures are evident and host vein mineralization. Later stage normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Drag features are also present.

On the Corinth property, the sedimentary rocks strike 145 degrees and dip 50 degrees northeast. The mineralized structure strikes east, dips 50 degrees south and has been explored with three or more adits and vertical raises that break through to the surface. The mineralized vein is within a 60 centimetre wide brecciated shear zone. The fissure vein is mostly filled with crushed wallrock and lesser amounts of galena, sphalerite and pyrite in a gangue of coarse calcite with minor rhodonite. The ore is concentrated in narrow pockets along the vein.

Intermittent past production from the property between 1900 and 1978 yielded 263,568 grams of silver, 69,210 kilograms of lead, 5556 kilograms of zinc and 78 grams of gold from 154 tonnes mined.

CAPSULE GEOLOGY

The Sunshine property is situated near the headwaters of Howson Creek at 1875 metres elevation above sea level, in the Slocan Mining Division. The property includes underground workings on the Sunshine No. 2 and Yakima Crown grants (Lots 3096 and 3097).

This group, comprising the Sunshine, Monday Fraction, Monday, Kass Fraction, Yakima, Cuba (082FNW195) and Oregon (082FNW044) Crown-granted claims, is situated on both sides of and adjoining the Corinth group (082FNW045).

The Sunshine lode was explored by a series of adits crossing the ridge between Miller and Howson creeks, 2 of which on the west slope were still accessible in 1952. The lower adit was followed in 1946 for a length of 161.5 metres. A drift from this adit follows the lode for 94.4 metres. The upper adit is a drift on the lode 62.4 metres long, and a connection exists with the lower adit nearly 30.4 metres below. Small caved adits near the ridge crest and down the eastern slope may or may not be on the same lode.

Three adits driven on the Yakima claim at an elevation of nearly 1829 metres are all caved. Another adit completely caved, but with a

CAPSULE GEOLOGY

large dump, is at the fork of the road on the east side of the claim.

In 1935 Silver Ridge Mining Company Limited was incorporated and acquired the property, which up to this time had been developed by the Sunshine Mining Company Limited. An adit was started in 1936, on the western side of the Miller Creek basin to intersect the lode at a lower level. This adit encountered broken ground and in 1946 was caved 45.7 metres from the portal.

In 1937 a large amount of stripping was done on the Oregon, Yakima and Cuba claims and some underground exploration carried out. Following this it was decided to drive a long cross-cut to explore old and now showings at depth. The crosscut was begun near the north side of the Oregon claim at an elevation of 1592.5 metres, in 1938. Work was suspended in March 1940, but recommenced in the fall of 1945 and continued until July 1946 when the crosscut was abandoned because of unsatisfactory results and a heavy inflow of water. This adit when abandoned had a length of 655.3 metres and had reached a point directly beneath the old Yakima workings.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted by predominantly interbedded black argillite, quartzite and limestone of the Slocan Group. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slocan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Several fault structures are evident and host vein mineralization. Later stage normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Drag features are also present. The sedimentary sequence is cut by a few felsic and mafic dikes.

On the Sunshine property the sedimentary rocks strike north and dip 50 degrees east. The underground workings include several adits on the Sunshine No. 2 and Yakima claims. On the Sunshine No. 2 claim, a series of adits explore a fissure vein striking 114 degrees and dipping 55 to 70 degrees southwest. The central part of the fissure vein is partly occupied by a mafic dike. Galena, sphalerite and pyrite with minor tetrahedrite are mainly concentrated on both sides of the dike and associated with a matrix of coarse calcite, siderite and quartz. The surface exposures of the vein are strongly oxidized.

On the Yakima claim, three short adits explore a vein striking 110 degrees and dipping 50 degrees south. The vein is within a narrow shear mostly filled with carbonate minerals. Another adit on the east side of the claim explore a third vein locally known as the Granville. Samples collected from this vein in 1939 assayed 3085 grams per tonne silver and 70 per cent lead (Property File - Prospectus, Silver Ridge Mining Company, 1939).

Production from the Sunshine property between 1895 and 1928 yielded 290,502 grams of silver, 53,470 kilograms of lead and 31 grams of gold from 105 tonnes mined.

CAPSULE GEOLOGY

the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted by predominantly interbedded black argillite and limestone of the Slocan Group. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slocan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Several fault structures are evident and host vein mineralization. Later stage normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Drag features are also present.

Mineralization is hosted in a breccia zone at the contact between argillite and limestone strata. Most of the mineralization appears to be as replacement of limestone and consists of quartz and coarse calcite with minor galena and sphalerite. Azurite and limonite are also present in minor amounts. The breccia vein is exposed near the top of the ridge on the Dixie Hummer Crown grant where it is about 1.5 metres wide.

Four short adits were driven in a northerly direction from the Minnesota Fractional Reverted Crown grant but all failed to intersect the mineralized zone. Several large mineralized boulders were found on the Minnesota claim below the workings. A grab sample collected from one of these boulders in 1926 assayed 5232 grams per tonne silver, 72.9 per cent lead and 1.4 per cent zinc (Minister of Mines Annual Report 1926). No production is reported for this property.

CAPSULE GEOLOGY

The Carnation property is situated on the south side of Carpenter Creek, near the headwaters of Tributary Creek at 1980 metres elevation above sea level in the Slocan Mining Division. The underground workings are on the Carnation Crown grant (Lot 575).

The initial discoveries and development work were at the higher elevations, on the Read, Robertson and Jennie Lind claims (082FNW183) on the west side of the ridge, and on the Carnation and Tenderfoot claims on the east side. Later work was at lower elevations on the east side of the ridge on the Violet & Violet Fr. claims, and in a crosscut adit driven from the adjoining Minniehaha property.

The Read, Robertson & Tenderfoot claims, owned by W.M. Robertson and associates, were under bond in 1892 to the London Mercantile Association, and in 1893 to J.A. Finch and associates. The Jenny Lind claim was owned by Paul & Chas. Anderson of Silverton. They reported a small shipment of ore in 1895. The Carnation claim, owned by D.D. Mann was under development from 1895 or earlier. Crown-grants were issued in 1897 as follows: the Carnation (Lot 575) to D.D. Mann, the Read (Lot 1247) and Tenderfoot (Lot 1248) to E.E. Evans, the Jennie Lind (Lot 1806) and Robertson (Lot 1808) to The West Kootenay (B.C.) Exploring and Mining Company, Limited. In 1904 the Robertson and Jennie Lind claims were held as part of the adjacent Wakefield property (82FNW059) which was under lease to The Anglo-Slocan Syndicate Limited. The Read and Tenderfoot claims were worked in 1906 by M.S. Davys who shipped a small amount of ore.

During the period 1917 to the mid 1920's claims on the east side of the ridge, including the Carnation, Violet (Lot 3168) and Violet

CAPSULE GEOLOGY

Fr. (Lot 3170) were held by G.W. Clark & associates under bond from A.R. Mann and others. During that period considerable development work was done in Nos. 2 and 3 adits. The Victoria Syndicate, Limited, of London, acquired an option on the property in 1925. Development work was carried out on both sides of the ridge, mainly in No. 2 drift adit which was driven southwesterly for 853.4 metres through the mountain to the Jennie Lind claim. A raise was driven to the old Read workings. A 3048-metre tramline was installed at the west portal of No. 2 adit at an elevation of 1967 metres. The syndicate dropped the option in 1928 and work was resumed by G.W. Clark. In January 1929 A.R. Mann & associates incorporated Carnation Silver Lead Mines, Limited to acquire the 17 claims and fractions. The claims were electrically prospected for one month by The Radiore Company of Canada, Limited. Underground work began in August in No. 3 adit on the east side of the ridge. Operations ceased in 1930.

Early exploration on the Jennie Lind and Read claims on the west side of the ridge was carried out in a series of 8 or more short adits and open cuts. On the east side of the ridge, to 1930, the main lode (Carnation lode) had been partly explored on and close to the northeast corner of the Carnation claim by 3 adits and a 6-metre shaft. A 36.5-metre drift adit was driven on the "D" vein at the 1996-metre elevation about 183 metres northwest of No. 2 adit; the latter as mentioned earlier, had been driven through the mountain at the 1966 metre elevation. A third adit, begun in 1929 at the 1920 metre elevation, was driven as a crosscut for 45.7 metres northwesterly to the lode, which was drifted on southwesterly for about 122 metres.

Kelowna Exploration Company, Limited in 1939 optioned the Carnation and adjacent claims and began an extensive geological survey. The option on the Carnation was given up in 1940 but control of the adjacent claims was retained. In August 1945 the company purchased the Carnation group of 14 Crown-granted claims and fractions. In 1948 the old No. 3 adit at 1920 metres elevation was reopened. In 1949 a new low level adit at elevation 1670 metres was begun at the south edge of the Western Fr. claim of the Minniehaha property, and a second, 1670-metre east adit, was driven the following year. Two crosscuts were driven across the lode in the old 1920-metre adit and a new adit (1859 metres) was driven westerly for 166 metres after the lode had been uncovered at that level by stripping. The new low-level 1670-metre adit was driven in search of the downward extension of the Carnation lode exposed in the 1920 adit, 243.8 metres above. The new adit was driven 70 metres southwesterly into the hill, then 420.6 metres in a south 7-degree west direction through the adjacent Evening claim (082FNW049). Two mineralized lodes, about 122 metres apart, were encountered. The first, probably related to the Minniehaha lode, was drifted on for 103.6 metres in the 1670 main adit and for 97.5 metres in the 1670 east adit. The second lode (Carnation lode) was drifted on westerly for about 548.6 metres to a point down dip from the upper levels and a crosscut was driven 100.5 metres into the hangingwall. The company name was changed in 1951 to Kelowna Mines Hedley Limited. The results of the exploration work were disappointing and operations ceased in June 1951.

Silver Standard Mines Limited, in 1961, acquired an option on 59 claims from Oil Participations Incorporated who had acquired the claims from Kelowna Mines when that company was dissolved in 1958. Drilling was done to test the Carnation lode 122 metres below the 1670 level. Subsequent exploration was on claims down dip to the east (see Silvana (82FNW050)). Silmonac Mines Limited was incorporated in 1963 to acquire the property. The company name was changed in 1977 to Silvana Mines Inc.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The Carnation deposit is hosted by predominantly interbedded black argillite and medium to dark grey quartzite and argillaceous quartzite of the Slocan Group. Argillaceous limestone, limestone and

CAPSULE GEOLOGY

slate are also found in varying proportions in the sequence. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slocan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Several fault structures are evident and host vein mineralization. Later stage normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Horizontal displacement can be several metres to over 90 metres. Drag features are also present. A post-deformational shear zone is subparallel to the Carnation vein structure for two-thirds of its strike length. Silicification is present in the sedimentary rocks and the vein structures. Graphitization from late stage shearing is also present throughout these structures.

Two veins exist on the Carnation ground. The Main or Carnation vein is part of a vein system that extends for about 8 kilometres to the east and includes the Silvana (082FNW050), and possibly the Ruth-Hope (082FNW052) deposits. The second or Footwall vein is a branch of the Main vein that extends southwest and may correlate with the vein on the Wakefield property (082FNW059).

The Main vein is not a single vein but a system of branching fissures that is about 30 metres wide. The vein is exposed near the northeast corner of the Carnation Crown grant where it has been explored with at least three adits and a shaft. On the Carnation property the Main vein strikes between 045 and 050 degrees and dips 55 to 70 degrees southeast. The vein is 1 to 1.5 metres wide and follows a porphyritic dike on its hangingwall. It is mostly filled with crushed wallrock cemented by coarse calcite. The ore consists of brecciated fragments of galena and sphalerite cemented by coarse calcite. Clean bands of lead-zinc mineralization also occur along the hangingwall of the vein.

The Footwall vein is about 120 metres north of the Main vein at the northeast corner of the property. The two veins appear to converge to the west. The Footwall vein strikes 010 degrees and dips 40 degrees southeast. It is about a metre wide and consists mainly of crushed wallrock. Pods and bands of galena and sphalerite some 40 centimetres wide and up to a metre long are distributed along the fissure vein. The gangue mineral is mostly coarse calcite.

Production from the Carnation between 1922 and 1951 yielded 376,097 grams of silver, 22,991 kilograms of lead, 19,598 kilograms of zinc and 186 grams of gold from 502 tonnes mined. See Jennie Lind (082FNW183) for shared production.

limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted by predominantly interbedded black argillite and medium to dark grey quartzite and argillaceous quartzite of the Slocan Group. Argillaceous limestone, limestone and slate are also found in varying proportions in the sequence. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slocan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Several fault structures are evident and host vein mineralization. Later stage normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Horizontal displacement can be several metres to over 90 metres. Drag features are also present.

The occurrence consists of a fissure vein that strikes 065 degrees and dips 45 degrees southeast. The vein is 20 to 30 centimetres wide and has been mined for about 100 metres along strike. The fissure is mostly filled with crushed wallrock. Bands of galena and sphalerite 2 to 5 centimetres wide occur in a gangue of quartz, calcite and oxidized sulphide material (probably pyrite).

Production from the occurrence before 1911 to 1914 yielded 253,961 grams of silver and 11,092 kilograms of lead from 57 tonnes mined.

COMMENTS: Reserves at the Silvana and Hinckley (082FNW013) mines as of April 1993.

REFERENCE: Information Circular 1995-1, pages 8,11.

CAPSULE GEOLOGY

The Silvana mine is situated on the south side of Carpenter Creek, between White and Tributary creeks at 1430 metres elevation above sea level in the Slocan Mining Division. The Ruth-Hope property (082FNW052) adjoins to the east and the Carnation (082FNW048) and Jenny-Evening (082FNW049) to the west. See also Hinckley (082FNW013).

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The Silvana mine is hosted by predominantly interbedded black argillite and medium to dark grey quartzite and argillaceous quartzite of the Slocan Group. Argillaceous limestone, limestone and slate are also found in varying proportions in the sequence. The argillite-quartzite sequence commonly has thin graphite, pyrite and pyrrhotite layers. An altered fine grained siliceous layer has also been observed. Coarse grained porphyritic biotite-rich diorite occurs as irregular bodies throughout the sedimentary sequence. To the east of the mine area, an altered fine grained diorite dike has been traced for about 610 metres underground. It is subparallel to the Silvana vein structure which often contains fragments of the dike. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slocan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Several fault structures are evident and host vein mineralization. Later stage normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Horizontal displacement can be several metres to over 90 metres. Drag features are also present. A post-deformational shear zone is subparallel to the Silvana vein structure for two-thirds of its strike length. Silicification is present in the sedimentary rocks and the vein structures. Graphitization from late stage shearing is also present throughout these structures.

The Main vein is the most productive in the area and strikes east or northeast and crosscuts the synclinal axis. It is an 8 kilometre long structure that has hosted various producing mines. The strike is mainly east with a variable dip of 13 to 68 degrees south. The Main vein has a separate hangingwall and footwall structure for the majority of its strike length. In places these structures can be separated by up to 45 metres. To the west-southwest of the Silvana mine are the Carnation workings (082FNW048) which are part of the Main vein. The Wakefield (082FNW059) is to the southwest and the Ruth-Hope (082FNW052) is to the east. The Minnie Ha Ha (Lot 3171) is included with the Silvana mine but it is a separate vein structure that occurs 457 metres (true) in the hangingwall of the Main vein structure. The Minnie Ha Ha does not connect with the Carnation workings to the west. The Main vein apparently pinches to the south and east against Nelson intrusive rocks.

Two types of breccias are found in the Silvana mine. The first type is the "fragmental" or "vein" breccia. This breccia contains very angular fragments of country rock with a calcite, siderite and minor quartz matrix. The fragments have a varying degree of coarseness. The second type is the "sheared" or "flow" breccia. This breccia is characterized by elongated, mylonitic-style

CAPSULE GEOLOGY

argillaceous quartzite fragments in a graphite matrix with or without calcite and siderite. This type of breccia is derived from late-stage shearing deformation. This post-deformational shearing has deformed "fragmental" breccia and previously non-brecciated material into "flow" breccia. These breccias have shredded and boudinaged the ore minerals. The vein structures are less than 15 metres wide and most are approximately 0.6 to 3 metres wide. Within the lode structure there can be up to 4 mineralized veins present which pinch and swell along strike and downdip.

The main ore mineralization, dated at 169 Ma +/- 3 Ma (Middle Jurassic), consists of argentiferous galena and sphalerite (D.K. Makepeace, personal communication). There are minor amounts of chalcopryrite, tetrahedrite, native silver, pyrargyrite and very minor amounts of stephanite, argentopyrite and acanthite. Other metallic minerals present in varying amounts are pyrite, pyrrhotite and arsenopyrite. The gangue minerals are calcite, quartz, orthoclase, siderite, tourmaline, chlorite, clay minerals and laumontite. Other minerals that have been identified in the area include smithsonite, anglesite, chrysocolla, malachite, manganese wad, limonite and hematite.

To the east of the mine area the Ruth-Hope-Line Star fault system strikes 160 degrees with steep west dips. In places the fault is over 60 metres wide. Horizontal displacement is up to 430 metres with an unknown vertical displacement and a probable rotational component. The West Hope fault is 460 metres west of the mine area and strikes 010 degrees with steep dips. This fault is 15 metres wide and has a 110 metre horizontal displacement with an unknown vertical displacement. The Carnation Basin fault strikes north and dips 30 to 35 degrees to the east. It comes to surface in the Carnation workings (1670-2133 metre elevation) and cuts off the west end of the Silvana orebody (1371-1429 metre elevation). The Wakefield vein structure (thrust fault) in the southwest would also cut the west end of the Silvana orebody further to the west.

The claims in this grouping include, in addition to the Boss Fr. (Mascot) (Lot 15272), Orient Fr. (Lot 5831), Diamond Fr. (Lot 5832), Oom Paul (Lot 5973), C & K (Lot 5974), Tornado (Lot 5537), Blimp Fr. (Lot 15275), and Best Fr. (Lot 15273).

The oldest workings in the vicinity are apparently on the Mascot claim which was staked in 1895. There is no record of work done on the adjoining Tornado claim which was Crown-granted in 1903 to The Selkirk Mining & Milling Company, Limited Liability, and re-Crown-granted to J.P. Wilson in 1919. On the Mascot claim two adits 11 and 18 metres long were driven during early activity. A small shipment of ore was reported in 1913. A third and lower adit was driven by Joe Johnson of Silverton during 1925-27 under a lease agreement with owner A. Waddell. The adit was driven southerly for about 143 metres to the lode, which was drifted on for 15 metres to the east and 79 metres to the west, with a crosscut 18 metres to the south from the west drift.

Underground work on the Minniehaha claim (Lot 3171) during, and possibly prior to 1898 totalled 91 metres of adit. The claim was Crown-granted in 1902 to Patrick Burns. By 1926 the claim had been acquired by the Alex Mann interests of Vancouver, owners of the adjacent Carnation property. Exploration and development work during 1923-24, under the direction of George Clark, included trenching, crosscutting and drifting. The adjacent Minniehaha Fr. (Lot 13006), Western Fr. (Lot 13033) and Western Fr. No. 2 (Lot 13027) were Crown-granted in 1926 to W.G. Clark.

In 1925 the claims were optioned by The Victoria Syndicate, Limited, of London, in conjunction with the Carnation (082FNW048) and other claims in a large group. Work continued in 1927 when 90 tonnes of ore were shipped from the Minniehaha. The option was dropped in 1928. The claim reverted to A.R. Mann & associates who had incorporated Carnation Silver Lead Mines, Limited, however, no further work was reported. The workings comprised 4 or 5 adits and considerable surface work over a vertical range of about 152 metres. The main adit has an aggregate length of about 244 metres and is very irregular. A second adit, 111 metres to the northeast, is 34 metres in length.

Kelowna Exploration Company, Limited held this ground and adjacent claims during the period 1939-1951. Extensive geological investigations were carried out over the company's holdings, and underground exploration was done on the Carnation property about 1.6 kilometres to the west. The company name was changed in 1951 to Kelowna Mines Hedley Limited.

Silver Standard Mines Limited in 1961 acquired an option on 59 claims from Oil Participations Incorporated, who had acquired the claims from Kelowna Mines when it was dissolved in 1958. Drilling by Silver Standard in 5 surface holes in search of the Carnation-Hope

CAPSULE GEOLOGY

lode suggested a target area just west of the Ruth-Hope property. An agreement was negotiated with Carnegie Mining Corporation Limited to use the Ruth-Hope No. 5 level (1219.2 metres elevation) which terminated near the east boundary of the Orient Fr. claim. The Silmonac Syndicate was formed in October 1962 with Silver Standard Mines Limited, Moneta Porcupine Mines, Limited and ViolaMac Mines Limited each having a 28.8 per cent interest, and the original owners a 13.6 per cent interest; the latter two companies held a share interest in Carnegie Mining. Rehabilitation of the 1219-metre level was carried out late in 1962 and exploration work began in January 1963. The level was extended westerly for about 1305 metres to a lode intersection which was subsequently explored for about 244 metres. The initial program, which was completed in November 1963, included 921 metres of crosscuts and drifts, 39 metres of raise, and 1130 metres of diamond drilling.

Silmonac Mines Limited was incorporated in November 1963 to succeed the Syndicate as operator. Work during the first half of 1964 included 316 metres of drifting, 98 metres of raising, and 1528.5 metres of diamond drilling. Work was suspended in June 1964 and not resumed until 1966. A further 152 metres of drifting and crosscutting was completed. Drilling in several up holes located a small orebody about 91 metres above the 1219-metre level workings. Work was discontinued in the latter part of 1967 due to lack of funds.

In September 1968 Silmonac entered an agreement whereby KamKotia Mines Limited (formerly ViolaMac Mines) and Burkham Mines Limited, a wholly owned subsidiary of Burden Investors Services Inc. of New York, would provide further exploration funds in equal proportion. Development work was resumed in October 1968 in a new adit which was collared at the 1318 metre elevation at the north edge of the Minniehaha claim. During 1968-69 the crosscut adit was driven southerly some 853 metres to the lode which was explored along 305 metres of strike and 61 metres down dip by 1503 metres of drifts and raises and 865 metres of diamond drilling in 23 holes. By April 1970 sufficient reserves had been outlined to justify production. The 150 ton per-day mill owned by Carnegie Mining Corporation was rented and production began August 26, 1970. A decline below the 1410-metre level was begun in 1973 and a ventilation raise was driven to the old Mascot workings at the 1524 metre elevation. During the following years exploration down dip at the east end of the mine located additional mineralized zones.

Silmonac Mines was reorganized and the name changed in September 1977 to Silvana Mines Inc. Kam-Kotia held a 39 per cent interest and Carnegie Mining a 20 per cent interest. The Carnegie Mill was purchased. The 1219-metre Ruth-Hope level was rehabilitated in 1978 and the No. 2 west lateral was advanced about 442 metres. Drilling in 1979 cut ore-grade intersections at elevations from 1292 to about 1341 metres. Subsequent work indicated in excess of 136,000 tonnes at 548.5 grams per tonne silver, 5.9 per cent lead, and 5.7 per cent zinc (CMH 1977-78, p 257).

Production through the 1219-metre level began in 1979. A raise was driven to connect the 1219 and 1410 level workings. During 1980, lateral work on the 1219 level totalled 621 metres. In the east decline area, lateral work and raising totalled 1865 metres. There were done 5058 metres of underground exploration drilling. Silvana amalgamated with Dickenson Mines Limited under the name of Dickenson Mines Limited.

The Silvana mine closed indefinitely in April, 1993. In October, 1994, Amcorp Industries Ltd. signed an agreement to buy the Silvana mine and mill at Sandon from Treminco Resources Ltd. A review of the Silvana and Hinckley (082FNW013) mines' ore reserves by Amcorp indicated that about 54,400 tonnes of ore grading 290 grams per tonne silver, 3.4 per cent lead and 4.7 per cent zinc, remain in the developed areas of the mines with potential to develop additional reserves. Amcorp expected to resume production in early 1995 (Information Circular 1995-1, page 8). Amcorp changed their name in May 1996 to Molycor Gold Corporation, part of the Verdstone Group of companies.

Production from the Silvana between 1913 and 1993 yielded about 242 tonnes of silver, 28,691 tonnes of lead, 26,299 tonnes of zinc and 72 tonnes of cadmium from 510,964 tonnes mined.

During the end of 1997, underground access to the Hinckley and Silvana lodes was re-established. Mining started on the Hinckley lode and the Silvana mill was re-commissioned.

In 1998, Treminco signed a Letter of Intent with Regeena Resources Inc. to purchase the Silvana and Hinckley operations. Treminco changed their name to Elkhorn Gold Mining Corporation in February 1999.

Klondike Gold Corp acquired the Silvana and Hinckley (082FNW013)

CAPSULE GEOLOGY

mines in May 1999 and commenced selective mining on the 4625 level of the Silvana mine in the fall. Test milling commenced in September 2000, and was completed by December 2000. A total of 3,577 tonnes of ore was mined yielding 138 tonnes of lead, 114 tonnes of zinc and 1,443 kilograms of silver. The project cost \$883,545 and returned total revenues of \$614,927. Excess costs were attributed to slower than projected production due to winter conditions. Revenues were lower than projected due to lower than expected grade mined, lower silver prices and recovery problems during mill startup. The project is in care and maintenance status as of February 2003.

CAPSULE GEOLOGY

The Dorothy occurrence is located southwest of Sandon at 1463 metres elevation above sea level in the Slocan Mining Division. The property includes the Dorothy Crown grant (Lot 2034) and the Irene Fraction Reverted Crown grant (Lot 4530). It lies along the west side of the Ruth-Hope property (082FNW052).

Very little of the history of the development of this property has been recorded. It was Crown-granted to the Ruth No. Two Mining Co. Ltd. in 1899.

The owner of the claim in 1926 was J.P. Wilson of Sandon and apparently some of the development work was done by him at about this time. In 1935 the claim was reported owned by C.B. White of New Denver. About 1952 the claim was owned by Kelowna Exploration Co. Ltd. The upper workings were reported to be caved at this time.

The property is developed by two adits, the one 38 metres lower than the other. The lower adit, was driven 67 metres at south 60 degrees east to a raise driven upwards at 30 degrees. A 30-metre branch to the northeast ends in another short raise.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity

CAPSULE GEOLOGY

of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Dorothy occurrence is hosted by thinly bedded argillite and quartzite of the Slocan Group. The sedimentary rocks typically contains up to 3 per cent graphite. Limonite is present in the exposed outcrops and is derived from the oxidation of pyrite. Many small fractures striking 130 to 150 degrees and dipping 35 to 75 degrees northeast cut the sedimentary sequence. Many small veins of calcite and quartz with minor pyrite are present throughout the sequence and disseminated pyrrhotite is common.

Two fissure vein structures are present on the Dorothy property, the Minnie Ha Ha and the Dorothy vein. The Silvana (082FNW050) Main vein passes just south of the Irene Fraction Reverted Crown grant. The Minnie Ha Ha vein strikes east and dips 30 to 40 degrees south. The vein is exposed on the northern part of the Dorothy Crown grant. On the Dorothy property, the Minnie Ha Ha consists mostly of graphitic gouge with calcite and minor galena and sphalerite. The Dorothy vein strikes north and dips 60 degrees east. It is about 396 metres long and runs between the Minnie Ha Ha and the Silvana Main vein to the south. It has been explored with a short adit on the Dorothy Crown grant and surface trenches on both claims. The vein is brecciated and includes large blocks of argillite and quartzite in a matrix of massive calcite with minor siderite and pyrite. The vein contains thin but consistent bands of mineralization which include galena, sphalerite, anglesite and pyrite. A weighted average of four chip samples yielded 209 grams per tonne silver, 5.1 per cent lead and 6.3 per cent zinc. The samples were taken across a 1.1 metre width and over a 9 metre vein length (Assessment Report 15774).

On the Irene Fraction Reverted Crown grant, the vein is more sheared and brecciated than on the Dorothy Crown grant. It consists of 50 to 75 per cent calcite with minor siderite and pyrite with lesser amounts of galena and sphalerite.

CAPSULE GEOLOGY

Aurora Fraction, and Zuma Fraction claims (Lots 754, 2029-2031, 2036, 2037 respectively) were Crown-granted to the company in 1898. A mill with a capacity of 4 tons per hour was built in 1899, and modified to recover zinc in 1904. The mine operated steadily until about 1916. The Ruth and Hope veins were largely worked out during this period. Lessees worked part time during the following years.

In the fall of 1922 the 14 Crown-granted claims were acquired by Messrs. Stewart, Lennie, and associates, of Vancouver, who incorporated the Ruth-Hope Mining Company, Limited, in April 1923. The Ruth No. 2 or Stewart vein was discovered and worked at this time. The company rehabilitated the old mill and added a 50 ton per day flotation unit in 1928. Work by the company ceased in 1930. The underground workings to this date extended over a vertical range of 427 metres and comprised nearly 8 kilometres of drifts and crosscuts. The Ruth vein had been explored by 5 adits. At higher elevations, southwest of the Ruth, 5 adits explored the Hope vein. In 1923 the Ruth No. 2 or Stewart vein was discovered, to the west of a fault zone that marked the end of the Ruth lode, and developed from the surface down to the Ruth No. 5 level by the Ruth-Hope Mining Company. This company also drove an 823-metre long crosscut south from the Ruth No. 5 level into the Blue Grouse claim (Lot 1846). The crosscut was driven about parallel to and some 79 metres west of the Silversmith property boundary in search of the possible westerly extension of the Silversmith lode; the lode was found to occur in two branches about 90 feet apart. Ore was mined up to No. 4 level and down to No. 6 level, a vertical distance of 67 metres.

Lessees carried on small scale intermittent work from 1930 to 1944. Kelowna Exploration Company, Limited, optioned 7 of the Ruth-Hope claims and adjacent ground in 1946. Crosscutting and diamond drilling was done from the Ruth No. 5 level to explore for extensions of the Silversmith vein. The option was given up in 1948. Kootenay Belle Gold Mines, Limited, optioned the property in 1951 and shipped ore from the mine dumps.

Carnegie Mines Limited, which was controlled by Viola Mac Mines Limited, purchased the Ruth-Hope group and adjacent ground, totalling 46 Crown-granted claims, in 1952. Intermittent exploration work was done in various levels of the mine and lessees continued to work part time. The company name was changed in 1958 to Carnegie Mining Corporation Limited. The Silmonac Syndicate, jointly financed by Viola Mac Mines Limited, Moneta Porcupine Mines Limited, and Silver Standard Mines Limited, was organized in 1963 to further explore the ground west of the Silversmith property, where the extension of the Silversmith lode was thought to be offset to the north by one or more northwest trending faults. The lode was found to the west of the Ruth-Silversmith fault zone and drifted on westward for about 182.8 metres; the mineralization encountered was below ore grade. Silmonac Mines Limited was incorporated in November 1963 to continue the exploration work. During 1964 the Ruth No. 5 level was extended 317 metres and 98 metres of raising and 1528.5 metres of diamond drilling was done. Subsequent to the cessations of operations by Silmonac Mines, Carnegie Mining explored below the old Ruth workings by crosscutting from No. 5 level and diamond drilling; this work failed to disclose the downward extension of the Ruth lode. Surface stripping was done on the Ruth Fraction claim in 1965.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Ruth-Hope occurrence is hosted by massive, locally calcareous argillite and quartzite of the Slocan Group and by quartz feldspar porphyry and lamprophyre dikes related to the Nelson intrusions. The sedimentary rocks are folded into an anticlinal structure that generally strikes northwest. The rocks dip moderately to the southwest on the eastern part of the Ruth Crown grant and northeast on the eastern part of the Hope Crown grant. The quartz

CAPSULE GEOLOGY

feldspar porphyry dikes strike northwest, subparallel to the sedimentary rocks, but dip at different angles from the sedimentary sequence. The felsic dikes are restricted to a 100 metre northwest-striking belt in the southern part of the Ruth claim. The dikes are pre-mineral and appear to have played some structural control on the vein emplacement. The lamprophyric dikes are irregular, appear later than the quartz feldspar porphyry dikes and are probably closely related in time to the mineralizing event.

The Ruth-Hope property contains three veins, the Ruth, the Stewart or Ruth No. 2, and the Hope. The mine workings on the Ruth-Hope vein system extend over a vertical range of 425 metres and include over 8 kilometres of underground development.

The Ruth vein is exposed on the Ruth and Ruth Fraction claims. The vein is within a well-defined fissure striking 070 degrees and dipping about 70 degrees southeast. It has been explored with at least five adits covering about 210 metres of strike length and 180 metres down dip. The vein is about 1.2 metres wide and composed largely of sphalerite and galena mixed with siderite. It is in the axial region of a recumbent fold, convex to the west. There is evidence of crumpling of beds in the general crest zone of the fold and the western end of the vein appears to split and terminate within the crest zone. The fissure vein was apparently not persistent enough to penetrate the apical zone of crumpling (Geological Survey of Canada Memoir 184).

The Stewart or Ruth No. 2 vein is exposed west and a few metres north of the termination of the Ruth vein. The vein was accessed from the Ruth workings and a small vertical shaft on the Ruth Fraction claim. The vein has been explored for about 150 metres of strike length and ranged in width from a few centimetres up to 9 metres. The fissure vein was essentially composed of crushed wallrock with thin seams of galena, sphalerite and siderite concentrated on the fissure walls. Elevated silver values were associated with sphalerite. Ore shoots varied from a few metres to 30 metres in length and from a few centimetres to a few metres in width. Crystalline cerussite was abundant in the upper levels of the mine.

The Hope vein is exposed on the Hope Crown grant. The vein is believed to be the faulted-off extension of the Silversmith (082FNW053) and Richmond-Eureka (082FNW054) vein which has been continuously mined from the Hope Crown grant through the Lone Star (Lot 1844), the Silversmith (Lot 1010) and the Slocan Star (Lot 545) (082FNW053), the Slocan King (Lot 547) (082FNW196), the Eureka No. 2 (Lot 2284) and the Richmond (Lot 1472) (082FNW054) for a total strike length of about 1.5 kilometres.

The vein has been developed in five adits on the Hope and Lone Star claims which include over 1800 metres of drifting. The Hope vein represents a system of subparallel fissure veins striking east and dipping between 25 to 40 degrees south. Collectively, the zone is 0.3 to 12 metres wide and includes a combination of anastomosing mineralized fractures and shears. In general, the steeper dipping part of the shears are more regular and better defined and are coincident with the intersection of the more competent rock units. Where the shears dip at shallower angles and tend to follow bedding, the wallrock is crushed and the fissure veins are irregular and discontinuous. On the Hope claim, the vein was mined for about 150 metres of strike length. The vein pinched out to the east against the northwest trending Silversmith-Hope fault. The Hope vein is mostly filled with crushed rock, calcite, siderite, quartz and ore. The ore shoots were irregular, pinching, swelling and in places abruptly terminating at their greatest thickness against a crossfault. They varied in thickness from a few centimetres to 60 centimetres and averaged about 30 metres in length. The ore consisted of galena, sphalerite and pyrite with minor tetrahedrite and chalcopyrite. Limonite and anglesite occurred in the oxidized part of the orebody.

Production from the Ruth, Stewart and Hope veins between 1895 and 1962 yielded about 76 tonnes of silver, 10,122 tonnes of lead, 1605 tonnes of zinc, 1 tonne of cadmium and 7 kilograms of gold from 60,575 tonnes mined.

CAPSULE GEOLOGY

The Silversmith occurrence is located immediately south of Sandon at 1463 metres elevation above sea level, on the west side of Sandon Creek, in the Slocan Mining Division. The occurrence is developed on a vein that traverses the entire property which includes, from east to west, the Slocan Star (Lot 545), Jennie (Lot 546), Windsor (Lot 1016), Silversmith (Lot 1010) and Rabbit Paw (Lot 1252) Crown grants.

The Slocan Star oreshoot was located in October 1891, and first produced ore in 1893. The first operating company was Byron N. White Company, of Spokane, Washington. In 1904 litigation began which involved extralateral rights of the Rabbit Paw claim, owned by the Star Milling and Mining Company. The suit lasted about 7 years and was finally settled against the Byron N. White Company. Following this the two companies were amalgamated as the Slocan Star Mining Company, in 1911. In 1917, with the Slocan Star orebody exhausted and other development not very productive, the company got into financial difficulties and was reorganized the following year as Silversmith Mines Limited. The rich Silversmith orebody which was mined until 1926 was found shortly afterwards. Mining was sharply curtailed in 1927, and from then until 1936 production amounted to only about 13,600 tons. No further work was carried out by the

CAPSULE GEOLOGY

company.

In 1948 an agreement to purchase was entered into with Carnegie Mines Limited, later (1951) Carnegie Mines of British Columbia Limited. Mining and underground development has been carried on intermittently since both by the company and by lessees. In 1958 under terms of an agreement with Violamac Mines Limited, Carnegie Mines of British Columbia Limited was reorganized and renamed Carnegie Mining Corporation Limited.

The workings of the Silversmith and Slocan Star Mines include 6 adits, Nos. 1, 2, 3, 4, 5 and 10, connected by shifts and raises from which 6 principal blind levels, Nos. 6, 7, 8, 9, 11 and 12 have been run. These workings are described by both Cairnes (1935) and Hedley (1952).

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The rocks hosting the occurrence consist of massive, more or less carbonaceous argillite, quartzite and limestone of the Slocan Group. The structure is complicated by folding and faulting but in general, the beds strike south to southeast near the Slocan Star workings and swing west on the Silversmith Crown grant. Dips are generally between 30 and 75 degrees south.

The sedimentary rocks have been intruded by a plug of biotite feldspar porphyry and numerous light coloured, medium to fine grained quartz or feldspar porphyry dikes and sills less than 10 metres thick and dark coloured, irregular olivine, pyroxene or biotite lamprophyre dikes usually less than a metre thick. The more felsic dikes are altered and strongly sheared. Most are regular and conform to the general strike of the bedding. The mafic dikes are younger than the felsic dikes and appear associated with the fissure vein structures.

The Silversmith occurrence represents the continuation of the Slocan King (082FNW196) and Richmond-Eureka (082FNW054) deposits to the east and Ruth-Hope (082FNW052) deposit to the west. On the Silversmith property, the deposit has been exploited for a total strike length of 825 metres in six adits connected by raises and shafts. The main access was from the lowest or No. 10 adit.

The deposit consists of a vein within a fissure zone that has a curving strike swinging from due east on the Slocan Star claim to northwest on the eastern part of the Silversmith and Windsor Crown grants and southwest on the western part to the Silversmith and Rabbit Paw Crown grants. The average dip is about 47 degrees south. In the lower levels of the Silversmith mine, the vein steepens to about 75 degrees. The irregular trace of the deposit is due to the changing trend of the enclosing sedimentary rocks and also in part due to a large porphyry plug located in the central part of the property. The fissure vein is widest where its attitude conforms to bedding and is most sharply defined and narrow where it cuts bedding at high angles. The vein also widens at the marked bends in its course. Although the fissure zone is continuous across the entire property, it is mainly composed of a series of en echelon fractures and shears striking northeast and northwest. The northeast fractures are open and usually carry most of the mineralization while the northwest fractures resemble shears and are rarely mineralized. The fissure varies in width from a few centimetres to 25 metres. It is mostly filled with crushed wallrock. Large blocks of feldspar porphyry and massive sulphide have been incorporated within the fissure zone. Large nodules of massive sulphide and fragments of strongly folded ore have been transported a considerable distance from their site of deposition by extensive post-mineralization movement within the shear zone.

Two separate orebodies were mined, the Silversmith and the Slocan Star. The Slocan Star orebody has been stoped for approximately 365 metres down dip. The stopes varied in length from 10 metres up to a maximum of 150 metres between the second

CAPSULE GEOLOGY

and fourth levels of the mine. Galena, sphalerite, tetrahedrite, pyrite, chalcopyrite, quartz and siderite formed discontinuous lenses, some of massive ore but most were mixed with crushed wallrock. The lenses were up to several metres wide aligned diagonally across the fissure. Galena was the most abundant sulphide and usually associated with quartz.

The Silversmith orebody has been mined for about 150 metres along strike and 180 metres downdip. The deposit was widest above the No. 8 level where two mineralized fissures joined to form a 10 metre wide orebody. Ore minerals were similar to the Slocan Star.

Production from the Silversmith and Slocan Star orebodies between 1893 and 1965 yielded about 226 tonnes of silver, 32,524 tonnes of lead, 11,751 tonnes of zinc, 17 tonnes of cadmium and 37 kilograms of gold from 355,110 tonnes mined.

CAPSULE GEOLOGY

The Richmond-Eureka occurrence is situated at 1480 metres elevation above sea level on the east side of Sandon Creek, about 3.2 kilometres by road south of Sandon.

The Richmond-Eureka vein was staked by Bruce White in 1891 and development work on a small scale was begun in about 1895. In 1899 the Richmond claim was Crown-granted to G. Gooderham and the Eureka No. 2 to the War Eagle Consolidated Mining & Development Co. Ltd.

The period of greatest development and production was from 1908 to 1916 when it was owned and operated by the Consolidated Mining & Smelting Co. Ltd. Closed in 1916, the mine was reopened in 1925 and operated intermittently by leasers until 1928.

The Richmond claim had a small amount of development and assessment work done on it in 1940-41 by C. Lindstrom.

The property was optioned by R. Crowe-Sword of Vancouver from Cominco. In 1950 the property was optioned from him by Kootenay Belle Gold Mines. They built a sink-float plant at the base of the lowest, or No. 6 dump and reopened No. 5 & 6 levels. In 1952 they recovered ore from between No. 5 and 6 levels.

In December the property, which included the Silversmith, Slocan Star (082FNW053), Ruth Hope (082FNW052), and Slocan King (082FNW196) claims, was transferred to Carnegie Mines of B.C. Ltd. They produced about 63 tonnes per day all year except during March & April. The Slocan King adit, which is on the same lode but 79 metres below No. 6 adit, was connected to No. 6 adit by a raise.

In 1958 the company was merged with Violamac Mines Ltd. and the name changed to Carnegie Mining Corp. Ltd. In 1959 and 1961 leasers

CAPSULE GEOLOGY

did some small scale mining.

The workings comprise a shaft, a series of open-cuts and short adits, and four main adits connected by raises and stopes. The underground work comprises about 1829 metres of drifts and crosscuts and over 304 metres of raises. The workings have explored the main lode over a horizontal distance of about 610 metres and a vertical distance of nearly 305 metres.

Leasers worked the Ruth Hope claim part time during 1962.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Richmond-Eureka occurrence is hosted by massive, commonly calcareous quartzite and argillite of the Slocan Group intruded by various dikes of quartz diorite, lamprophyres and minettes. The rocks are dislocated by strong reverse faults subparallel to north to northwest bedding.

The Richmond-Eureka deposit is the extension of the Silversmith (082FNW053) and Ruth-Hope (082FNW052) deposits to the west. On the Richmond and Eureka No. 2 Crown grants, the deposit consists of a vein hosted by an oblique normal-sinistral fault of unknown displacement. The vein strikes 080 degrees and generally dips 45 degrees southeast. The fault consists of a strongly brecciated and sheared zone up to 14 metres wide that curves locally to follow bedding especially near the basic dikes. The fault appears to widen in soft rocks and tightens in the more siliceous strata and dike rocks. The ore consists of up to 2.5 metres of massive sheared galena located at the hangingwall of the fault and bands and veinlets, up to 5 centimetres thick, of sheared galena at the footwall. A vertical zoning of sulphides with sphalerite becoming more abundant with depth and gangue with siderite-calcite passing downwards to siderite-quartz are reported. Pyrite, tetrahedrite and chalcocopyrite are present in minor amounts and leaf silver has been noted.

The deposit has been exploited with a shaft and a series of short adits. The underground workings comprise 1830 metres of drifts and 300 metres of raises and stopes. The workings which extend for 600 metres along strike and about 300 metres vertically explore two separate deposits along the same fissure zone. The largest deposit was 3 metres thick, 45 metres long and extended 80 metres down-dip.

Production from the Richmond-Eureka deposit between 1896 and 1961 yielded about 24 tonnes of silver, 2322 tonnes of lead, 761 tonnes of zinc, 1499 kilograms of cadmium and 590 grams of gold from 36,650 tonnes mined.

CAPSULE GEOLOGY

The Freddie Lee property is situated on Crown grant Lot 475 at 1860 metres elevation above sea level in the Slocan Mining Division. The property is on the east side of the ridge that separates Cody and Sandon creeks.

The claims extend from the creek, at the 1310-metre elevation, to the summit of the north trending ridge at an elevation of about 1981 metres. The Airdrie Fraction, Freddie Lee, Colonial (082FNW069), and Cristein (082FNW254) claims are located from north to south near the crest of the ridge. The Chicago No. 2, Chicago Fraction, and Pullman Fraction claims (082FNW194) cover the ground down slope from the Colonial and Freddie Lee.

The Freddie Lee claim (Lot 475), staked in 1891 by J. Wardner under the law providing for extralateral rights, was the first property in the Slocan district to ship ore. The Freddie Lee Mining Co. was incorporated in March 1893 and by the end of the 610 metres of development work had been done. The claim was Crown-granted to the company in 1894. Intermittent exploration and development work was carried on for a number of years; in 1902 a total of 152.4 metres of tunneling and 61 metres of raising and sinking was reported. The company charter was surrendered in 1912. The claim was acquired by U. McCune, of Salt Lake City, in about 1917 and further exploration and development work was done at that time. Some work was reported on the Freddy Lee claim by lessees in 1940.

The Colonial claim (Lot 5313) was owned and intermittently explored by A.D. Coplen, of Spokane, from about 1906. In 1928 the Colonial, Freddie Lee, Cristein, Airdrie Fraction, and Nellie claims were acquired under option by W.G. Wasmandorff of Vancouver. The Cristein claim (Lot 5369) had been Crown-granted to Messrs. McDonald and Taylor in 1904; the Airdrie Fraction (Lot 9832) had been Crown-granted to Messrs. McAllistar and Bigney in 1910. Colonial-Slocan Mines, Limited, was incorporated in May 1929 to acquire the claims and carry on exploration work. Work by the company ended in January 1930 and the company charter was surrendered

CAPSULE GEOLOGY

in 1932.

The workings on these claims include 9 or more short adits and several raises and intermediate levels. The upper 4 adits explore the Freddie Lee vein down dip. The lower adits comprise the principal workings on the Colonial and Chicago No. 2 claims.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Crown grant is underlain by sedimentary rocks of the Slocan Group which form a broken syncline composed chiefly of massive quartzite and limestone. To the east the syncline is faulted against another broader syncline in which the strata dip generally to the east. The core of this syncline is occupied by slate and argillite. The occurrence is hosted within quartzite beds of the western synclinal structure.

The occurrence consists of a fissure vein striking 065 degrees and dipping 65 degrees southeast. The vein has been stoped for at least 30 metres along strike. Mineralization included galena, sphalerite and pyrite in a gangue of quartz and siderite.

The first ore shipment from the Sandon area was from the Freddie Lee property in 1892. Total production from the property between 1892 and 1940 yielded about 2834 kilograms of silver, 443,396 kilograms of lead, 100 kilograms of zinc and 93 grams of gold from 741 tonnes mined.

CAPSULE GEOLOGY

The Noonday occurrence is situated on the north side of the ridge that separates Cody Creek into two forks, in the Slocan Mining Division. The property includes the Noonday, Grey Eagle, Fourth of July, Bolander and Baby Fraction Crown grants (Lots 2136, 2137, 2138, 2143 and 5542 respectively). Most of the underground workings are on the Noonday Crown grant at 1677 metres elevation above sea level.

The property was operated in 1893 by G.J. Atkins and Company, but was acquired by the White interests of Spokane, Washington, prior to 1898. Bruce White, along with his brother, Oscar, carried out development work as funds were available during the next several years until 1915 when Noonday Mines Company was formed to bring the property into production. However, shortly after this time, and before any amount of work had been done, Bruce White died and the property remained more or less idle until 1925. In that year Leadsmith Mines, Limited, was incorporated and during the next few years, until 1930, carried out extensive development work. Nothing further was done on the property until 1951 when Noonday Mines Limited, a wholly owned subsidiary, incorporated in 1947 of Alpine Mining Company of Spokane, Washington, reopened and examined No. 4 adit. In 1954 the property was under lease, and a small amount of ore was taken out.

Mine workings include 4 adits over a vertical range of between 152 and 183 metres. Production has been entirely from the upper 3 levels, most of it coming from above No. 2 level, which contains about 244 metres of drifts. The drift on No. 3 level is 213 metres in length. Some stoping was done above this level. The No. 4 level, examined in 1951, contains over 914 metres of workings, but work on this level was disappointing. According to Cairnes, (1935, p. 65), room exists between No. 3 and No. 4 levels for important mineral deposition.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity

CAPSULE GEOLOGY

of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The rocks on the Noonday property include banded, calcareous, tuffaceous and cherty argillite and minor slate of the Slocan Group. The strata strike 025 degrees, dip 60 degrees southeast and are intruded by quartz feldspar porphyritic dikes and sills.

The occurrence consists of a mineralized shear developed subparallel to the strike of the sedimentary rocks. The shear has been exploited in four adits over a vertical range of about 180 metres. It is about 60 to 90 centimetres wide in the upper levels of the mine and averages 1.5 metres on the No. 4 level. The shear is composed essentially of crushed wallrock containing bands and disseminations of sulphides within a matrix of coarse calcite or siderite in the lower levels of the mine. Coarse, cubic argentiferous galena is the dominant sulphide mineral. It occurs with sphalerite and a trace of pyrite in bands and lenses up to a metre thick in the upper levels of the mine.

Production from the property between 1894 and 1954 yielded 548,378 grams of silver, 147,499 kilograms of lead, 4946 kilograms of zinc and 31 grams of gold from 357 tonnes mined.

CAPSULE GEOLOGY

The Ivanhoe occurrence is situated on Crown grant Lot 743 at 2058 metres elevation above sea level, between Sandon and Selkirk peaks, in the Slocan Mining Division. The underground workings cover most of the eastern portion of Lot 743 and extend east on to the Elgin Crown grant (Lot 742).

This property was owned in 1952 by the Minnesota Silver Company, Limited, who have owned the claim since 1894.

The property was located about 1893 and was worked fairly steadily up to 1905, after which it lay idle until 1913 when operations were resumed and continued until 1921. Since that time little if any work has been done within the property limits. In 1900 a 100-ton mill was erected at Sandon. This was connected to the mine workings by an aerial tramway 2590 metres long. The mill was burned in 1915, and subsequently rebuilt by the Rosebery-Surprise Mining Company who acquired an option on the Ivanhoe property in 1919. This option was allowed to lapse the following year and in 1921 Silversmith Mines, Limited, took over the mill and remodelled it.

The mine was developed by 8 levels over a vertical range of about 183 metres. Nos. 1, 2, 4 and 8 levels are adits. Ore was stoped from No. 6 to 12.1 metres above No. 1 level, a vertical distance of 99 metres, but most of the stoping was done between levels Nos. 2 and 4. No. 2 level, driven on parts of a large and complex lode was partly accessible in 1948. No. 8 adit reaches the Ivanhoe lode at 399 metres and No. 4 adit reaches it at about 152 metres from the portal. The longest levels are Nos. 4 and 8. The former extends 224 metres east and 780 metres west and southwest of the crosscut, including in the latter direction an extension of 335 metres into the adjoining property of the Canadian group (082FNW197). No. 8 level drifts about 152 metres west of the crosscut and 286

CAPSULE GEOLOGY

metres east and also passes into Canadian ground for 247 metres. These levels are only partially accessible and the other levels are short and for the most part inaccessible.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slokan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slokan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slokan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Ivanhoe occurrence is hosted by limestone, argillite and quartzite of the Slokan Group that are intruded by quartz feldspar porphyries. The rocks are folded in a synclinal structure with the limbs striking north-northwest and dipping moderately southwest and northeast. The occurrence consists of a broad and irregular zone of faulting and shearing over 7 metres in width containing brecciated wallrock cemented by quartz and siderite with local lenses and veins of sulphides up to 1.5 metres thick. The walls of the fissure vein are marked by consistent gouge. The shear zone strikes east-west for most of the property but swings sharply southwest as it approaches the Canadian property (082FNW197). Veins within the shear zone dip 52 degrees south. On the Ivanhoe and Elgin Crown grants the vein system has been developed on at least eight underground levels and over a vertical range of about 180 metres. Above the No. 3 level of the mine the stopes were continuous for about 180 metres. Within the productive section of the veins the ore consisted of argentiferous galena and sphalerite in a matrix of siderite and quartz. Much of the ore was concentrated in semimassive lenses up to 1.5 metres wide between the second and fourth levels.

Production from the Ivanhoe between 1895 and 1935 yielded about 14 tonnes of silver, 2366 tonnes of lead, 330 tonnes of zinc and 31 grams of gold from 40,293 tonnes mined.

CAPSULE GEOLOGY

The Oakland claim was Crown-granted to F.F. Liebsher in 1904. Only one report has been written on this property, possibly due to the fact that the work done on it has been largely of a prospecting nature.

In 1946 the Oakland group, consisting of 9 located claims, was owned by F. Mills of Silverton. Development work at this time consisted of 5 short adits over a vertical range of about 91 metres. The lower adit is 15 metres long; No. 2 adit is 56.3 metres long, No. 3 adit is 30 metres long; the upper two are very short.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

On the Oakland property the Slocan Group comprises massive argillite and quartzite. The strata are tightly folded, faulted and cut by granitic dikes. The occurrence is hosted within a shear zone that strikes northeast and may correlate with the Canadian occurrence (082FNW197). The mineralized vein is strongly silicified and follows an altered granitic dike on its northwest wall. The vein dips 30 to 40 degrees southeast, varies from 30 to 180 centimetres in width and is hosted within a 7 metre wide shear zone. It carries pockets of galena and sphalerite in a gangue of siderite and quartz. The vein has been explored with at least five short adits over a vertical range of 90 metres.

A sample of high grade galena ore assayed 2948 grams per tonne silver, 47.5 per cent lead and 5.6 per cent zinc while a sample of sphalerite ore assayed 55 grams per tonne silver, 0.28 per cent lead and 26.7 per cent zinc (Minister of Mines Annual Report 1946).

CAPSULE GEOLOGY

The Wakefield property is situated on Wakefield Creek, southwest of Selkirk Peak at 1783 metres elevation above sea level in the Slocan Mining Division. The underground workings are on the Wakefield Crown grant (Lot 1527).

The Wakefield group was developed originally by Wakefield Mines Limited who began mining operations on the property in 1897, and in 1900 completed a 100-ton mill on Silverton Creek. An aerial train line connected mine and mill. This company suspended operations in 1902 and for five years thereafter the property was worked under lease by various interests. Further work was done in 1915 and in 1918 an option on the claims was taken by Clarence Cunningham, and later by the Victoria Syndicate. In 1912 the mill burned down and was rebuilt by the owners of the Hewitt mine. In 1929 the Wakefield property was leased to A. Jarvis, who is reported to have shipped several tonnes of ore.

Workings at Wakefield mine comprise 7 adits over a vertical range of about 61 metres. The longest adit, No. 2, is 259 metres long, and most of the ore mined came from this adit and the No. 1 adit, both of which are now inaccessible. This group was owned in 1952 by Kelowna Exploration Company Limited.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin.

CAPSULE GEOLOGY

Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

On the Wakefield property the Slocan Group comprises carbonaceous argillite, quartzite and limestone. The strata are folded, faulted and cut by granitic dikes. On the property the sedimentary rocks generally strike 040 degrees and dip 15 degrees southeast. The occurrence consists of a fissure vein that is subparallel to bedding. The vein has been developed in at least seven adits covering a vertical range of about 60 metres and 300 metres along the dip slope. In the mine the vein averaged 1.8 metres but did swell up to 6 metres in places. It consisted of bands and lenses of coarse calcite and quartz mixed with gouge and wallrock. Galena, sphalerite and tetrahedrite formed bands, lenses and disseminations within the calcite. The largest lens extended for about 35 metres along strike and 12 metres updip.

The vein is crudely zoned with galena being more concentrated on the margins and sphalerite occupying the central portion of the vein. The proportion of sphalerite to galena also increases with depth. The vein is brecciated and banded and may have resulted from multiple injections of ore and gangue minerals (Geological Survey of Canada Memoir 184).

Production from the Wakefield between 1899 and 1929 yielded about 6 tonnes of silver, 1111 tonnes of lead and 5 tonnes of zinc from 8943 tonnes mined.

CAPSULE GEOLOGY

mill operated from July 1935 until March 1936, and again from the spring of 1937 until December 1937.

Following a period of inactivity when company attention was directed to reopening the Standard and reclaiming tailings from Slocan Lake, the mine again came into production in 1942. By 1944 the orebody between Nos. 7 and 5 levels was mined out, and a considerable amount of exploratory drilling was done, much of it below No. 7. In the same year a new adit, the Monarch, was started to investigate intersections obtained by surface drilling. All work ceased in May 1945. The company began driving No. 9 level in September 1948. The aerial tramway was rehabilitated in 1950 and the mill operated from November of that year until November 1952. During 1954-55 the No. 7 level was extended westerly through the Monarch claim into the Hecla zone (082FNW062) of the Standard property. Production from the Mammoth resumed in 1956. During 1958-59 the No. 12 crosscut adit was driven 792 metres to the downward extension of the Mammoth zone. The adit for the most part parallels, and in two places cuts the vein on the adjacent Buffalo property (082FNW182). Work ceased in June 1959.

Loma Minerals Ltd. acquired a lease on the property and carried out development work from February 1961 until October 1962. Johnsby Mines Limited was incorporated in November 1962 to operate the property under the terms of an agreement between the owner, Western Exploration, and Rayrock Mines Limited and Faraday Uranium Mines Limited. Development work began in a new exploration adit on the Standard property. Mining began on the Mammoth between 9 and 12 levels in 1965 and continued until the ore was exhausted late in 1966. Total development work to that date is estimated at approximately 2560 metres of drifts and crosscuts in 6 adits, Nos. 1, 2, 4, 7, 9, and 12, and 6 intermediate levels. No. 3 1/2 and two other short adits lie to the west of the main orebody, and an exploratory cross-cut, the 152-metre long Monarch adit, lies farther to the west.

Arjan Pacific Ltd. by an agreement dated September 26, 1973 purchased the Mammoth and adjacent properties from Western Exploration Company, Limited. In 1976 the Mammoth and Buffalo properties were owned by D.W. Pengelly, of Silverton.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The Mammoth occurrence is hosted by various, more or less calcareous, mostly massive argillites and quartzites of the Slocan Group intruded by various sills and dikes of feldspar porphyry and bodies of hornblende or quartz diorite related to Nelson intrusions. Although deformation is intense, the rocks are generally flat lying in the immediate area of the mine.

The deposit occurs within an oblique, normal and sinistral shear zone up to 15 metres wide with displacement probably in the order of 100 metres. The mineralized vein has been developed from five main adits over a vertical range of 300 metres on the Mammoth claim and at least one crosscut adit on the Monarch claim. The orebody is pipe-shaped and appears to have a 20 degree plunge to the southeast. Above the No. 5 level it divides into two tabular masses in a comparatively straight fissure that strikes 075 degrees and dips 40 to 65 degrees southeast. On the No. 8 level the Buffalo (082FNW182) vein intersects and merges with the Mammoth vein. The Mammoth vein is believed to continue to the west and correlate with the "I vein" on the Standard property (082FNW180).

Within the mine mineralization was fairly continuous over a length of 130 metres and consisted of streaks, bands, lenses and disseminations of ore and gangue associated with abundant brecciated wallrocks. The ore occurred in massive lenses 1 to 1.5 metres wide and consisted of coarse to fine grained cubic and sheared galena with coarsely cleavable masses of sphalerite and minor tetrahedrite. Mineralization was more common at the footwall of the shear zone but was also observed at the hangingwall as well as in irregularly dispersed masses within the shear zone. The ore minerals occurred

CAPSULE GEOLOGY

with coarse calcite, siderite and minor quartz. Deformation subsequent to mineralization resulted in the fracturing of sphalerite and to the development of a well defined gneissic structure in which galena has flowed around and surrounded fragments of sphalerite.

Complete production figures are not available because the Mammoth mine ore was jointly milled with that from the Standard (082FNW180) and Enterprise (082FNW148) properties prior to 1958, and Hecla (082FNW062) property after 1964. However, production from the Mammoth mine between 1925 and 1980 yielded about 25 tonnes of silver, 2622 tonnes of lead, 4158 tonnes of zinc, 20 tonnes of cadmium, 46 kilograms of copper and 3 kilograms of gold from 63,865 tonnes mined.

CAPSULE GEOLOGY

The Echo occurrence is located at about 1524 metres elevation, on the southwest flank of Idaho Peak and between Bartlett and Emily creeks.

Work began on the Echo occurrence in about 1914 and continued intermittently until 1926. Most the workings are close to the Echo-Alpha (Lot 562) claim boundary. Development was carried out in four adits. The uppermost adit was driven on the Link Fr. claim. The other three adits were driven northeast into Echo ground from the Alpha claim (082FNW180), crossing the claim boundary at about 61, 129 and 229 metres from their respective portals. The No. 3 adit is 30 metres vertically below the No. 4 adit and 76 metres vertically above the No. 2 adit.

Hostrocks of the Echo occurrence include argillite, calcareous argillite, limestone and quartzite of the Triassic Slocan Group. The general strike varies from north to northwest and dips vary from east to northeast at about 50 degrees.

Mineralization consists primarily of galena and sphalerite hosted in a strong fissure zone with considerable fault movement. Other minerals included tetrahedrite, pyrite and locally abundant chalcopyrite. Gangue minerals include calcite, quartz and siderite. Calcite is commonly coarsely crystalline forming bands up to 90 centimetres thick carrying brecciated fragments of galena, sphalerite and wallrock. The fissure zone is 8 to 21 metres wide and is composed of brecciated and faulted country rock hosting vein mineralization.

The adits explored the main Standard-Alpha lode which on the Echo-Alpha properties has a general strike of 060 degrees and dips

CAPSULE GEOLOGY

about 45 degrees southeast. Several ore shoots were discovered and partially stoped from this fissure. One of these shoots was near the portal of the No. 3 adit and another on the Echo-Alpha claim boundary between the Nos. 2 and 3 levels.

Production records indicate 752 tonnes of ore was mined periodically between 1913 and 1928. This ore yielded 2,047,542 grams silver, 31 grams gold, 239,282 kilograms lead and 104,203 kilograms zinc.

CAPSULE GEOLOGY

The Hecla occurrence is located on the southwest flank of Idaho Peak at about 1219 metres elevation. Silverton, British Columbia is located 2.75 kilometres to the west.
The Surprise Crown grant (Lot 563) covers the ground hosting the Hecla occurrence. This should not be confused with the Hecla Reverted Crown grant (Lot 13576) or the Hecla ore zone on the Mammoth No. 7 level (082FNW060).
In 1961, Loma Minerals Ltd. held a lease that included the Hecla, Standard (082FNW180), Mammoth (082FNW060), Monarch and Enterprise (082FNW148) groups. Property title was transferred to Johnsby Mines Ltd. in the following year and an extensive development program was commenced on the hangingwall branch of the Standard-Mammoth lode system. This branch follows a general eastern course to the Mammoth mine which lies about two kilometres to the east. The Hecla ore zone lies along this lode between the Standard and Mammoth occurrences. Work on the Hecla occurrence was confined to the Hecla drift, with a total length of 1006 metres, following the trend of the lode. An additional 293 metres of crosscutting and 76 metres of raising was done. Three new ore shoots were discovered during a diamond drilling program, totalling 1452 metres, in the newly collared adit on the north-neighbouring Surprise claim. Stopes were started at about 231, 427 and 518 metres east of the portal

CAPSULE GEOLOGY

crosscut. Production continued until 1966 when the new ore was exhausted. Panoil Canadian Minerals Associates optioned the property in 1967 with further development work on the Mammoth occurrence. Arjan Pacific Ltd. acquired ownership of 32 Crown grants in 1973 which included claims covering the Standard, Hecla and Mammoth lodes. Mengler Leasing Co. operated the property in the early 1980s.

The Hecla occurrence is hosted by siliceous, carbonaceous and locally calcareous argillite, minor quartzite and limestone of the Triassic Slovan Group. These are intruded by a granodiorite stock and various quartz porphyry and biotite hornblende porphyry dikes. The dikes are highly altered to quartz, calcite and sericite, close to the Standard veins. The structure of these strata is extremely complex owing to intricate folding and faulting.

Ore shoots discovered at the Hecla occurrence in 1964 ranged from 30 to 46 metres length. The shoots are along the westward projection of the Mammoth and Hecla zones.

No information could be found regarding the nature of the Hecla lode. Its proximity to the Standard lode along the Standard-Mammoth lode system suggest the types and style of mineralization are similar. Therefore a description of the Standard occurrence is given. The Standard lode-fissure consists of a wide, up to 50 metres, shear zone. Underground, the lode has been followed for nearly 2.39 kilometres. While the lode is somewhat sinuous, it strikes about 065 degrees and dips 20 to 80 degrees, averaging 45 degrees. Near the main orebody the lode has a maximum width of 46 metres. The zone has many small offsets and split in north-northeast and east-northeast branches at its eastern extremity. This is where the main orebody was found. The main ore shoot, known as the Big or Million Dollar stope, extends 366 metres vertically downward from the No. 3 level to below the No. 6 level. Other orebodies, which include the I vein, 640 vein, 620 vein and Spur vein, are scattered along the structure. The ore shoots are generally at angle to the main footwall shear and a sigmoidal shape is reported for some of them, joining the footwall and hangingwall of the structure.

The orebodies occurred generally close to the footwall of the structure and consisted of up to 4 metres of massive, sheared and coarse-grained galena or up to 3 metres of massive galena and sphalerite in veins, stringers and lenses. Breccia composed of argillite, quartzite and porphyry are common in the footwall of the structure. Other reported minerals include varying minor amounts of pyrite, chalcopyrite, tetrahedrite and rare pyrargyrite. The Big ore shoot consisted primarily of relatively clean galena. Ore mined in later years contained mixed sphalerite and galena with the former predominating. Quartz, calcite and siderite comprise the gangue mineralogy.

The controlling factors on mineralization are thought to be the extent of shearing, brecciation and faulting of hostrocks with the presence of porphyry playing a minor role.

Production records for the Hecla occurrence indicate 20,108 tonnes of ore was mined between 1964 and 1983. This yielded 7,301,796 grams silver, 456 grams gold, 911,872 kilograms zinc, 647,478 kilograms lead, 5578 kilograms cadmium and 390 kilograms copper.

CAPSULE GEOLOGY

known as the Lucky Thought.

The mine lay idle until 1956 when Messrs. Nesbitt, Cordon and Nixon did some exploratory work on the lowest level. The property is developed by 4 adits over a vertical range of about 152 metres. A sublevel was established off a raise between the No. 4 and No. 3 adits. No. 4 adit was driven as a crosscut 198 metres long and then follows the vein for 183 metres. No worth-while mineralization was found at this level. Most of the ore was found in a shoot above the sublevel and this had been stoped out prior to 1918.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slovan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slovan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slovan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The Lucky Thought occurrence is hosted by quartzite, calcareous quartzite and argillites of the Slovan Group that strike 140 degrees and dip 73 degrees northwest. The occurrence is just north of the contact with the Nelson intrusions and the sedimentary sequence has been affected by contact metamorphism from the emplacement of the nearby intrusions. Near the occurrence the Nelson intrusions are composed of medium-grained granodiorite and quartz diorite.

The occurrence consists of a zone of faulting and shearing that strikes 065 degrees and dips 60 degrees northwest. The shear has been explored in four adits over a maximum strike length of about 300 metres. Within this length vein material containing bodies of massive galena, sphalerite and tetrahedrite occurred as lenses up to a metre wide. The lenses were separated by crushed wallrock cemented by quartz and calcite. Tetrahedrite appeared to be associated with galena and sphalerite was generally more abundant than galena.

Production from the Lucky Thought between 1914 and 1979 yielded about 6 tonnes of silver, 532 tonnes of lead, 701 tonnes of zinc, 350 kilograms of cadmium, 287 kilograms of copper and 584 grams of gold from 9321 tonnes mined.

CAPSULE GEOLOGY

The Van Roi occurrence is situated southwest of the junction of
Maurier and Silverton creeks, in the Slocan Mining Division. The

CAPSULE GEOLOGY

underground workings are on the Mackinaw and Mountain Boomer Crown grants (Lots 6528 and 740).

The original claims were staked in 1892 and the initial production of ore was in 1893 from the Mountain Boomer claim. The Vancouver group, comprised of the Vancouver, Mountain Boomer, Le Roi, Iowa, and Poona claims, was operated from 1896 to 1907. In 1908 the Vancouver was acquired by the Van Roi Mining Co., an English syndicate, and operations continued until 1914.

The Van Roi and Hewitt (082FNW065) properties were acquired by C. Cunningham, of Sandon, in 1917 and intermittent mining operations were carried out under the name of Cunningham Mines Ltd. until 1927. Leasers worked the property the following two years and then it was reported to have been acquired by Amalgamated Mines Ltd. of Vancouver. That same year (1929) Van Roi Mines Ltd. took over the property and operated it intermittently until 1931. Helena Gold Vines Ltd. acquired the property in 1933 but did not open the mine.

In 1942 International Metals Inc. Ltd. began to rehabilitate the mine but abandoned the project before it was completed. The Granby Co. Ltd. did some rehabilitation work on the property in 1946.

Van Roi Mines (1947) Ltd. reopened the mine and operated it for two years. In 1950 the Van Roi Consolidated Mines Ltd. was formed to operate the Van Roi and Hewitt properties. Controlling interest in this company was held by Transcontinental Resources Ltd. Options on the Galena Farm (082FNW067) and Metallic (082FNW066) properties were held for one year. In 1954 the company was reorganized under the name of Slocan Van Roi Mines Ltd. and leasers operated the mine until it was closed in 1957. The name of this company was changed to Kopan Developments Ltd. in 1960.

The property is developed on 9 levels, the workings following the fault zone for nearly 914 metres and to a depth of about 366 metres. To the west the same zone has been explored by the Hewitt mine and possibly it continues to the shore of Slocan Lake in the vicinity of the Galena Farm mine.

In December 1970 Kopan Developments Limited entered into a joint venture agreement with Arjan Pacific Ltd. Geological mapping was carried out in 1971. Arjan Pacific in 1973 acquired title to 43 Crown-grants covering the Van Roi and Hewitt properties.

In 1987 and 1989, PBX Resources Ltd. surveyed the property. The CDO showing lies 450 metres southeast of the Van Roi veins. The Wedge showing lies on the Le Roi claim, 800 metres east of the Van Roi veins. Adits and trenches occur at both of these showings.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The Van Roi occurrence is hosted by quartzite, calcareous quartzite and argillites of the Slocan Group that strike 140 degrees and dip 73 degrees northwest. The occurrence is just north of the contact with the Nelson intrusions and the sedimentary sequence has been affected by contact metamorphism from the emplacement of the nearby intrusions. The quartzite generally contains epidote and the argillite beds are bleached and silicified. Near the occurrence the Nelson intrusions are composed of medium-grained granodiorite and quartz diorite. A few mafic and felsic dikes and sills, some up to 15 metres wide, cut the sedimentary rocks in the mine.

The Van Roi deposit is hosted by a zone of faulting and shearing with oblique normal-sinistral movement. The zone averages 35 metres in thickness, strikes 070 to 075 degrees and dips 75 degrees northwest. It has been explored in seven adits covering 900 metres of strike length and 365 metres vertically. The structure probably correlates with the North vein on the Hewitt property (082FNW065) and may extend as far west as the Galena Farm property (082FNW067).

The shear zone hosts two main veins and numerous, less important ones. The Main or North vein is parallel to the shear structure. It has been developed on all the underground levels. The South or Beryl vein is present in the western part of the mine and exposed on levels 3 to 5. The South vein strikes 050 to 060 degrees and dips 65 to 75

CAPSULE GEOLOGY

degrees northwest. A number of orebodies are scattered at irregular intervals along both vein systems. The ore shoots generally plunge about 55 degrees to the west. Most of the ore was mined from shoots that were 30 to 60 metres long and 1 to 3 metres thick. Most shoots occurred between levels 2 and 5 of the mine. All ore shoots were similar and consisted of lenses and veins of massive galena and sphalerite, commonly associated with brecciated zones with fragments of ore and hostrocks cemented by quartz, siderite and calcite. The high grade portions of the ore shoots locally carried tetrahedrite, pyrrargyrite and some native silver. Pyrite and chalcopyrite were common accessory minerals.

In general, the boundaries of the ore zones were determined by the limits of commercial values rather than a structural break. However, in the western part of the mine the Main vein was terminated against a southeast striking fault zone. West of the fault the North vein could not be located but lateral displacement was probably not great because the Hewitt North vein lies almost directly on strike with the termination of the Van Roi North vein.

Production from the Van Roi mine between 1893 and 1958 yielded about 86 tonnes of silver, 8091 tonnes of lead, 7600 tonnes of zinc, 16 tonnes of cadmium and 9 kilograms of gold from 284,706 tonnes mined.

Klondike Gold Corp. acquired the Van Roi and Hewitt mines in December 1999.

CAPSULE GEOLOGY

The Hewitt mine is situated on the north flank of Mount Twigg south of Silvertown Creek, in the Slokan Mining Division. The underground workings include at least fourteen separate levels and straddle the north face of the mountain. The adits are located on the Hewitt and Lorna Doone Crown grants (Lots 4440 and 1401). The portal of the No. 10 or main working level is at 1495 metres elevation above sea level.

Adits were driven on the Lorna Doone claims in 1893 by owners Rathbourne and Culver, and on the Hewitt claim in 1896 by owners Tatlow, Yates and associates of Vancouver. The Lorna Doone was Crown-granted to Frank Culver in 1898 and the Hewitt to Robert Insinger in 1902. Development work to that date totalled about 1524 metres in 4 adit levels and 2 intermediate levels on the west (Hewitt) side of the hill. Lessees M.S. Davys, R. Sutherland and associates worked both claims from about 1903.

A New York syndicate acquired an option in 1907 and Hewitt Mining Company was incorporated in Delaware later that same year to operate the Hewitt and Lorna Doone. A 1524-metre long aerial tram was built from No. 3 adit to connect with the Wakefield mill. Ore shipments in 1908 were under the name Silver Cord Mining Company, Limited, which had been incorporated in March 1908 with head office at Sandon.

Silvertown Mines, Limited was organized in about 1909 by M.S. Davys and G. Stillwell to lease and option the property. By 1911

CAPSULE GEOLOGY

three of the adits had been driven through the hill to the east (Lorna Doone) side. The camp was moved to the east side where No. 7 adit level was begun. An aerial tram was built from this adit to the Wakefield mill, which was leased. The mill, which was based on the water concentration principal, burned in 1912 and a new 150 ton per day flotation mill was installed, however due to metallurgical problems satisfactory operation was not achieved until 1915.

The property was acquired by C. Cunningham of Sandon in 1917 and intermittent mine and mill operations continued into 1920. Lessee M.S. Davys resumed work on the property in 1922. Hewitt Mines, Limited was incorporated in June 1925 with head office in Nelson. The property was acquired in 1925 or 1926 by The Victoria Syndicate, Limited and development work on Nos. 8 and 9 adit levels continued into 1928.

The Galena Farm Consolidated Mines Limited acquired the property in 1929. Plans were made to establish No. 10 level which was to be driven through the mountain for a total length of over 1828 metres. Development work began from both ends (No. 10 east and No. 10 west adits). An aerial tram was installed from No. 10 west portal to the Galena Farm mill, a distance of 2682 metres. Work ceased in January 1930 with some 228.6 metres remaining to make the connection between the two adit faces. Lessees worked intermittently during the period of 1935 to 1942. The Granby Consolidated Mining, Smelting and Power Company, Limited optioned the lease in 1946 and during 1947 drove a raise from No. 10 east adit to No. 9 level, the option was given up later that year.

Van Roi Mines (1947) Ltd. was re-organized in 1950 to consolidate the Hewitt and nearby Van Roi (082FNW064) properties under the name Van Roi Consolidated Mines Ltd.; control of the company was acquired by Transcontinental Resources Limited. A 100-ton per day mill was installed on Slocan Lake 1.6 kilometres south of Silverton in 1951 and stoping was carried out on No. 10 east level; operations ceased in July. The company name was changed in 1955 to Slocan Van Roi Mines Limited. The mine reopened in the latter half of the year and diamond drilling was done below No. 10 level. In 1956 a 198-metre winze was sunk in the hangingwall and a crosscut driven 30 metres south to the vein to establish No. 11 level. The ore shoot developed by this work was leased to J. Heichert and mined out by July 1957. The company name was changed in 1960 to Kopan Developments Limited. Lessees during 1962-64 deepened the internal winze to establish No. 12 level and stoping was carried out. In 1969 the property was leased to Frank Pho for a period of 10 years and the shaft was deepened to establish No. 13 level. Mr. Pho in 1970 assigned the lease to Surfside Explorations Ltd. No. 13 level was extended and stoping over a length of 18 metres was carried up to No. 12 level. Ground failure in stopes and the shaft area necessitated closing of operations in 1970 before all the known reserves were extracted. Indicated reserves were reported at 54,432 tonnes at 514.2 to 685.7 grams per tonne silver, 5.0 per cent lead and 7.0 per cent zinc (B.C. Published Reserves File). The company name (Kopan) was changed in 1972 to Jordesco Resources Limited.

Arjan Pacific Ltd. in April 1973 purchased the property and the 125-ton per day mill from Jordesco. Some rehabilitation work was done in No. 10 west adit.

Dungannon Explorations Ltd. and Sabina Industries Limited purchased the property early in 1977 under a joint venture agreement and subject to the prior lease by Pho. In May 1977 a new lease agreement for 3 years, with the option to renew for a further 5 years, was reached with Mr. Pho. During the year a new inclined shaft beneath No. 10 east level was sunk 27 metres, and 24 metres of drifting carried out.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The Hewitt mine is hosted by quartzite, calcareous quartzite and argillite of the Slocan Group intruded by an apophysis of hornblende granodiorite to quartz diorite of the Nelson intrusions and thin

CAPSULE GEOLOGY

felsic dikes. The felsic dikes are strongly altered in the vicinity of the mineralized veins and in places difficult to distinguish from the sedimentary rocks. The strata strike 077 degrees, dip 70 degrees northwest and have been affected by contact metamorphism from the emplacement of the nearby intrusion.

Mineralization is hosted within a brecciated shear zone striking east and dipping 70 degrees north. The shear consists of at least four separate fissures that have been explored for about 365 metres vertically. The maximum width of the shear zone, as developed in the upper workings, was 30 metres. The fissures are composed largely of crushed and brecciated wallrock and gouge cemented by quartz.

Locally, ore minerals and vein material form an important constituent of the fissures. The main fissure or North vein marks the northern extent of the shear zone. It has been traced west as far as the Galena Farm property (082FNW067) and east as far as the Van Roi property (082FNW064), for a total strike length of about 4 kilometres. The North vein was the most persistent of all veins mined and has provided the bulk of the ore from the mine. Above the No. 4 level the North vein followed the intrusive contact on its footwall. Below the No. 4 level the vein was entirely hosted within the Slocan Group.

Other veins in the mine include the South or Main South, the West and the Main veins. The Main South vein marks the southern extent of the shear zone. It has been mostly worked above the No. 3 level and for a strike length of 75 metres. The vein strikes northeast, dips northwest and lies mostly along the intrusive contact. The West vein occurs between the Main South and Main veins. It is about 15 to 30 metres in length and strikes 010 degrees. The Main vein has been developed for about 135 metres on the second and third levels. The vein merges with the North vein to the east and west on the third level. Both the West and Main veins lie partly in the intrusion and partly in the sedimentary rocks.

Most of the ore came from two main ore shoots lying directly beneath the summit of the divide. The stopes on the North and Main veins have an aggregate length of 210 metres on the second level and average about 3 metres in width. Where the North and Main veins intersect the third level, the ore was 4.8 metres wide. The North vein extended to the No. 7 level about 135 metres vertically below and contained the highest zinc ore, assaying up to 20 per cent zinc (Geological Survey of Canada Memoir 184). The ore shoot plunged about 70 degrees to the west.

The second ore shoot is in the eastern section of the mine. This ore zone was mined, between levels 6 and 10, for a vertical distance of 350 metres and 60 metres along strike. The ore had a maximum width of 7.5 metres. This ore zone also had a westerly plunge of about 70 degrees. The lateral boundaries of the ore zones were determined by fault planes or narrow zones of bedding plane shears. Most of the movement along these faults is pre-mineral but slight left-lateral displacement of the veins was observed in a number of places. The richest parts of the ore shoots were mainly above the No. 3 level of the mine.

The vein filling consists of brecciated rock cemented by dense white quartz or a grey, sugary friable quartz with numerous vugs with fine clusters of crystals. A banded, ribbon, or agate structure also occurs and alternates with bands and streaks of galena and sphalerite. The ore minerals fill cavities, occur in specks, streaks and patches and form crusts on fragments of wallrock. In part, quartz is later than the sulphides. Siderite is subordinate to quartz and calcite is in very small amounts. Ore minerals consists of galena, sphalerite and tetrahedrite. Pyrite and pyrrotite are abundant within the ore. Pyrrargyrite and native silver occur in the high grade portions of the ore shoots and minor stibnite and a mineral resembling boulangerite have been observed in ore samples.

Production from the Hewitt between 1900 and 1983 yielded about 59 tonnes of silver, 2708 tonnes of zinc, 1770 tonnes of lead, 2 tonnes of cadmium and 3 kilograms of gold from 112,573 tonnes mined.

Klondike Gold Corp. acquired the Van Roi and Hewitt mines in December 1999.

CAPSULE GEOLOGY

The occurrence consists of a vein-fissure zone composed of quartz and calcite cementing brecciated argillite wallrock. The fissure width varies from a few centimetres to about 3 metres. The fissure strikes from 280 to 060 degrees, the average strike 075 degrees. The dip varies from 35 to 50 degrees north. Persistent veins, 10 to 13 centimetres wide, occurring as streaks, bunches and elongate lenses are found beneath a heavy hangingwall gouge. The vein walls are sharply defined. To the east the vein is terminated against a wide fault zone that dips gently east.

Mineralization occurs as seams up to 15.24 centimetres wide composed of massive sphalerite with disseminated galena. Elsewhere disseminated sphalerite, galena with pyrargyrite and tetrahedrite comprised vein mineralogy. Some pyrite and chalcopyrite are also present.

Production records indicate 234 tonnes was mined periodically between 1909 and 1950. This yielded 491,737 grams of silver, 93 grams of gold, 25,825 kilograms of lead and 23,249 kilograms of zinc.

CAPSULE GEOLOGY

in 1927 and the old mill was converted to flotation with a 36 to 45 tonne per day capacity. Additional underground work was carried out. In 1929, a total of 35 claims including those of the Galena Farm, were optioned to Galena Farm Consolidated Mines Limited. The mill capacity was increased from 91 to 136 tonnes per day. Operations ceased in 1929 due to low silver and zinc prices. Various lessees worked the property from 1936 to 1937. No further work was done until 1949 when F. Mills, under option, began mining small ore remnants in the old workings. The lease was worked until 1964 with further mining of stope remnants, pillar recovery and surface stripping. Other properties holding leases during this period included Transcontinental Resources Limited, Van Roi Consolidated Mines Ltd. and Hardex Mines Ltd. In 1964, Larch Mining Ltd. optioned the property and in 1966 carried out geochemical and geophysical surveys.

Mine workings included the 259 metre main crosscut on the 150 foot level, a 67-metre shaft and a 61-metre drift off the 200 foot level. The main lode was developed by three main levels at 15, 30 and 38 metres depth below the surface. Most of this ground has been mined out to surface and over a length of about 107 metres.

The Galena Farm occurrence is hosted by porphyritic granite of the Middle Jurassic Nelson intrusions containing pendants of metamorphosed quartzite and argillite of the Triassic Slocan Group. Xenoliths of quartzite and argillite were commonly found throughout the underground workings as lenses, belts and irregular inclusions near the Main lode.

The Galena Farm occurrence comprises two lode systems, the Main and Noonday lodes. The Main lode is about 24 metres thick, forming the hangingwall to the Noonday lode (082FNW068). The Main lode strikes 300 degrees and dips about 50 degrees to the northeast. The hangingwall is well defined but the footwall was poorly defined and was determined by the grade of mineralization. Lode width varies from about 60 centimetres to 61 metres but narrows with depth where it is faulted at the 150 foot level. The fault strikes 285 degrees and dips 28 to 30 degrees. To the east, the Main lode is truncated by a north-trending fault and offset by numerous other smaller north-trending faults. The Main lode ore zone consists of a series of subparallel quartz veins separated by varying widths of brecciated wallrock. The veins are also brecciated locally, particularly near the western end of the workings. Alteration of wallrock is reported but not described. The ore consists of massive lenses of sphalerite, galena and pyrite up to 1.5 metres thick in veins composed of quartz with lesser siderite, calcite and locally abundant fluorite. Some native silver has also been reported.

Most production was from the Main lode of the Galena Farm occurrence. The Galena Farm occurrence is renowned for significant ore recovered from shallow workings. Total production figures indicate 84,098 tonnes of ore was mined intermittently from 1900 to 1977. From this, 17,542,637 grams silver, 2068 grams gold, 2,856,577 kilograms lead, 4,638,348 kilograms zinc and 2250 kilograms cadmium were recovered.

CAPSULE GEOLOGY

Wilson-Smith and the Bank of Montreal, were leased to A. Erickson who subleased the property to G.W. Lyon, A. Lyon, and H. Cleaver, of Silverton. During the year about 45 tons of backfill was drawn from an old stope near the portal of the upper adit. The property was idle again until 1954 when lessees did some underhand mining about 61 metres from the portal of the main adit. Further work was done by lessees in 1956 and a small amount of high grade ore was shipped. In 1958 an outcrop of ore was exposed by hydraulicking in the bed of Hasty Creek immediately below the lowest portal of the Noonday workings; lessees shipped 80 tons of ore during the year.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slokan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slokan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

The Slokan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted within a narrow belt of argillite, argillaceous quartzite, quartzitic siltstone, greywacke and pebble sandstone of the Slokan Group that has been rafted within the Nelson intrusions. In the vicinity of the occurrence the rocks of the Nelson intrusions comprise coarse grained potassium feldspar porphyritic granite.

The workings include four adits along Hasty Creek covering a vertical range of about 30 metres. The upper two adits are between 91 to 122 metres long each, and explore a lode striking 292 degrees and dipping at a low angle to the northeast. A shoot of considerable size was stoped out to surface in 1899. The shoot contained galena, sphalerite and tetrahedrite mineralization. Little other mineralization was discovered. The main gangue mineral is quartz. Towards the face of the upper two adits the lode has been faulted. The vein may correlate with the Noonday vein on the Galena Farm property to the west (082FNW067). To the east, the vein terminates against a fault zone.

The Noonday has produced 577 tonnes of ore intermittently from 1899 to 1980, with the bulk of production in the 1950s. From this ore, 1,531,885 grams silver, 93 grams gold, 240 kilograms cadmium, 105,159 kilograms lead and 13,861 kilograms zinc have been recovered. Most of the production came from a single stope developed above the upper adit in 1899. Most of the ore mined in the 1950's was sent directly to the Trail smelter.

CAPSULE GEOLOGY

The Colonial property is situated on Reverted Crown grant Lot 5313 at 1768 metres elevation above sea level in the Slocan Mining Division. The property is on the east side of the ridge that separates Cody and Sandon creeks.

The claims extend from the creek, at the 1310-metre elevation, to the summit of the north trending ridge at an elevation of about 1981 metres. The Airdrie Fraction, Freddie Lee (082FNW055), Colonial, and Cristein (082FNW254) claims are located from north to south near the crest of the ridge. The Chicago No. 2, Chicago Fraction, and Pullman Fraction claims (082FNW194) cover the ground down slope from the Colonial and Freddie Lee.

The Colonial claim (Lot 5313) was owned and intermittently explored by A.D. Coplen, of Spokane, from about 1906. In 1928 the Colonial, Freddie Lee, Cristein, Airdrie Fraction, and Nellie claims were acquired under option by W.G. Wasmandorff of Vancouver. The Cristein claim (Lot 5369) had been Crown-granted to Messrs. McDonald and Taylor in 1904; the Airdrie Fraction (Lot 9832) had been Crown-granted to Messrs. McAllistar and Bigney in 1910. Colonial-Slocan Mines, Limited, was incorporated in May 1929 to acquire the claims and carry on exploration work. Work by the company ended in January 1930 and the company charter was surrendered in 1932.

The workings on these claims include 9 or more short adits and several raises and intermediate levels. The upper 4 adits explore the Freddie Lee vein down dip. The lower adits comprise the principal workings on the Colonial and Chicago No. 2 claims.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of

CAPSULE GEOLOGY

the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The property is underlain by sedimentary rocks of the Slocan Group which form a broken syncline composed chiefly of massive quartzite and limestone just west of the occurrence. To the east, the syncline is faulted against another broader syncline in which the strata dip generally to the east. The core of this syncline is occupied by slate and argillite. The occurrence is hosted within limestone beds of the eastern synclinal structure.

The occurrence consists of a fissure vein striking 025 degrees and dipping 50 degrees southeast. The vein has been explored with at least four adits on the Colonial property and the underground workings extend northeast across the Freddie Lee Crown grant (Lot 475) all the way to the Airdrie Fraction Crown grant (Lot 9832). Galena and sphalerite are associated with narrow crossfissures striking due east and dipping vertically. The vein was only a few centimetres wide but carried nearly massive galena and sphalerite with a little quartz. This vein does not correlate with the vein found at higher elevations on the Freddie Lee property (082FNW055).

Production from the Colonial property between 1906 and 1981 yielded 558,578 grams of silver, 134,246 kilograms of lead, 15,092 kilograms of zinc and 62 grams of gold from 306 tonnes mined.

CAPSULE GEOLOGY

1972. In 1975, the Little Daisy claim group was acquired by P. Leontowicz and W.C. Wingert. Ownership was partially transferred to Rio Tinto Canadian Exploration Ltd. in 1979 with the remaining being optioned.

The Little Daisy occurrence is located within an outlier of Lower Jurassic Rosslund Group metavolcanics and Early Jurassic subvolcanic equivalents. Lithologies comprising the Rosslund Group at the Little Daisy occurrence include augite porphyry, greenstone and argillite. These rocks have been tentatively correlated with the Elise Formation. Subvolcanic equivalents include quartz latite porphyry and feldspar porphyry. These hostrocks are enclosed by medium grained biotite hornblende diorite and fine-grained granite of the Middle Jurassic Nelson intrusions.

At the Little Daisy, mineralization is hosted in a narrow, banded quartz fissure-vein consisting of a 10 to 15 centimetre width of pyrite and galena carrying gold values in small seams, and occasionally chalcopyrite and pyrrhotite. The vein-fissure is hosted in a fine grained phase of porphyritic granite of the Nelson batholith. Minor molybdenite has been reported associated with quartz veinlets and feldspar subvolcanics. The Little Daisy occurrence has been described as a gold-silver polymetallic vein deposit (GSC Memoir 308).

Production records for the Little Daisy occurrence indicate 45 tonnes of ore were produced intermittently from 1904 to 1936. A total of 2768 grams silver and 2768 grams gold were recovered.

CAPSULE GEOLOGY

largely pyroclastic in origin and steeply dipping. The volcanics range from coarse breccia to tuff and volcanic siltstone. Augite porphyry is a significant component in the mineralized area and may be in the form of sills and/or flows. The Rossland volcanics are predominantly of basaltic composition but does include some low silica andesite.

The fragmental rocks range from volcanic agglomerates and conglomerates, with porphyritic clasts up to 50 centimetres in diameter, to finely bedded crystal and lithic tuffs. The volcanic breccias predominate and are generally monolithologic.

Most of the augite porphyry occurs near or within the quartz latite porphyry ring dike complex. Augite porphyry occurs in two types of bodies: irregular intrusive bodies that crosscut the inferred bedding, and stratiform flows and tuff breccias.

Volcanic siltstones are usually thin bedded and intercalated with augite porphyry and less frequently with other types of volcanics.

Quartz latite porphyry forms a ring and radial dike complex centred about a feldspar porphyry heterolithic breccia pipe complex. It generally ranges in composition from quartz monzonite to monzogranite to granodiorite, but much of this variation is probably due to potassic alteration (Heather, 1985). The ring dike portion of the complex is elliptical in plan view, 1 by 5 kilometres, with the long axis trending 050 degrees. Numerous dikes radiate inward and outward from this ring dike complex.

Feldspar porphyry forms a hypabyssal stock centred within the quartz latite porphyry ring dike complex. The stock has an elliptical surface plan with the long axis trending north-south.

Centrally located within the quartz latite porphyry ring dike complex, a heterolithic breccia forms a crudely cylindrical pipe-like body whose surface expression is an ellipse, 350 by 200 metres, with the long axis trending roughly north-south. Horizontal sections through the breccia pipe reveal that with increasing depth the width remains relatively constant but the length, at least to 1050 metres (ASL) increases to 450 metres. Rock types found as fragments within this breccia body include: pyroclastics, augite porphyry, volcanic siltstones, biotitic schist, quartz latite porphyry and feldspar porphyry. The breccia pipe appears to plunge to the north-northeast at a steep angle and commonly grades outward into a marginal crackle breccia which ranges in width from a few metres to several tens of metres.

Within the mineralized area only dikes and/or sills related to the Nelson intrusions were intersected in drilling. Mafic dikes crosscut all other rocks and appear to be post-mineralization.

Distinctive fracture patterns can be related to igneous intrusive events and post-intrusive deformational events. Structures observed include faults, fractures, intrusive and tectonic breccias, and late stage shear zones.

The most prominent structure within the Aylwin Creek mineralized area is the Willa shear zone. The Willa shear is a near-vertical zone which strikes 045 degrees and is an intensely fractured or shattered zone. The zone is a few tens of metres wide and has been traced for approximately 350 metres. Offset on mafic dikes indicates minimal left-lateral (5 metres) movement. This major structure is clearly post-mineralization and crosscuts all rock types within the mineralized area.

Three superimposed fracture sets were found which could be related to major geologic features within the mineralized area. The first set strikes 045 degrees parallel to the Willa shear zone with fractures of this set being most abundant within and near this zone. These fractures crosscut all earlier fractures. The second fracture set tangentially rings the breccia pipe. This set is best developed on the eastern margin of the breccia pipe. The third fracture set is north-south oriented and can be correlated with the trace of the Main mineralized zone and is well developed in the southern portion of the pipe, but weak in the central portion. The pattern is obscured in the north by the fractures associated with the Willa shear zone. Somewhat weaker north-south fractures are evident on the eastern and western margins of the breccia pipe; the East and West mineralized zones may be related to these (Heather, 1985).

A series of superimposed alteration and mineralization types are spatially related to the Willa deposit. Early potassic alteration centred on the feldspar porphyry stock grades outward to a propylitic alteration of the country rock. Superimposed on this is a calcsilicate alteration related to the late stages of heterolithic breccia pipe development. Retrograde alteration is superimposed on the calcsilicate mineral assemblages. Postdating all other alterations is a group of late-stage veinlets.

Potassic alteration consists predominantly of biotite and

CAPSULE GEOLOGY

associated but less abundant potassium feldspar, occurring predominantly within and around the central feldspar porphyry stock. Limited surface data indicates that the potassium feldspar alteration is more abundant (relative to the biotite alteration) in the centre of the potassic alteration zone. Locally the potassium feldspar alteration appears to be overprinting the biotite alteration, but in general the two appear to be approximately coeval. The biotite alteration is of two types. The first and most prominent type consists of fine, disseminated secondary biotite within the feldspar porphyry stock and the immediately surrounding country rock. Rocks with this alteration have a pink hue. The second type consists of felted masses of biotite pseudomorphing original hornblende phenocrysts in quartz latite porphyry dikes which lie peripheral to the area of pervasive pink biotite alteration.

Calcsilicate alteration consists of various combinations, in order of generally decreasing abundance, of pyroxene, amphibole, epidote, garnet, plagioclase, potassium feldspar, quartz, anhydrite, sphene and calcite. These occur as matrix replacements within the heterolithic breccia pipe and as vein material within peripheral crackle zones. The calcsilicate alteration can be subdivided into four types which represent increasing degrees of calcium metamorphism: amphibole, pyroxene, epidote and garnet(-anhydrite) types.

There are two distinct types of mineralization within the Aylwin Creek mineralized area: molybdenite mainly associated with quartz veinlets in the quartz latite porphyry, and gold-copper-silver associated with the calcsilicate alteration. Only the gold-bearing mineralization is of economic significance.

Extensive molybdenite +/- quartz mineralization is locally developed in the quartz latite porphyry and ring dikes and the volcanics surrounding them. Plagioclase phenocrysts are commonly albitized within a narrow halo about the quartz veinlets. An extensive pyrite halo partly overlaps, and is peripheral to the mineralization. Locally associated with these molybdenite-bearing quartz veins are thin quartz-sericite-pyrite alteration envelopes.

The gold-copper-silver mineralization at Willa occurs in three major zones (Main, West and East) hosted within the heterolithic breccia pipe and its peripheral crackle breccia. The central Main zone contains the bulk of the mineralization and is comprised of two near-vertical, en echelon tabular bodies that strike north-south across the core of the breccia pipe. The West and East zones occur in marginal crackle breccia and may form one continuous arcuate zone around the southern portion of the breccia pipe (Heather, 1985).

The Main zone is near vertical, strikes north and extends at least to the 1000 metre level (ASL) or approximately 270 metres below the surface. The trace of this zone on surface is 200 metres in length. The width is variable, ranging from 10 to over 60 metres locally, with the average being 30 metres. It attains a length of 400 metres. The southern end of the Main zone is predominantly a crackled breccia made up of volcanic and feldspar porphyry fragments. The central portion occurs in heterolithic breccia, and the northern end terminates against the quartz latite porphyry ring dike (to the north of the breccia pipe). The maximum width of the mineralized zone is in the central portion of the breccia pipe, where it is intersected by the Willa shear zone.

The West zone is situated approximately 60 metres west of the Main zone at a depth of 240 metres below the surface. The West zone may wrap around the southern periphery of the heterolithic breccia pipe. The West zone does not crop out at surface and appears to be hosted within a crackle breccia on the west side of the heterolithic breccia pipe.

The East zone is in an area of intense crackle breccia in volcanics, with abundant sulphides and associated calcsilicate alteration. The zone can be traced for 100 metres in Aylwin Creek on the eastern edge of the heterolithic breccia pipe. The East zone appears to be localized in crackle breccia similar to the West zone, possibly with the two wrapping around the southern portion of the heterolithic breccia pipe and joining up (Heather, 1985).

Mineralization consists of pyrite, pyrrhotite, chalcocopyrite, native gold, magnetite, minor sphalerite, and traces of native silver, in virtually any combination. Locally these minerals may be accompanied by hematite and traces of lead-bismuth bearing antimony sulphosalts. The mineralization occurs as massive sulphide, breccia matrix replacements, stockworks in peripheral crackle breccia zones and as disseminations and veins. The mineralization is associated with a suite of calcium-rich minerals including salite-ferrosalite, actinolite, andradite, epidote, anhydrite, scapolite and calcic plagioclase. These calcsilicate alteration minerals occur as massive to vuggy replacements of rock-flour breccia matrix in the central

CAPSULE GEOLOGY

part of the breccia pipe and as veins and veinlets in the marginal crackle breccia. There is a strong spatial relationship between the mineralized zones (high gold grades) and the development of high calcium mineral assemblages, with andradite being particularly localized in the upper portions of the mineralized zones and anhydrite in the lower portions. The andradite-magnetite assemblage overprints the pyroxene-pyrite-pyrrhotite assemblage, with the gold mineralization being deposited during this transition (Heather, 1985).

U/Pb analyses of 5 zircon fractions obtained from the Aylwin Creek porphyry (stock related to mineralization) resulted in a range of ages from 176-185 Ma; a precise age cannot be assigned. The best-fit lower intercept, ca. 183 Ma, is considered to be a reasonable estimate of the minimum age (GSA Special Paper 299, pages 159-171, 1995).

The Willa deposit has features in common with the alkalic-type porphyry copper-gold deposits, the Rosslund gold-copper camp, and copper and iron skarns (Heather, 1985).

Development on the property began as early as 1899 when a 30-tonne shipment of copper-gold ore was reported from the Rockland claim. To 1904, underground work totalled approximately 91 metres of drifts in three adits, one on the north side of the creek and two on the south. Work in 1937 included 32 metres of drifting and 3 metres of raising.

Measured geological reserves at the West zone are 414,297 tonnes grading 6.03 grams per tonne gold and 0.92 per cent copper (George Cross News Letter October 24, 1988). Combined (probable and possible) reserves at the Main and East zones are 219,518 tonnes (George Cross News Letter October 24, 1988).

Production records for the Willa occurrence indicate 300 tonnes mined with no recorded recovery in 1899. In 1988, 7883 grams silver, 2873 grams gold, 4418 kilograms copper, 63 kilograms lead and 4154 kilograms zinc were recovered from 495 tonnes of custom ore.

Orphan Boy Resources Inc. entered into an option to purchase agreement, in June 2002, to acquire the property.

CAPSULE GEOLOGY

The Silver Nugget occurrence is located at 1981 metres elevation, in the headwaters of Aylwin Creek. Silverton, British Columbia lies 8.25 kilometres to the north.

The Silver Nugget occurrence is located within but near the boundary of an outlier of Lower Jurassic Rossland Group metavolcanics and Early Jurassic subvolcanic equivalents. Lithologies comprising the Rossland Group at the Silver Nugget occurrence include pyritic quartzite, augite porphyry, greenstone and argillite. These rocks have been tentatively correlated with the Elise Formation. Early Jurassic subvolcanic equivalents include quartz latite porphyry and feldspar porphyry. These hostrocks are enclosed by potassium feldspar porphyritic granite of the Middle Jurassic Nelson intrusions. For a more detailed description of the geology of this outlier refer to the Willa occurrence (082FNW071).

The occurrence is composed of a quartz-filled fissure lode hosting pyrite and one or more silver-bearing sulphides. These may include tetrahedrite, pyrargyrite, native silver, argentite and stephanite. The lode has a strike of 063 degrees and dips 55 degrees to the southeast.

The lode has been explored and developed by two short adits. One adit was a crosscut 24 metres long, from which drifting occurred.

CAPSULE GEOLOGY

Production records indicate 1 tonne of production in 1907 from which 7060 grams of silver were recovered. However, 1 tonne of production is also reported in 1908. The ore in both years averaged 7783 grams per tonne silver (Geological Survey of Canada Memoir 184, page 124).

CAPSULE GEOLOGY

The Highland Light occurrence is located at 1828 metres elevation on a ridge west of Beaverton Creek, a tributary to Enterprise Creek. Silverton, British Columbia lies 9 kilometres to the north.

The Highland occurrence is located on the Trenton (Lot 5232) and Last Chance No. 11 (Lot 5233) Reverted Crown grants, formerly the Highland Light and Victor claims.

The occurrence is underlain by metavolcanics of the Lower Jurassic Rossland Group. Lithologies consist of augite porphyry, greenstone and argillite, tentatively correlated with the Elise Formation. These form part of an outlier composed of Rossland Group volcanics and Early Jurassic subvolcanic equivalents. Quartz latite porphyry and feldspar porphyry comprise subvolcanic equivalents. For a more detailed description of the outlier geology refer to the Willa occurrence (082FNW071).

On the lower Trenton (Victor) claim, a 23 metre long adit crosscuts a fracture zone. The zone is 7.6 metres wide, strikes 060 degrees, dips 60 degrees southeast and is composed of a series of vuggy quartz-filled fractures carrying disseminated galena and sphalerite. A second adit, 64 metres long and 20 metres vertically above, intersected the same zone hosting a few stringers and little or no mineralization. On the Last Chance No. 11 (Highland Light)

CAPSULE GEOLOGY

claim, an adit explored a 60 centimetre wide fault-fissure zone. The strike of this fissure is 310 degrees and dips 75 degrees northeast. The fissure hosted a little quartz and calcite and a few nodules of barite. A little pyrite was found.

Production records for the Highland Light occurrence indicate a total of 10 tonnes of ore were produced in 1904, 1906 and 1918. A total of 88,395 grams silver were recovered.

CAPSULE GEOLOGY

The Daisy occurrence is located at 1219 metres elevation on the west bank of Beaverton Creek, a tributary of Enterprise Creek. Silverton, British Columbia lies 10 kilometres to the north.

The occurrence was originally located on the former Daisy Group, composed of three claims. No work has been reported on this occurrence since 1925.

Hostrocks of the Daisy occurrence are potassium feldspar porphyritic granite of the Middle Jurassic Nelson intrusions.

At least two lodes have been discovered at the Daisy occurrence. One of these is a fissure up to 10.7 metres wide that strikes 015 degrees and dips 60 to 75 degrees to the southeast. The lode includes several narrow fissures 2.5 to 5.0 centimetres wide composed of gouge, quartz and calcite with galena, sphalerite, pyrite and chalcopyrite mineralization. Mineralization is restricted to the narrow fissures.

The lode has been explored by two adits. The lower adit is 91 metres long and was driven along the hangingwall of the lode. The lode has been traced on surface for 213 metres vertically above the lower adit. Here, the fissure hosts up to 15 to 18 centimetres of massive galena in an oxidized gangue or 18 to 20 centimetres of massive sphalerite.

The second adit is located about 30 metres vertically above the lower adit. It was driven for 30 metres. A 10.6 metre inclined shaft and several opencuts also explore the lode at this location. The lode strikes 320 degrees and dips 20 to 25 degrees to the northeast. The lode consists predominantly of a quartz vein with disseminated galena, sphalerite and chalcopyrite.

CAPSULE GEOLOGY

The Comstock occurrence is located at about 2103 metres elevation on the divide between Fennell and Silverton creeks. Silverton, British Columbia is located 11.5 kilometres to the northwest. The Comstock Group historically consisted of seven claims including the Ruby Trust (Lot 1804), Silver Chief (Lot 1813) (forfeited to the Crown February 9, 1993) and Comstock (Lot 1814) (forfeited to the Crown February 9, 1993), Silver Cup (Lot 1815), Isabel Fraction (Lot 1817) and Kentucky Girl (Lot 1818).

The earliest recorded work was in 1898 and continued intermittently until 1920. Early workings consisted of nine adits totalling 853 metres length. A mill was erected in 1897 to treat Comstock ore but was only used for two months. No further work was recorded until 1970. Work in 1970 was conducted by R.H. Murphy and partners and included a small shipment of dump material to the Trail smelter. Further work was done in 1972 and 1973. In 1976, H.S. Murphy and R.H. Murphy conducted a geochemical survey, trenching and

CAPSULE GEOLOGY

one 25-metre drillhole. In 1988, Dragoon Resources Ltd. custom smelted ore in a mill in Ainsworth.

The area is dominated by granitic rocks of the Middle Jurassic Nelson intrusions. At the Comstock occurrence these consist of biotite lamprophyre and quartz monzonite.

At the Comstock mine, mineralized quartz veins occur predominantly along the contact of a biotite lamprophyre body and quartz monzonite, both of the Nelson intrusions. The quartz monzonite is fine to medium grained, massive and fresh. The biotite lamprophyre is dark grey to black, medium grained with local coarse biotite crystals; magnetite is common. Monzonite blocks occur within the lamprophyre body.

Quartz veining and related mineralization is hosted in a brecciated zone 5 centimetres to 2 metres wide, striking 035 to 055 degrees and dipping 35 to 55 degrees southeast. Mineralization consists of galena, sphalerite, minor tetrahedrite and trace pyrrargyrite. Gouge is evident on both the hangingwall and footwall of the zone which also contains crushed quartz monzonite and lamprophyre fragments. The zone has been traced over a strike length of approximately 2100 metres between the 1670 and 2040 metre elevations (Assessment Report 17821).

Intense iron carbonate alteration, limonitic fractures and minor quartz-carbonate veining occur adjacent to the main mineralized zone. Several east striking lamprophyre dikes and quartz veins intersect the main zone.

Measured geological (proven) reserves at the Comstock-Silver Cup property is 45,355 tonnes grading 1199.8 grams per tonne silver, 6 per cent lead and 10 per cent zinc (Western Investment News - May 1987).

The Comstock mine was developed by nine adits. Stoping was carried out between the second and third levels and between the fifth and seventh levels, for a strike length of 15 metres and 109 metres respectively. The underground workings have explored the mineralized zone over a vertical distance of 121 metres.

Production records indicate 455 tonnes of ore mined. From this, 1,687,774 grams silver, 12,387 grams gold, 217,634 kilograms lead and 126,657 kilograms zinc were recovered.

CAPSULE GEOLOGY

The Lou Dillon occurrence is located on a tributary, east of Silverton Creek and 2 kilometres west of Long Mountain. Silverton, British Columbia lies 12.5 kilometres to the northwest.

By 1935, the workings consisted of a lower crosscut adit 84 metres long and intersecting the lode at its face. The lode was drifted for 5.4 metres to the northeast and 22 metres to the southwest.

Hostrocks of the Lou Dillon occurrence are coarse grained porphyritic granite of the Middle Jurassic Nelson intrusions. Occasional fine grained biotite granite dikes crosscut the coarser granite.

Drifting has exposed a fault-fissure lode composed of brecciated wallrock and gouge cemented with interstitial quartz, siderite and lesser calcite. The lode strikes 045 degrees and dips 65 to 90 degrees southeast. At about 9 metres above the main crosscut, a 47.5 metre long drift exposed up to 1.9 metres of ribbon quartz with galena, sphalerite, pyrite and an unidentified silver-bearing mineral. The pyrite carries gold and silver.

CAPSULE GEOLOGY

folded are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

The Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted within coarse grained potassium feldspar porphyritic granite of the Nelson intrusions near the northern contact with the Slocan Group rocks. Within the workings the porphyritic granite is cut by a few hornblende biotite dikes. The occurrence consists of a fissure vein striking 160 degrees and dipping 75 degrees west. The vein has been explored with at least five adits over a vertical range of about 145 metres. Within the adits the vein varied from a few centimetres up to 3 metres in width. The wider portions of the vein consisted mainly of gouge and crushed granite. The vein followed a hornblende biotite dike on its hangingwall for most of its length. Between the No. 5 and No. 4 levels the ore zone was mined for an average strike length of 22 metres and 50 metres updip. The zone varied between 15 centimetres and 2.5 metres and was composed of a series of overlapping lenses of vein material carrying layers of massive ore 15 to 30 centimetres thick. The massive ore layers consisted of sphalerite, galena, argentite, pyrrargyrite and native silver in a gangue of quartz-calcite and minor barite.

A second mineralized zone is situated about 180 metres south of the main workings on the Troy claim. This zone strikes 060 degrees and dips steeply northwest. It consists of an 18 metre wide brecciated zone within porphyritic granite. The breccia consists of large blocks of granite cemented by quartz and calcite containing sphalerite, galena, argentite and native silver.

Production from the Fisher Maiden between 1894 and 1979 yielded about 2319 kilograms of silver, 59,023 kilograms of lead, 59,896 kilograms of zinc, 289 kilograms of cadmium and 31 grams of gold from 1132 tonnes mined.

the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

The Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The Comstock-Virginia occurrence consists of a quartz vein located within a northeast trending fault zone in the porphyritic granite phase of the Nelson intrusions. The vein dips steeply northwest and varies from a few centimetres to 0.75 metre in width. It consists mainly of white quartz which cements fragments of the wallrock and is mineralized with galena, sphalerite, tetrahedrite, pyrite, pyrargyrite and argentite. The vein walls are well defined and marked by a narrow gouge seam.

The vein has been exposed in three adits 23 metres apart vertically. The middle adit was rehabilitated for a distance of 55 metres in 1980. A grab sample taken from the middle adit assayed 9052 grams per tonne silver, 28.9 per cent lead and 29.1 per cent zinc (Property File - Ash, W.M., 1988).

In 1909, 5 tonnes of ore were mined from the property to produce 15,552 grams of silver and 2722 kilograms of lead.

CAPSULE GEOLOGY

The Mountain Con occurrence consists of two Reverted Crown grants (Lots 9840 and 9841). The workings are located on Lot 9841 (Mountain Con), near the headwaters of Long Creek, in the Slocan Mining Division at 2410 metres elevation above sea level.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

The Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The Mountain Con occurrence consists of a 10 to 80 centimetre wide quartz vein associated with a narrow lamprophyre dike that is emplaced parallel to a northeast trending joint set within the porphyritic granite phase of the Nelson intrusions. The dike occurs in places on the hangingwall, and in places on the footwall side of the vein. The vein is regular and persistent and has well defined walls. It consists of galena, sphalerite, pyrite and cerussite in a matrix of white quartz, siderite and crushed wallrock.

The vein has been explored with at least four adits covering a vertical range of 150 metres. Surface outcrops of the vein are strongly oxidized.

Sporadic production from the Mountain Con between 1899 and 1927 yielded 6,417,608 grams of silver, 130,826 kilograms of lead, 485 kilograms of zinc and 373 grams of gold from 448 tonnes mined.

CAPSULE GEOLOGY

The Granite King occurrence consists of a single Reverted Crown grant (Lot 4538) situated on the southeast flank of Mount Carlyle, in the Slocan Mining Division, at 2347 metres elevation above sea level.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

The Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence consists of narrow, brecciated quartz-siderite veins emplaced along shears within porphyritic granite of the Nelson intrusions. The veins consist mostly of broken angular blocks of granite cemented by quartz and siderite. Galena, sphalerite and pyrite are disseminated within the gangue minerals. Small amounts of

CAPSULE GEOLOGY

native silver occurs as wires on the vein walls and minor scheelite has been noted. A grab sample collected from the vein in 1979 assayed 199 grams per tonne silver, 17.2 per cent lead, 11.5 per cent zinc and 0.08 per cent tungsten (Assessment Report 7950). At least two veins have been explored, the main vein is 5 to 70 centimetres wide, strikes 050 degrees and dips 60 degrees northwest. The second vein is 3 metres east and parallel to the main vein. It is 5 to 30 centimetres wide and has the same mineralogy.

The veins have been exposed in three short adits and a crosscut was driven from the lower Flint adit (082FNW083), 750 metres northeast, to intersect the vein 100 metres below the Granite King workings.

CAPSULE GEOLOGY

The Flint mine is situated near the headwaters of Carlyle Creek between the two Flint lakes, in the Slocan Mining Division. The underground workings are at 2050 metres elevation above sea level.

This property was staked in 1898 and the first recorded production was in 1905. The Flint lode has been opened up by 3 crosscut adits driven in a westerly direction. The lowermost adit reaches the lode at 67 metres from the portal, and has been extended beyond the lode for 72 metres, to a point believed to be within 15 metres of the Granite King lode. The portal of No. 2 adit is located about 46 metres southwest of, and about 24 metres above the portal of the lowest adit, and the portal of the uppermost or No. 1 adit is 46 metres above and 152 metres southwest of this same portal. No. 2 adit reaches the lode at 15 metres, and the No. 1 at about 30 metres. At each adit level drifts have been run southerly along the lode for distances of 183, 85, 18 metres at levels 3, 2, and 1, respectively, and from near the face of No. 3 adit a raise extends to the surface.

In 1953, after remaining idle since about 1917, some work was done on the property, and a little ore taken out.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of

CAPSULE GEOLOGY

the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

The Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence consists of a brecciated quartz-siderite vein emplaced along a shear within porphyritic granite of the Nelson intrusions. The vein strikes 010 degrees, dips 60 degrees to the west and consists mostly of broken angular blocks of granite cemented by quartz and siderite. Minor tourmaline occurs disseminated within the quartz. The vein varies in width from a few centimetres up to 3.4 metres. Galena, sphalerite, pyrite, pyrrhotite and minor scheelite occur as disseminations within the quartz and as massive to banded pods, some up to 1 metre wide, concentrated along the hangingwall. Most of the high-grade ore was mined out in the early 1930s.

The vein has been explored with four adits and extensive drifting. The lowermost adit extends to the Granite King vein (082FNW082), 750 metres to the southwest.

A grab sample taken from the vein in the uppermost adit assayed 576 grams per tonne silver and 4.88 per cent tungsten but later sampling of the vein failed to duplicate the tungsten assay. However, scheelite was observed in the underground workings (Assessment Report 7950).

Production from the Flint vein between 1905 and 1985 yielded 360,491 grams of silver, 69,087 kilograms of lead, 6445 kilograms of zinc and 43 grams of gold from 177 tonnes mined.

CAPSULE GEOLOGY

The Martin occurrence is situated on Carlyle Creek in the Slocan Mining Division. The property is at 1815 metres elevation above sea level.

The Martin group consists of 7 claims located in the upper basin of Dago Creek. The property was located in 1902, and some work was done each year until 1925.

The main workings consist of 2 adits 41 metres apart vertically, and intermediate levels at 20 and 27 metres above the lower adit. No. 1 adit is about 183 metres, and No. 2 adit 44 metres in length, and the intermediate levels total about 110 metres. The workings are connected by raises. Several metres of crosscutting to, and drifting on lodes other than the main lode, has been done on No. 1 level and the intermediate levels.

There has been no record of any work done on this group since 1925.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

The Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence consists of quartz veins emplaced along a northeast trending fault zone within coarse grained, porphyritic granite of the Nelson intrusions. In the mine workings a narrow band of altered dark micaceous rock (probably an altered mafic dike)

CAPSULE GEOLOGY

follows the main vein. The fault zone and veins dip 65 to 70 degrees northwest. The main vein consists mainly of crushed and altered granite cemented with white quartz, siderite and calcite. Sphalerite and galena with minor pyrite and chalcocopyrite are interstitial to the broken granite blocks. The ore, where best developed, was nearly massive galena that ranged from a few centimetres up to 0.6 metre in thickness. The largest shoot, 30 metres long, appeared to plunge 45 degrees southwest. Two other small veins converge eastwards and intersect the main vein in the underground workings. The veins have been explored with two adits and a minimum of 350 metres of drifting. Production from the Martin occurrence between 1915 and 1924 yielded 101,645 grams of silver, 28,387 kilograms of lead and 1981 kilograms of zinc from 54 tonnes of ore mined.

CAPSULE GEOLOGY

The Mohawk occurrence is situated on Twelve Mile Creek, on Crown grant Lot 14111 at 1815 metres elevation above sea level, in the Slocan Mining Division.

This property is about 1.6 kilometres southeast of Utica Mine (082FNW086) and to the south of and adjoining the Rainbow group (082FNW087). Workings consist of 5 adits and considerable surface stripping. Two adits 18 metres apart vertically, were driven to explore a southeasterly dipping lode. The upper adit is 12 metres long and follows the lode which has andalusite schist on the hanging-wall and a quartzite foot-wall. The lode dips 70 degrees southeast, is marked by about 15 centimetres of gouge, and carries some siderite and a little galena. The lower adit is about 38 metres long. At this level the lode is from 1.5 to 1.8 metres wide and contains galena in bunches and narrow stringers.

The second lode was exposed by an opencut for 46 metres, and it is reported that \$7000 worth of ore was taken out of these surface workings. An upper adit at an elevation of about 1920 metres was driven 38 metres on a mineralized shear zone which dips 70 degrees northwest, and is from 1.5 to 1.8 metres wide. In this drift some silver, some silver-lead ore, was encountered in bunches associated with pyrite and calcite. From the face at the adit a raise extends to the surface 15 metres above. Fifteen metres below this adit is another adit 15 metres long on the lode, and about 18 metres below this vertically, another adit was driven apparently on the same lode, for 100 metres. This zone is from 1.5 to 1.8 metres wide, and is filled with crushed wall-rock, streaks of gouge, and small bunches of galena associated with calcite gangue.

There has been no record of recent work on this property. Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed

CAPSULE GEOLOGY

shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

Immediately south of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson Intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5). The sedimentary sequence has been affected by contact metamorphism from the emplacement of the nearby Nelson intrusions.

Rocks on the Mohawk property are massive andalusite schist and quartzite of the Slocan Group, striking 035 degrees and dipping steeply southeast. The occurrence consists of two brecciated veins, one dipping steeply southeast and the other dipping steeply northwest, both veins strike 035 degrees. The southeast dipping vein is 1.5 to 1.8 metres wide and follows the andalusite schist-quartzite contact for about 40 metres. It consists of broken rock cemented by siderite. Galena occurs in small amounts, concentrated in pockets along the vein. The vein has been explored with two adits driven 20 metres apart, vertically.

The northwest dipping vein has been exposed in three separate adits and consists of crushed wallrock mixed with calcite and siderite. Galena, pyrite and tetrahedrite with minor pyrargyrite are concentrated in pockets along the vein. The vein had a maximum width of 1.8 metres where it was stoped (Geological Survey of Canada Memoir 184).

Limited production from the Mohawk occurrence between 1918 and 1921 yielded 109,515 grams of silver and 13,118 kilograms of lead from 21 tonnes mined.

CAPSULE GEOLOGY

The Utica property is located between elevations of 1830 and 2290 metres on the northeast side of Paddy Peak, 18 kilometres northwest of Kaslo. The property is near the headwaters of Utica Creek, a tributary of Twelve Mile Creek. The main portal (No. 4 adit) is at 1981 metres on Crown grant 4566.

The showings were discovered and staked in July 1892 by Patrick McCue. Development work during the following years was limited to the annual assessment requirements. In about 1899 a nine-month option was acquired by Messrs. Peyton and Corbin, of Spokane. Development work to that date had been carried out in 3 adit levels. In about 1900 the property was optioned to G.H. Hughes, who drove No. 4 adit. Five claims, the Utica, Alice No. 5, Andrew Jay, Rock Boulder, and Colorado (Lots 4566, 4567, 5304, 5305 and 5308 respectively) were Crown-granted to McCue in 1903. The Sol, Sol No. 1, Minerva Fr., Hercules, and Time & Tide claims (Lots 14107-14111) were apparently Crown-granted at a later date.

No further activity was reported until 1909 when the first production was recorded. The property was acquired from the McCue estate by C.F. Caldwell & associates who incorporated Utica Mines, Limited in October 1911. Operations by the company continued into 1918. Production, mainly from the East vein, was hand sorted for shipment, the milling-grade material being stockpiled. During this period the workings on Nos. 3 and 4 levels had been expanded to a total of about 1524 metres of crosscuts and drifts. The No. 7 level,

CAPSULE GEOLOGY

107 metres below No. 4, was driven as an exploratory crosscut for 610 metres in about 1917, however, the veins were not located. Lessees worked the property during the period 1919-23.

The owners reached an agreement with Major H.H. Armstead & associates on the formation of a new company in which Utica shareholders would receive shares in the new company. Accordingly, Utica Mines, Limited was wound up voluntarily in November 1923 and Canadian Mines Merger Company, Limited was incorporated in July 1924; the name was changed in December 1924 to Canadian Mines Merger, Limited. Exploration work resumed in the lower adit in search for the vein extensions on that level. About 305 metres of additional crosscutting was carried out before work was suspended in 1925.

Shareholder dissatisfaction with the former arrangement led to an agreement with Strobie, Forlong & associates under which a new company Utica Mines, Limited was incorporated in May 1928. Exploration work was resumed and in 1929 the West vein was encountered in the lower crosscut, but was apparently only sparsely mineralized and work ceased. The company wound up voluntarily in March 1937.

Utica Mines (1937) Limited was incorporated by the former owners and some development work was carried out during the year, and briefly by a contractor during 1938. Further development work was carried out by the company in 1940 and 1946-50. The West vein was drifted on for about 259 metres. A raise from the East vein was completed to No. 4 level in 1947. This work encountered a mineralized zone on which No. 5 sublevel was driven. Some ore was shipped from No. 7 level dump in 1950.

J.A. Cooper of Kaslo held a lease on the property from the fall of 1954 until the fall of 1957 and sections of the East vein were mined on No. 5 and No. 7 levels. Cooper, backed by New York interests incorporated Lajo Mines Limited in June 1957 to acquire the property under a long term lease. A 50 ton-per-day mill was installed and operated on a testing basis in early 1958. The mill operated again in 1960, milling about 4630 tonnes.

Standard Beryllium Corporation of New York obtained a controlling interest in Lajo Mines and carried out an extensive examination of the property early in 1961. A pilot run of 820 tonnes of dump and backfill material was put through the mill. The grade of the material was: 263.9 grams per tonne silver, 0.65 per cent lead; 2.3 per cent zinc. During the fall 30 metres of drifting was done on the East vein on No. 5 level and 13 metres of winze was sunk below No. 7 level. On the surface some trenching was done on the West and Sol veins.

Peerless Canadian Explorations Limited optioned the mine and mill from Lajo in March 1963. Development work was done on No. 4 and No. 5 levels. Underground diamond drilling was done to test the East vein and surface diamond drilling in 5 holes totalling 213.3 metres was done on the Sol and Andrew J veins. The option was abandoned prior to April 1964.

Continental Consolidated Mines Ltd. optioned the property in 1965 and some geological work was reported. Silver Peak Mines Ltd. held an option on the property in 1968. Sampling and diamond drilling was reported.

Turismo Industries Ltd. in 1978 obtained an option on a 50 per cent interest in the property. The company name was changed in July 1978 to General Energy Corp. By a further agreement of June 1979 with Martin & Lilly Ltd. and Lorede Resources Ltd. the company acquired a 30 per cent interest in the mine dumps. The dumps were estimated to contain 9072 tonnes at 257.1 grams per tonne silver (VSE SMF 12/09/79, General Energy Corp.). Lessees under the name Keen Creek Developments Ltd. during 1979 mined about 1360 tonnes on the 1130-metre level on the Last Chance claim. A new adit at the 1100-metre level was driven 66 metres to the main shear; the lease was terminated. David Minerals during 1980 carried out diamond drilling on the 1100 level, drifting to a new vein discovery, and raising to the 1130 level. The milling of 5366 tonnes of dump ore at the Ainsworth mill to May 15, 1981 proved unprofitable.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slokan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slokan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slokan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six

CAPSULE GEOLOGY

texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Utica occurrence is hosted by andalusite schist, after argillites and limestone of the Slocan Group metamorphosed by contact metamorphism of nearby Nelson intrusions. The strata generally strike northwest and dip 25 to 60 degrees northeast but locally they can be complexly folded. The metasedimentary rocks are intruded by three stocks of biotite granite, probably related to the Nelson intrusions.

The Utica consists of two subparallel brecciated veins occurring within fault zones with sinistral strike-slip movement and later normal movement. The faults strike 040 degrees, dip between 60 and 70 degrees southeast and have well-defined walls marked by thick seams of carbonaceous gouge. It is suspected that the two faults, which are 35 metres apart in the No. 4 adit, merge toward the surface. The East vein varies in thickness from tens of centimetres up to 2 metres. It has been stoped in the No. 4 adit for a strike length of 210 metres and for 80 metres updip above that level. It contains mostly brecciated hostrocks cemented by siderite, quartz and calcite. The ore occurs as scattered lenses and veinlets of interbanded argentiferous galena and sphalerite with gangue minerals, averaging 70 centimetres in width. Tetrahedrite, arsenopyrite, pyrite, chalcopyrite, and native silver occur in minor amounts within the sphalerite-rich layers.

The west vein varies from 1 to 6 metres and is largely composed of crushed and sheared wallrock. The ore occurs in parallel shoots aligned across the vein and apparently associated with crossfractures. Silver appears to be associated with sphalerite. Late movements in the faults induced fracturing of sphalerite and shearing of galena with galena flowing around fragments of sphalerite. The veins have been explored with five adits and at least 2400 metres of drifting.

Production from the Utica mine between 1909 and 1983 yielded about 30 tonnes of silver, 1551 grams of gold, 1600 kilograms of cadmium, 171 kilograms of copper, 992 tonnes of lead and 718 tonnes of zinc from 21,823 tonnes mined.

CAPSULE GEOLOGY

The Rainbow occurrence is situated on Utica Creek, on Crown grant Lot 14615 at 1890 metres elevation above sea level, in the Slocan Mining Division.

Workings include a shaft and 2 adits. The latter are about 70 metres apart vertically and the collar of the shaft about 30 metres above and 40 metres southwest of the portal of the lower adit. All three lodes are encountered in the lower adit level. This adit was driven as a crosscut for 38 metres to the most easterly lode, and continued for about 43 metres southwest as a drift on the lode. A crosscut from near the face of the drift was driven 55 metres to the northwest cutting a second lode at 26 metres, and a third lode, known as the "McInnis vein", at 50 metres. The second lode is about 1.2 metres wide with gouge on both walls and is composed of crushed rock containing a little calcite and siderite. The McInnis lode at this level is about 3 metres wide but shows little mineralization. Higher up, however, this lode was intersected at 9 metres from the portal by the upper crosscut adit, and was followed southwest by a drift for 18 metres. In this drift a few lenses of vein matter were encountered at the face of the lode was about 45 centimetres wide.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

Immediately south of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from

CAPSULE GEOLOGY

diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5). The sedimentary sequence has been affected by contact metamorphism from the emplacement of the nearby Nelson intrusions.

Rocks on the Rainbow property are massive andalusite schist and quartzite of the Slocan Group, striking 035 degrees and dipping steeply southeast. The occurrence consists of three brecciated veins emplaced along narrow shears parallel to the foliation. The veins have been explored with a shaft and two adits about 40 metres apart vertically. All three veins are exposed in the lower adit. The veins vary from 1.3 to 6 metres in width and consist mainly of crushed wallrock cemented by calcite and siderite. Galena, sphalerite and pyrite form narrow seams, 10 to 40 centimetres wide, on the footwall side of the vein and are concentrated in lenses and stringers at irregular intervals along the vein.

Production from the occurrence in 1924 and 1926 yielded 17,200 grams of silver, 2963 kilograms of lead and 31 grams of gold from 6 tonnes of ore.

CAPSULE GEOLOGY

The Helen occurrence is located at 1690 metres elevation above sea level, between Robb and Twelve Mile creeks, in the Slocan Mining Division.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

CAPSULE GEOLOGY

The occurrence consists of a brecciated vein within a northwest striking shear zone cutting a porphyritic granite stock-like apophysis of the Nelson intrusions. The shear dips 45 degrees southeast and is composed essentially of broken and crushed granite, 1 to 1.5 metres wide, sparsely mineralized with galena, cerussite, sphalerite and carbonate as filling between the granite blocks. A 45 centimetre wide chip sample taken from the mineralized portion of the shear assayed 1.3 grams per tonne gold, 1920 grams per tonne silver and 12 per cent zinc (Minister of Mines Annual Report 1919). The vein has been explored with a shaft and two adits driven 30 metres apart vertically.

CAPSULE GEOLOGY

The Keno occurrence is located at 1980 metres elevation above sea level, between Robb and Twelve Mile creeks, in the Slocan Mining Division.

According to Cairnes (1935, p. 227): "The Keno property, comprising one or more claims held by location is about 1067 metres above and 6.4 kilometres by trail southeast of Baylock. The workings include three adits, of which the lower two were inaccessible in 1925."

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The occurrence consists of a brecciated vein within grey limestone and calcareous argillite of the Slocan Group. The shear strikes north and dips 50 degrees east and is composed essentially of broken wallrock and gouge. The shear, which has been explored with three adits, is 30 to 120 centimetres wide. At 16 metres from the portal the shear splits into an east trending, vertically dipping segment and a south trending, east dipping segment. The east-trending shear cuts a porphyritic dike 10 metres from the split and pinches out 6 metres past the dike. The drift following the

CAPSULE GEOLOGY

south shear was abandoned 14 metres past the split where the shear was 60 centimetres wide. Mineralization within the shear consists of galena, sphalerite and tetrahedrite in the quartz matrix cementing the brecciated wallrock.

Production in 1921 yielded 4665 grams of silver and 1361 kilograms of lead from 3 tonnes of ore.

CAPSULE GEOLOGY

The Big Ben occurrence is located at 1478 metres elevation above sea level, on the north side of Twelve Mile Creek, in the Slocan Mining Division. The occurrence includes the Marble Arch and California showings which are believed to be the extension of the Big Ben occurrence. This occurrence is likely the Silver King, a producer in 1916, operated by J. Koski.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six

CAPSULE GEOLOGY

texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The occurrence consists of a brecciated vein cutting carbonaceous limestone, calcareous argillite and schist of the Slocan Group and a granitic stock of the Nelson intrusions. The vein strikes 070 degrees, dips 67 degrees northwest and is composed essentially of broken wallrock and gouge. The shear has been explored with 3 shafts and 5 adits along 400 metres of strike length.

On the California claim, disseminated galena, sphalerite and pyrite occur along a band of fractured limestone and calcareous argillite. The shear has a maximum width of 6 metres. The shear extends up the slope on the Marble Arch showing where a shallow shaft and two short adits are developed on a quartz-filled shear containing stringers of galena and tetrahedrite. A grab sample of a mineralized stringer assayed 4.8 grams per tonne gold, 13,495 grams per tonne silver and 70 per cent lead (Minister of Mines Annual Report 1926). The wallrock is calcareous schist.

Further up the slope, at the Big Ben occurrence, the vein is 45 to 50 centimetres wide and mineralized with stringers and masses of galena and pyrite in quartz. Here, the vein is hosted within porphyritic granite of the Nelson intrusions.

CAPSULE GEOLOGY

This group of claims was located in 1891 by Messrs. Becker, McLeod, Rossiter and Sandon. Most of the exploratory work on the Montezuma (Lot 2041) and Mexico (Lot 2042) claims was done by the Kaslo-Montezuma Mining & Milling Co. of Seattle in the years 1898-1899. The No. 1 adit, driven 6 metres below the surface outcrop, showed pronounced mineralization along the foot and hanging-wall sections of the zone across widths of from 1.5 to 3 metres. No. 2 adit, 24.3 metres below No. 1, crosscuts to the same lode. A third adit, nearly 92 metres below No. 2 level, reached the lode by a long crosscut and was connected by a raise with the upper workings. Most of the ore was stoped from the upper levels over a maximum length of about 46 metres. Below No. 2 level the ore became lean and formed a more or less chimney-shaped mass. This ore was stoped out without, apparently, discovering further deposits. A mill was built on Keen Creek but it was destroyed by fire shortly after operations at the mine ceased.

The property was taken over by H. Giegerich of Kaslo in 1906. Development work underground was confined to the blocking out of a body of concentrating ore. About 90 tonnes of high grade galena was taken out in the process. The body of concentrating ore was taken out and very little has been done with the property since. A shipment of zinc was made from the mine dump in 1918. During 1950 B.W. Price and J.H. Lassen held a lease on the property. In 1951 Kootenay Belle Gold Mines Ltd. of Vancouver acquired ownership of the property and mined 33 tonnes of ore from the old workings. Operations of this company were suspended in 1952 and the assets taken over by the Canada Trust Company of Vancouver.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

West of the occurrence the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The rocks underlying the Montezuma property are andalusite schist, phyllite, quartzite, calcareous argillite and limestone of the Slocan Group that have been affected by contact metamorphism due to the emplacement of the Nelson intrusions. The sedimentary rocks are folded in a vertical dipping series of isoclinal folds striking northwest and plunging steeply to the south.

Mineralization consists of galena, sphalerite, pyrrhotite and pyrite as replacement in limestone strata. The mineralization is in a chimney-like structure, 15 metres wide and 25 to 30 metres in length, which plunges 70 degrees southeast. The mineralized chimney has been explored with a gloryhole and two short adits. A grab sample from the dump near the portal of the upper adit assayed 446 grams per tonne silver, 12.85 per cent lead and 0.4 per cent zinc. The dump is estimated to contain 475 tonnes of material (Property File - Prospectus, Hilroy Mines Ltd., 1967). A 2 to 3 metre wide feldspar porphyritic dike that cuts the limestone beds near the mineralized chimney contains small amounts of pyrite, chalcopyrite and sphalerite concentrated in quartz veins. A chip sample taken from the mineralized porphyritic dike assayed 46 grams per tonne silver, 0.15 per cent lead and 0.3 per cent zinc across 1.5 metres (Property File - Prospectus, Hilroy Mines Ltd., 1967).

Production from the limestone-hosted mineralization between 1898 and 1951 yielded 1,679,159 grams of silver, 555,491 kilograms of lead and 136,314 kilograms of zinc.

CAPSULE GEOLOGY

The Black Bear occurrence is located at 1019 metres elevation, on the Black Bear Reverted Crown grant (Lot 10783). The Reverted Crown grant lies northeast of the junction of Carlyle Creek with Keen Creek and adjoins the eastern edge of the Liberty, 082FNW093. Kaslo, British Columbia lies 15 kilometres to the east.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been

CAPSULE GEOLOGY

regionally metamorphosed to lower greenschist facies.

Immediately west of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5). The sedimentary sequence has been affected by contact metamorphism from the emplacement of the nearby Nelson intrusions.

In 1920, work by G.B. Gerrard was started on restoring the old workings of the Black Bear occurrence, which included a 10.6-metre shaft, a short crosscut adit below and an opencut above the shaft.

The workings intersected a vein that appeared to follow the bedding of contact metamorphosed, slaty argillites of the Slocan Group on the eastern edge of the Middle Jurassic Mount Carlyle stock. The stock is composed primarily of potassium feldspar porphyritic granite. The vein width varied from 30 to 45 centimetres and hosted galena, pyrite and minor sphalerite mineralization in a quartz gangue. The strike of the vein is 065 degrees and the dip is 67 degrees southeast.

A 48-centimetre chip sample taken near the bottom of the shaft in 1920 yielded 2.74 grams per tonne gold, 181.7 grams per tonne silver, 15 per cent lead and 3.6 per cent zinc (Minister of Mines Annual Report 1920, page 123).

Production records for the Black Bear occurrence indicate 5 tonnes of ore was mined in 1922 from which 1866 grams silver and 944 kilograms lead were recovered.

Cream Minerals Ltd. optioned the property in late 1997. A grab sample assayed 101.2 grams per tonne silver, 7.76 per cent lead, 12.82 per cent zinc, and 0.23 grams per tonne gold (GCNL #182 (September 22), 1998).

CAPSULE GEOLOGY

Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

Immediately west of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5). The sedimentary sequence has been affected by contact metamorphism from the emplacement of the nearby Nelson intrusions.

The Liberty occurrence is located immediately east of the contact between the Mount Carlyle stock of the Nelson intrusions and metasediments of the Slocan Group, which the Liberty occurrence is hosted in. Metasediments include interbedded slate, argillite, andalusite schist and limestone striking north to northeast. Quartz porphyry dikes and sills intrude. The border phase of the potassium feldspar porphyritic granite Mount Carlyle stock is coarse grained hornblende diorite and quartz diorite.

The lowest lode, at about 122 metres above Keen Creek, has been explored by at least two adits. The lode strikes 055 degrees and dips 60 degrees to the southeast. Mineralization intersected consists of streaks and pockets of galena, pyrite, chalcopyrite and sphalerite in a gangue of quartz and siderite. Less than 30 metres vertically above, an adit intersects porphyry and quartzite hosting a mineralized fissure. The fissure strikes northeast and dips 60 degrees southeast. At the face of the adit the lode is 60 centimetres wide and carries pyrite and galena in a gangue of quartz, siderite and brecciated wallrock. Copper staining was observed. Less than 113 metres vertically higher an adit intersects a fissure striking 055 degrees and dipping 75 degrees southeast. Other adits at higher elevations were unsuccessful at finding further mineralization.

Production records for the Liberty occurrence indicate ore was produced in 1899, 1923, 1925 and 1979 totalling 1457 tonnes. This ore yielded 61,193 grams silver, 12,426 kilograms lead, 103,331 kilograms zinc, 976 kilograms cadmium and 717 grams gold.

Cream Minerals Ltd. is exploring the area as the Kaslo Silver property.

CAPSULE GEOLOGY

The Cork-Province mine is situated south of Keen Creek, just west of the mouth of Ben Hur Creek at 1100 metres elevation above sea level, in the Slocan Mining Division. The property includes the Cork and Province Reverted Crown grants (Lots 4883 and 5042).

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast

CAPSULE GEOLOGY

inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

Immediately northwest of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5). The sedimentary sequence has been affected by contact metamorphism from the emplacement of the nearby Nelson intrusions.

Rocks on the property are massive andalusite schist, argillite, quartzite and limestone of the Slocan Group. The rocks strike 070 degrees and dip 80 degrees southeast away from the intrusive contact. Near the occurrence, the Nelson intrusions consist of coarse grained hornblende diorite.

The deposit consists of a fault or shear zone striking 050 degrees and dipping 65 degrees southeast. The shear zone has been developed with at least four adits and a vertical shaft. Within the mine, the shear is up to 2 metres wide and dextral displacement along the vein offsets the beds about 25 metres horizontally. Orebodies have a most pronounced development where the shear intersects limestone beds. Replacement of limestone occurs up to 30 metres from the fault zone and is determined largely by fracture development in calcareous beds. Orebodies have been discovered in at least three separate limestone beds and the most important orebody was found on the boundary between the Cork and Province claims.

The ore occurred as replacement of limestone and consisted of an intimate mixture of sphalerite and galena with small amounts of pyrite and chalcopyrite in a gangue of siderite with some quartz and calcite associated with altered wallrock.

The Cork group of 8 claims was staked for the Silver Star Mining Co. Ltd. in 1900. The Province group, consisting of 6 adjoining claims, was staked in 1902 and Province Mines Ltd. began the development work. For a number of years these two groups were operated as two mines, the Cork and the Province. The Province mine was operated by the Company or by leasers until 1908. The Cork mine closed in 1910 and remained closed the following year although the management was taken over by the West Kootenay Corporation. A shipment of ore, under the name of the Selkirk Mining Co. Ltd., was reportedly made from the Cork mine in 1913.

The two properties were combined in 1914 under the name of Cork-Province Mines Ltd. and its operated intermittently until 1930. Leasers made several small shipments of ore from clean up work on the surface and from underground during the period 1930-1948. In 1949 the property was acquired by Base Metals Mining Corporation Ltd. and operations continued until late in 1953 when the mine was closed and the lower workings allowed to flood.

During the early years of operation, development work was carried out on 5 levels. The main adit (No. 3 level) was driven as a crosscut tunnel for 274 metres. It is connected to No. 1 level by a raise and to Nos. 4 and 15 levels by a 70 degree shaft, which was later deepened to establish a 6th level. In 1952 a vertical shaft was sunk from No. 3 level for 169 metres and Nos. 7 and 8 levels established. These new levels required crosscuts, each about 61 metres long, to reach the vein. Drifts on these two lower levels indicated ore of average mine grade but insufficient work was done to determine its extent.

London Pride Silver Mines Ltd. acquired a 10 year lease on the property in April 1964. During the summer the mine was rehabilitated and the 150 ton mill was put into operation in September. The mine and mill were closed in May 1966, when known reserves were exhausted.

Production from the Cork-Province property between 1900 and 1966 yielded about 16 tonnes of silver, 5846 tonnes of lead, 9033 tonnes of zinc, 69 tonnes of cadmium and 1896 grams of gold from 191,410 tonnes mined.

Cream Minerals Ltd. sampled the property in 1997; a grab sample returned 677.8 grams per tonne silver, 5.68 per cent zinc and 29.54 per cent lead (GCNL #174, 1997). A 4-metre sample from a trench assayed 34.6 grams per tonne silver, 1.09 per cent zinc and 1.28 per cent lead (GCNL #230, 1997). In the Cork South trench, about 50 metres southwest of the mine workings, an 11-metre sample assayed 112.8 grams per tonne silver, 5.36 per cent zinc and 2.85 per cent lead (GCNL #230, 1997). A drill hole intersected 21.1 metres grading 209.27 grams per tonne silver, 6.02 per cent lead and 8.09 per cent zinc (GCNL #13, 1998). The mineralization is hosted in a carbonate rock that represents the down-dip extension of mineralization

CAPSULE GEOLOGY

uncovered in the trench. The zone has an interpreted true thickness of 6 to 7 metres with a weighted average grade of 179.52 grams per tonne silver, 5.12 per cent lead and 7.33 per cent zinc (GCNL #13, 1998). The mineralized shear has been traced for about 3 kilometres in a northeast direction.

Cream Minerals Ltd. is exploring the area as the Kaslo Silver property. See Black Bear (082FNW092), Black Fox (082FNW093), Bismark (082FNW096), Wintrop (082FNW097), Silver Bear (082FNW100), Index (082FNW101), Gold Cure (082FNW185) and Silver Bell (082FNW186).

CAPSULE GEOLOGY

The Black Fox occurrence is located at 1128 metres elevation on the southeastern side of Keen Creek, between Ben Hur and Briggs creeks. Kaslo, British Columbia is located 16 kilometres to the east.

The Black Fox occurrence is located on ground covered by the Black Fox Group, consisting of Daisy (Lot 2175), Black Fox (Lot 2176) and California (Lot 2177) Crown grants. Other claims also historically related to the Black Fox occurrence include the Ainsworth Fraction, Patrick and E.G. 1 to 12.

The Daisy claim was first located and worked in the 1890s. The Black Fox claim was added in 1898. During the 1890s, about 305 metres of drifting, crosscutting and shaft sinking was completed, mainly on the Daisy and California claims. This work was done by the Black Fox Mining Company. Operations ceased after exploration efforts directed towards lead-silver ore was never found. In 1951, the adit was reopened and mining commenced until 1953. Another 183 metres of drifting was done on the A and D veins, with drifting and overhand stoping of the A vein and a raise connecting to the old shaft. Mining was also carried out in 1960 and 1961 by the New Ainsworth Base Metals Ltd. In 1961, the main drift was extended north-south along the main lode. Other work included diamond

CAPSULE GEOLOGY

drilling to test the potential of vein to the east and a geophysical survey.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

Immediately north of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5). The sedimentary sequence has been affected by contact metamorphism from the emplacement of the nearby Nelson intrusions.

The Black Fox occurrence is hosted in argillite of the Slocan Group. Contact metamorphism has altered argillite to andalusite schist. The Middle Jurassic Mount Carlyle stock comprised of potassium feldspar porphyritic granite lies immediately to the northwest.

The veins at the Black Fox occurrence are banded and fissure hosted, the larger veins showing evidence of considerable faulting and shearing. Vein widths vary from a few to 60 centimetres, generally occurring concordant with bedding of the Slocan metasediments. The general strike of these veins is 060 degrees and the dip 65 degrees to the southeast. Quartz, minor siderite and sheared hostrock carry varying amounts of irregularly distributed sphalerite, galena and pyrite with minor silver and gold.

The largest of these veins occurs in the northwest corner of the Daisy claim. It is referred to as the main lode and has a maximum width of 3 metres and has been traced for about 61 metres on surface. A second lode, intersected in the crosscut, outcrops on surface north of the main lode, 30 metres south of and 23 metres vertically above the crosscut portal. The vein is 1.4 metres wide, strikes 052 degrees and dips 70 degrees to the southeast.

The old shaft intersected the California vein which has a strike almost perpendicular to the others and is reported to have contained some good ore.

Production records for the Black Fox occurrence show 886 tonnes of ore produced in 1951, 1952 and 1961. Recovery totalled 53,777 grams silver, 187 grams gold, 74,440 kilograms zinc, 5800 kilograms lead and 41 kilograms cadmium.

Cream Minerals Ltd. acquired the property in 1998. Grab samples assayed high in silver, lead and zinc.

Lead	1.5800	Per cent
Zinc	17.1000	Per cent

COMMENTS: Sample 1177, a 0.4-metre chip sample taken from the lower adit.

REFERENCE: Assessment Report 8437.

CAPSULE GEOLOGY

The Bismark occurrence is located at 1860 metres elevation on the east side of Briggs Creek, a tributary to Keen Creek. Kaslo, British Columbia lies 16 kilometres to the east.

The Bismark occurrence is located on the Bismark Claim Group, consisting of the Bismark (Lot 11273), Mountain Goat (Lot 11274) and Highland Laddie (Lot 11275) Crown grants and previously included the Black Bear claim.

The Bismark property was first staked in 1898 and then worked intermittently until 1910. In 1926, J.A. McKay began to reopen the mine, however, the work was never completed. Consolidated Mining and Smelting Co. Ltd. optioned the property in 1928. Their option was dropped after doing some exploration work. The early workings of the Bismark occurrence include three adits over a vertical range of 122 metres. B.C. Metals Mines Ltd. was formed in 1951 to develop the Bismark occurrence, now consisting of 8 claims. A contract was signed with Columbia Diamond Drilling Co. to explore the workings at depth but further records of the program and/or results are unknown. In 1957, the property was acquired by Castle Oil and Gas Ltd. In 1980, the property was examined by E. Denny, the owner, and Hudson Bay Exploration and Development Company Limited. An extensive sampling program was undertaken of surface outcrops and the lower adit. Greenwich Resources Inc. undertook an exploration program on the Bismark property in 1984, consisting of rock, silt and soil geochemistry, and a ground electromagnetic survey. Cream Minerals Ltd. sampled the property in 1997; a 60-centimetre chip sample assayed 2134.5 grams per tonne silver, 26.36 per cent zinc and 0.27 per cent lead (GCNL #174, 1997). A hole drilled in 1998 intersected 9.3 metres of 313.7 grams per tonne silver, 0.73 per cent lead and 0.92 per cent zinc (Northern Miner, May 3, 1999). The property is along a 25 to 80-metre northeast-trending shear zone that has been traced for 3.7 kilometres.

Hostrocks of the Bismark occurrence are Triassic Slocan Group sediments southwest of the Mount Carlyle stock, a satellite stock of the Middle Jurassic Nelson intrusions and about 600 metres northwest of the Nelson batholith. The stock and the Nelson batholith in the area are composed of potassium feldspar porphyritic and hornblende potassium feldspar porphyritic granite, respectively. The Slocan Group on the property consists of a sequence of well-bedded argillite, silicic sandstone and recrystallized limestone. Andalusite schist occurs locally, a result of contact metamorphism. Slocan Group metasediments strike 235 degrees and dip 70 degrees to the northwest. They are crosscut by a few dikes.

Mineralization is stratabound, along bedding-parallel faults and fractures and have formed partly by replacement of one or more limestone beds. Early reports and maps indicate that a shoot of oxidized lead ore, about 9 metre long, was exposed on surface and underground in the uppermost (No. 1) adit and persisted in chimney-shaped form to the No. 2 level 34 vertical metres below. The shoot intersected near the face of the No. 3 level is probably the downward extension, an additional depth of 72.5 metres. Here, the shoot is 60 centimetres wide. At a crosscut 41 metres from the portal, the lode was about 90 metres wide. At surface, the lode is 1.0 to 1.2 metres wide, consisting of calcite with bunches of galena, minor quartz and pyrite, all considerably oxidized. The best samples taken during the 1980 exploration program were Sample 1177 and Sample

CAPSULE GEOLOGY

22297. Sample 1177 was a 0.4 metre chip sample taken from the lower adit in a zone of fine sphalerite. It yielded 2040 grams per tonne silver, 17.1 per cent zinc and 1.58 per cent lead (Assessment Report 8437). Sample 22297, a 0.3 metre chip sample across a zone of galena, was taken from the raised stope to surface and yielded 1241 grams per tonne silver, 3.08 per cent lead and 1.98 per cent zinc (Assessment Report 8437). The southwest strike extension of mineralization outcrops at the Gold Cure claims (082FNW185).

Production records for the Bismark occurrence indicate nearly eleven consecutive years of production from 1898 to 1910. During this time, 868 tonnes of ore were produced from which 2,484,321 grams silver and 43,250 kilograms lead were recovered.

Cream Minerals Ltd. is exploring the area as the Kaslo Silver property. See Black Bear (082FNW092), Cork-Province (082FNW094), Black Fox (082FNW095), Wintrop (082FNW097), Silver Bear (082FNW100), Index (082FNW101), Gold Cure (082FNW185) and Silver Bell (082FNW186).

CAPSULE GEOLOGY

The Wintrop occurrence is located at 1554 metres elevation on the east side of Klawala Creek, a southeastern tributary to Keen Creek. Kaslo, British Columbia is located 18 kilometres to the east.

The Wintrop occurrence is also historically part of the former Gibson (until 1923) or Daybreak claim group. The main claims of this group are the Butte (Lot 12410) and Wintrop (Lot 12409) Crown grants.

The first shipments of ore from the occurrence were in 1896 and 1897 by the Gibson Mining Co. No further work was done until 1917 when D.K. May began more development work, which by this time consisted of about 914 metres of drifts on four levels over 122 vertical metres. In 1918, litigation proceedings forced the operation to close and a forest fire destroyed the camp in 1921.

The Daybreak Mining Co. reopened the mine in 1924 which operated intermittently until 1928 when further litigation forced the mine to close a second time. Leasers made small shipments of ore in 1935. The property remained idle until 1949 when the portals were reopened. In 1957, the Daybreak Mining Corp. (1952) Ltd. reopened the workings but no further work was reported. The total workings consisted of five adits between 1548 and 1661 metres elevation. Cream Minerals Ltd. sampled the property in 1997. The property is along a 25 to 80-metre northeast-trending shear zone that has been traced for 3.7 kilometres.

Hostrocks are primarily abundant pure limestones and calcareous argillites together with quartzites of the Triassic Slocan Group. Metasediments, biotite schists and psammites of the Slocan Group are also locally developed adjacent to the Middle Jurassic Nelson batholith to the southeast and the Mount Carlyle stock to the northwest. The Nelson batholith is composed of hornblende potassium feldspar porphyritic granite while the Mount Carlyle stock is composed of potassium feldspar porphyritic granite.

The Wintrop occurrence occupies a bedding parallel, northeast striking, steeply dipping lode structure in the Keen Creek metasedimentary reentrant. Mineralization is chiefly wallrock replacement and better developed where lodes crosscut calcareous horizons.

Five adits explore two parallel structures, the A and B lodes. The lodes are about 100 metres apart, strike 225 degrees and dip 75 degrees northwest and are roughly concordant with bedding. The A lode is a sheared and brecciated zone, 0.6 to 1.5 metres wide, comprised of cataclastic and fault gouge. Mineralization comprises disseminated sphalerite, galena and pyrite in a siderite and quartz gangue. Hematite is also present. The B lode consists of cubic and banded galena, mixed galena and sphalerite, pyrite and minor chalcopryrite in a gangue of hematite and brecciated hostrock. A third or C lode outcrops about 76 metres to the southeast of the B lode and has not been prospected to any great extent.

Production records for the Wintrop occurrence indicate 613 tonnes of ore have been mined intermittently from 1895 to 1935. From this ore, 367,388 grams silver, 103,771 kilograms lead, 53,318 kilograms zinc and 62 grams gold have been recovered.

A grab sample from the dump taken in 1987, assayed 490 grams per tonne silver, 0.22 gram per tonne gold, 0.18 per cent copper, 19.2 per cent lead and 15.8 per cent zinc (Open File 1988-11).

CAPSULE GEOLOGY

The Nome occurrence is located near the headwaters and on the east side of Klawala Creek, a tributary of Keen Creek. The occurrence lies in Kokanee Glacier Provincial Park, about 17 kilometres southwest of Kaslo, British Columbia.

Workings at the Nome occurrence include two adits about 61 vertical metres apart.

The underlying hostrock is hornblende potassium feldspar porphyritic granite of the Middle Jurassic Nelson batholith. Several basic dikes were also noted crosscutting granite.

Mineralization occupies a shear zone about 1.2 metres wide. The shear zone strikes 194 degrees and dips 48 degrees to the northwest. The lower adit explored this shear zone. A quartz vein hosted in this shear contained disseminated pyrite and minor galena and sphalerite were noted. The pyrite is partially oxidized near the surface.

CAPSULE GEOLOGY

The BNA occurrence is located east of Kyawats Creek, 750 metres south of its confluence with Keen Creek. Kaslo, British Columbia is about 20 kilometres to the northeast.

The BNA occurrence is covered by the BNA claim group, consisting of the BNA (Lot 5994), Humming Bird (Lot 5995), Onoka (Lot 5997) and Lynx Fraction (Lot 5996) Crown grants. The claims were Crown granted to the B.N.A. Mines Co. in 1904. The property was worked on a small scale from 1904 to 1911 and then lay idle until 1950. B.N.A. Mines Limited Liability owned the property in 1950. In 1950 and 1951, a small amount of surface stripping was done above the No. 6 adit and a raise was driven in the No. 6 adit, 62 metres from the portal.

The occurrence occupies a narrow belt of Triassic Slocan Group metasediments within the Keen Creek reentrant. Metasediments, in order of importance, include argillite, quartzite, biotite schist, limestone and siltstone. Slocan lithologies are flanked by potassium feldspar porphyritic granite of the Middle Jurassic Nelson batholith and hornblende potassium feldspar porphyritic granite of the Middle Jurassic Mount Carlyle stock.

Mineralization occupies a bedding-parallel breccia lode structure. The strike of the lode is 045 degrees and the dip 85 degrees to the southeast. The lode width varies from 1.5 to 7.6 metres. Mineralization is chiefly argentiferous galena, sphalerite and minor native silver replacements of wallrock or open-space fillings in a calcite and minor quartz gangue.

Production records for the BNA occurrence indicate 173 tonnes of ore produced intermittently from 1900 to 1981. Recovery totalled 475,442 grams silver, 197 grams gold, 11,484 kilograms lead and 11,361 kilograms zinc.

CAPSULE GEOLOGY

The Silver Bear occurrence is located at 1460 metres elevation midway between Desmond and Kyawats creeks, southeast of Keen Creek. The ground was covered by the former Silver Bear claim group, composed of the former Silver Bear and Broughton Crown grants. Kaslo, British Columbia is located 22 kilometres to the northeast.

Work began on the Silver Bear occurrence in 1919. During this year the claim was worked by the owners of the neighbouring Silver Bell occurrence (082FNW187). The claim was acquired by M.S. Davys in 1920 and worked intermittently until 1927. The following year, F. Helme acquired the property and also worked it intermittently until 1943. In 1951, a lease was granted to S. Hallgren, who in turn sub-leased the property for two years. Abacot Mines Ltd. acquired the Silver Bear and Broughton claims in 1953. The lowest level was restored and a small shipment of ore was reported made before the mine shutdown. N.E. Cloggie acquired ownership in 1956 and made a shipment of ore mined in the previous year. Cream Minerals Ltd. sampled the property in 1997 and reported up to 4536.5 grams per tonne silver, 6.20 per cent zinc and 15.59 per cent lead (GCNL #167, 1997). A 35-metre trench sample assayed 221.5 grams per tonne silver, 2.40 per cent zinc and 1.57 per cent lead (GCNL #230, 1997).

The Silver Bear shear zone has been traced for 1.2 kilometres. It averages 25 metres in width and hosts 3 sub-parallel mineralized bands. This shear may be the southern extension of the Gold Cure shear zone (see 082FNW096, 097, 185). Eight diamond drill holes were completed in 1998.

The property is developed by six adits, three or more intermediate levels and several opencuts. Underground workings aggregate over 914 metres. The principal workings are three crosscut adits that explore the main lode over a vertical range of 104 metres.

The Silver Bear occurrence occupies a narrow belt of Triassic Slovan Group metasediments within the Keen Creek reentrant. Metasediments, in order of importance, include slate, carbonaceous argillite, limestone, siltstone and biotite andalusite schist. Slovan lithologies are flanked by hornblende potassium feldspar porphyritic granite of the Middle Jurassic Nelson batholith and potassium feldspar porphyritic granite of the Middle Jurassic Mount Carlyle stock.

Two nearly parallel mineralized lodes, 24 metres apart, comprise the Silver Bear occurrence. These lodes have a general strike of 045 degrees and a dip of 65 degrees to the southeast. Each lode is composed of quartz-calcite-siderite veins in brecciated and crushed wallrock along the contact of slate and limestone that are part of a band of Slovan sediments with synclinal dips away from flanking granitic intrusions of the Nelson batholith. Galena, sphalerite, pyrite and silver-bearing sulphides occur as irregular replacements in limestone. The main or "footwall" lode has been traced for over 305 metres in underground workings. Most of the work has been done on the west or "footwall" lode. The hangingwall is marked by a heavy clay gouge. Most of the production has come from between the No. 2 level and surface. The main shoot had a maximum length on the No. 2 level of about 27 metres. The east or "hangingwall" lode is similar in character to the "footwall" lode but significant mineralization was not discovered. A third lode is intersected by an old adit six metres above the No. 1 crosscut adit and has been only lightly prospected.

A total of 459 tonnes of ore have been mined from the Silver Bear occurrence producing 791,074 grams silver, 93 grams gold, 10,213 kilograms lead and 8910 kilograms zinc.

Hornfels

CAPSULE GEOLOGY

The Index occurrence is located at 1219 metres elevation between Desmond and Kyawats creeks, southeast of Keen Creek. Kaslo, British Columbia is located 22 kilometres to the northeast.

The Index occurrence was first located in 1905 by F. Helme. The property was worked intermittently until 1918. Index Mining Co. held the property under bond in 1919, with plans to extend the lower adit to intersect a mineralized vein at depth. Operations were terminated in 1920 without the vein being intersected. In 1948, the property was re-staked by Kaslo Silver-Lead Co. Thirteen claims were held which included the old Index and Metropolitan workings. A small vein was exposed by surface trenching. Property ownership was transferred to Kaslo Base Metals Ltd. in 1951, with acquisition of an additional claim and two fractional claims. The lower adit was extended in a southeast direction for 246 metres without intersecting the mineralized zone of the upper adits. In 1969, Andex Mines Ltd. acquired the Index property and surrounding ground. A total of 642 metres of surface trenching and 70 metres of surface diamond drilling

CAPSULE GEOLOGY

in four holes were conducted. Further trenching was done by Andex Mines Ltd. in 1971. In 1972, trenching and 13.7 metres of rotary drilling in nine holes were done. Workings consist of three adits, totalling 396 metres. Workings of the Metropolitan lie about 305 metres above the Keen Creek road and consist of two adits of unknown length. Cream Minerals Ltd. sampled the property in 1997; a grab sample assayed 158.1 grams per tonne silver, 10.53 per cent zinc and 4.38 per cent lead (GCNL #174, 1997).

The Index occurrence occupies a narrow belt of tightly folded and contact metamorphosed Triassic Slovan Group metasediments within the Keen Creek reentrant. Metasediments, in order of importance, include slate, carbonaceous argillite, limestone, siltstone and biotite andalusite schist and are crosscut by several feldspar porphyry dikes and sills. Lithologies are flanked by hornblende potassium feldspar porphyritic granite of the Middle Jurassic Nelson batholith and potassium feldspar porphyritic granite of the Middle Jurassic Mount Carlyle stock.

A mineralized crush zone carries pockets and narrow veins of quartz and minor siderite with variable galena, sphalerite, arsenopyrite and pyrite. The zone strikes 125 degrees and dips 85 degrees to the southwest.

A total of 20 tonnes of ore is recorded mined intermittently from the Index occurrence. From this, 39,345 grams silver, 8863 kilograms lead and 1894 kilograms zinc were recovered. Production was from the upper two adits of the Index occurrence.

CAPSULE GEOLOGY

The Gluepot occurrence is located at 1524 metres elevation, northwest of Keen Creek and southwest of its junction with the Long Creek tributary. Kaslo, British Columbia lies about 19 kilometres to the east.

Workings of the Gluepot occurrence consist of a 55-metre long adit, driven along a shear zone hosted in coarse-grained diorite of the Middle Jurassic Nelson batholith. The shear zone is about 1.2 metres wide, strikes 235 degrees and dips 70 degrees to the northwest. A lamprophyre dike follows the hangingwall of the shear zone and an acidic dike the footwall. A number of opencuts prove a strike length of the shear zone of up to 61 metres.

A 15 centimetre or less quartz vein is hosted in this shear zone, and carries a little pyrite and a disseminated silver-bearing mineral, probably tetrahedrite.

CAPSULE GEOLOGY

The Fairmont occurrence is located 1 kilometre southeast of Fishermaiden Lake in the headwaters of Silverton Creek. Kaslo, British Columbia lies about 26 kilometres to the east.

Workings at the Fairmont occurrence consist of an upper incline adit, exploring the "Fairhope" lode and a 366-metre drift exploring the "Fairmont" lode. In 1935, the property was owned by W. Valetine.

Hostrocks of the Fairmont occurrence are coarse grained porphyritic quartz monzonite of the Middle Jurassic Nelson batholith.

The "Fairhope" and "Fairmont" lodes are roughly parallel. They have a strike of 025 to 030 degrees and a dip of 50 degrees to the southeast. The "Fairmont" lode has received the majority of exploration. The lode is stated to be traceable on surface for 942 metres. In an opencut 91 metres above the "Fairmont" adit, the lode is 3.6 metres wide and composed of 1.8 metres of gouge and a 1.2 metre wide quartz vein. The vein hosts sphalerite, galena, considerable pyrite and some argentite. The lower adit follows a remarkably straight lode. Mineralization is irregular along the lode and consists of pyrrargyrite, pyrite with minor galena and sphalerite.

CAPSULE GEOLOGY

The Christina (Lot 10596) and the adjoining Virgel (Lot 10595) reverted crown granted claims are located just south of Paupo Mountain, at about 2300 metres elevation, 17 kilometres northeast of the town of Slocan. Access to the property is by trail from a point one kilometre west of Paupo Creek on the Enterprise Creek road. The property lies in Kokanee Glacier Provincial Park.

The property was staked near the turn of the century by M. Murphy who did considerable surface prospecting and drove a couple of short adits. This work has explored a northerly trending fissure-vein lode hosted by a coarse grained, porphyritic phase of the Nelson batholith. The lode is narrow but persistent and somewhat like that on the Para claim (082FNW105) to the west. The vein is filled with quartz and a small amount of galena, pyrite and high grade silver minerals. Good silver values are reported to have been obtained at intervals on the vein which has been traced for more than 90 metres.

A grab sample taken in 1987, analysed 5.9 grams per tonne silver, 0.01 per cent lead and 0.19 per cent zinc (EMPR Paper 1989-5, page 21).

CAPSULE GEOLOGY

This property, comprising two claims, is situated at the head of Paupo Creek, a tributary of Enterprise Creek. The property lies in Kokanee Glacier Provincial Park.
 An adit drive along the strike is in about 76 metres, and if continued for a few metres further would strike daylight on the other side of the ridge. An 18-metre raise has been driven 48 metres from the portal. From these workings some 15 tonnes of ore has been extracted; of this, 6 tonnes was shipped in 1904. A sample taken across a width of 10 centimetres at the face of the tunnel ran 2.74 grams per tonne gold, 634.3 grams per tonne silver and 1.5 per cent zinc. A sample across a width of 10 centimetres in a small stope near the end of the tunnel ran 0.69 gram per tonne gold, 2005 grams per tonne silver, and 1.5 per cent zinc. A grab sample from a 9-tonne pile of sorted ore for shipment ran 0.69 gram per tonne gold, 4063 grams per tonne silver, and 4 per cent zinc (Annual Report 1919, page 131).
 Country rock is coarse-grained potassium feldspar porphyritic

CAPSULE GEOLOGY

granite. The vein occupies a fault-fissure, striking north 10 degrees west which varies in width up to a metre. The hangingwall is well defined and marked by 15 centimetres of gouge-argillic alteration. Mineralization includes pyrite, sphalerite, and galena in a quartz gangue. Tetrahedrite and pyrargyrite have been reported. Quartz vein is banded, alternating white and grey quartz containing disseminated pyrite.

A grab sample of dump material taken in 1987 assayed 1750 grams per tonne silver, 1 gram per tonne gold, 0.03 per cent copper, 2.16 per cent lead and 36.5 per cent zinc (Open File 1988-11).

CAPSULE GEOLOGY

This property, comprising the Revenue (Lot 7139), Revenue Fraction (Lot 7141), Birthday (Lot 7138) and Tamarac (Lot 7140) Crown-granted claims, lies on the north slope of Sturgis creek, an eastern tributary of Keen creek. It is accessible by the road up Keen creek from Zwicky and thence by trail for 4 kilometres up the valley of Sturgis creek. The property was acquired from the original owners by the Sturgis Creek Mines, Limited. The Revenue property lies within Kokanee Glacier Provincial Park.

Production in 1913, 1914, and 1916, amounted to 61 tonnes of silver-lead ore carrying an average of nearly 2640 grams per tonne silver and 54 per cent lead. In 1928 a further production of about 36 tonnes was reported.

The workings consist of four adits and some surface cuts. These explore a lode on a strike of north 15 degrees east and a dip varying from a high angle to the west to vertical. In June 1927, the underground workings aggregated over 180 metres of tunnelling.

A quartz filled fissure occurs in a strong shear-zone in rocks of the Nelson Batholith, carrying disseminations and concentrations of galena and sphalerite. The vein is 150 centimetres wide.

Sphalerite-rich layers and pods in quartz veins with patches of galena. Disseminated and massive pyrite in the veins. Limonitic fractures parallel the vein across a zone less than 3 metres wide.

Production from 1913 to 1941 totalled 246 tonnes yielding 676,832 grams silver, 217 grams gold, 78,776 kilograms lead and 20,679 kilograms zinc.

CAPSULE GEOLOGY

The property is located at 2580 metres elevation in the pass on the west side of Sunrise Mountain some 40 kilometres north-northeast of Nelson. Early access was by way of a trail up Silver Spray Creek, a tributary of Woodbury Creek. The property lies within Kokanee Glacier Provincial Park.

The Violet and Lookout claims were owned in 1921 by Dr. John Henry and J.M. Currie, of Ainsworth. Development work to that date had been done in two adits: a 15-metre drift adit on the vein, and 18 metres vertically below, a crosscut adit with hanging wall drift totalling 33.5 metres. Near the extremity of the lower adit a raise was driven to the upper adit.

By 1926 the property was owned by Dr. John Henry, W.G. McLanders, and Dan McLennan. Some activity was reported each year until 1931 but details are lacking.

Underlying rock is coarse-grained hornblende potassium-feldspar porphyritic granite. Mineralization occurs within an argillic, altered and silicified northeast trending shear zone situated in the

CAPSULE GEOLOGY

divide between Sunrise Mountain and Mount McQuarrie. Sulphides include galena, pyrite, lesser sphalerite, and "freibergite and silver sulphides (Cairnes, 1935)" in a much altered silicified fault zone.

A grab sample of dump material taken in 1987 assayed 7000 grams per tonne silver, 0.49 gram per tonne gold, 0.13 per cent copper, 16.4 per cent lead, and 3.4 per cent zinc (Open File 1988-11).

CAPSULE GEOLOGY

The Cable property lies northwest of Mount Woodbury, within Kokanee Glacier Provincial Park. Underlying rocks are hornblende potassium feldspar porphyritic granite. Trenches expose a 2.0 metre wide argillic altered fault zone which contains a 0.8 metre quartz vein. The footwall is defined by a fine-grained fractured and altered lamprophyre dyke. Alteration extends 0.6 metre into the hangingwall. Mineralization is restricted to sparsely disseminated pyrite. Values in silver, platinum, and traces of gold are reported from Cairnes, 1935, but have not been duplicated. A grab sample taken in 1987 analyzed 9.0 grams per tonne silver, 0.05 gram per tonne gold and 0.01 per cent zinc (Open File 1988-11).

CAPSULE GEOLOGY

This group of claims is located on Silver Spray creek, a south-east flowing tributary of Woodbury creek. A road, 4.8 kilometres long, was built to the property from a point on Woodbury creek, 14.4 kilometres from the Nelson-Kaslo highway. The property lies on the eastern edge of Kokanee Glacier Provincial Park.

During 1901-02 development work on the Baltimore group, then owned by Wm. English of Kaslo, amounted to a 43-metre tunnel on the vein and a 15-metre shaft.

The Baltimore claim was Crown-granted to G.H. Davison in 1903 and was operated through 1907 along with 5 other claims, the Chance Frac., Maple Leaf, Grafton, Foothill and Nipper. In 1930 English Bros. of Kaslo prospected the property but did not re-open the mine.

The mine lay idle from 1907 until 1952 when it was re-opened by Victoria Lines Ltd. of Calgary. This Company acquired the Baltimore

CAPSULE GEOLOGY

claim; the Grafton and Maple Leaf Crown-granted claims optioned from W. English of Kaslo; the Granite Crown-granted claim leased from the Crown; the Connection and Foothill recorded claims leased from W. English; the C.K. group of 3 recorded claims. In 1953 about 47 metres of drift was completed. The property by this time had been developed by 5 adits between the 1830 and 1980 metre elevations. Most of the work prior to 1907 was done in the upper 3 adits, which are now largely inaccessible. No. 4 adit is a drift on the vein 3 metres long. No. 5 adit, 91.4 metres lower and 152.4 metres west of the upper workings, is about 69 metres long. The vein at the portal was about 27 centimetres wide but narrowed to a crack only about a metre inside.

Victoria Mines Ltd. was struck from the register in 1957.

Country rock is hornblende potassium feldspar porphyritic granite. Muscovite - biotite schists and psammite occupy sections of hangingwall and/or footwall of the vein.

The vein, which has been traced along the surface for over 100 metres, occupies a strong east-west, north-dipping shear structure. Mineralization includes pyrite, galena, plus or minus sphalerite, and silver minerals in a quartz gangue. A sample of the vein assayed 2600 grams per tonne silver, 1.1 grams per tonne gold, 1.24 per cent lead, 1.4 per cent zinc and 0.0577 per cent copper (Open File 1988-11).

Intermittent production from 1902 to 1954 totalled 60 tonnes, yielding 352,025 grams silver, 31 grams gold, 5,609 kilograms lead and 131 kilograms zinc.

CAPSULE GEOLOGY

The Ontario No. 2 reverted Crown granted claim (Lot 3182) is located 4 kilometres southwest of Woodbury Mountain, 29 kilometres east-northeast of the town of Slocan. Access to the property is by road and trail up Woodbury Creek to Silver Spray Creek and thence 1.6 kilometres west-northwest to the top of the ridge - a total distance of 17 kilometres west of Kootenay Lake. The property lies in Kokanee Glacier Provincial Park.

Production from this property, consisting mostly of hand cobbled ore, began in 1907 and continued intermittently through 1921. Total

CAPSULE GEOLOGY

production was 161 tonnes, yielding 1743 kilograms of silver, 31 grams of gold and 15,854 kilograms of lead.

The workings include two adits connected by a 30-metre raise and stopes, comprising about 460 metres of underground development. These and other small workings explore a 1 to 10-metre wide shear zone in porphyritic Nelson granite. The lode strikes 075 degrees and dips 55 to 75 degrees northwest. Where visible, the deposit consists of gouge, crushed wallrock, quartz and ore minerals. The quartz is commonly banded and forms lenses of varying width. The ore minerals consist of massive and disseminated galena, pyrite and silver-bearing sulphides in the quartz that cements and replaces the shattered fragments of wallrock. Alteration of wallrock includes chlorite, limonite and sericite.

A vein sample taken in 1987 assayed 690 grams per tonne silver, 0.3 gram per tonne gold, 0.59 per cent lead and 0.0323 per cent zinc (Open File 1988-11).

CAPSULE GEOLOGY

The property is located between elevations of 1700 and 2130 metres astride Pontiac Creek, a northerly flowing tributary of Woodbury Creek, some 35 kilometres northeast of Nelson. The claims, which include the Pontiac, Scranton (082FNW112) and Sunset (082FNW113), lie within Kokanee Glacier Provincial Park, 1 to 2 kilometres from the eastern boundary.

A series of quartz veins striking northeastward are exposed at intervals for a distance of about 2135 metres. Most of the early exploration work on this vein system was done at its extremities and comprised the Pontiac workings at the northeasterly end and the Sunset workings at the southwesterly end. Following the consolidation of the property in 1930 development work was carried out at lower elevations in the mid section of the property on the Scranton claim on the east side of Pontiac creek (known as the Lower Pontiac workings), and in the "Sunset" workings on the Grandview Fr. claim on the west side of the creek.

The first reported activity and first production from the Pontiac claim was recorded in 1898. The Pontiac (Lot 2265) and Tecumsie (Lot 2261) claims were owned in 1899 to Messrs. Heap and Heath of Ainsworth. That same year the claims were acquired by, and Crown-granted to, Nelson-Slocan Prospecting and Mining Company, Limited Liability. Considerable development work was carried out during 1900-1904 under the management of C.F. Caldwell. During this period underground exploration and development was done over a length of 122 metres and depth of 58 metres in 3 adits.

The first reported activity at the southwesterly end of the vein system was in 1899 when Woodbury Mines, Limited, carried out development work on the Sunset Group.

CAPSULE GEOLOGY

Activities at the various workings ceased in about 1908 and some of the claims were subsequently acquired by C.F. Caldwell. The Pontiac and Tecumsie claims were owned in the 1920's by Alice G. Caldwell and the estate of W.C. Chaplin.

In 1930 Hon. J.D. Chaplin, C.F. Caldwell, T. Doyle and J. Henry, owners of the various claim groups, gave an option to purchase the Scranton Consolidated Mining Company which was incorporated in Portland, Oregon to consolidate and develop the property. Investigation of the Scranton claim began but little was accomplished until 1939-40 when the main workings on the Scranton claim (lower Pontiac workings) were driven. A new company Scranton Mines Limited, was incorporated in August 1951 to acquire the 14-claim property. A new adit about 30 metres long was driven 15 metres below the old Pontiac workings.

Blue Star Mines Limited optioned the property in 1964 and carried out stripping and diamond drilling on the Scranton claim and extended the lower Pontiac adit.

No further activity was reported until 1967 when exploration was begun in a new adit at the 1800-metre elevation on the west side of Pontiac creek at the southeast edge of the Grandview claim. Silver Star Mines Ltd. acquired the property from Blue Star Mines and Scranton Mines through a stock transaction. A new adit was begun in 1968 at the 1737-metre elevation to explore the downward extension of mineralization in the 1800-metre level; drifting, raising and stoping was carried out on both levels. Some ore was shipped to the Blue Star mill at Ainsworth. Stoping of ore proved uneconomical and the operation was shut down in 1970.

Country rock is hornblende potassium feldspar porphyritic granite within inclusions of biotite-grade metasediments and quartzites.

The Pontiac occupies the northeast end of the Pontiac-Scranton-Grandview-Sunrise vein system. The vein strikes between 25 and 45 degrees northeast. Vein material consists of quartz and calcite mineralized with blebs and stringers of galena, sphalerite, and finely disseminated pyrite. A sample taken in 1987 from the Pontiac lower portal assayed 41 grams per tonne gold, 220 grams per tonne silver, 12.3 per cent lead and 5.6 per cent zinc (Open File 1988-11).

Intermittent production from 1898 to 1970 totalled 1160 tonnes yielding 592,948 grams silver, 6,191 grams gold, 74,395 kilograms lead and 4,398 kilograms zinc.

CAPSULE GEOLOGY

the various workings ceased in about 1908 and some of the claims were subsequently acquired by C.F. Caldwell.

In 1930 Hon. J.D. Chaplin, C.F. Caldwell, T. Doyle and J. Henry, owners of the various claim groups, gave an option to purchase the Scranton Consolidated Mining Company which was incorporated in Portland, Oregon to consolidate and develop the property. Investigation of the Scranton claim began but little was accomplished until 1939-40 when the main workings on the Scranton claim (lower Pontiac workings) were driven. These comprised two adits, less than 9 metres apart vertically, the upper containing about 550 metres of drifts and crosscuts, the lower being a 122-metre long drift. The levels were connected by two raises and a sublevel was driven from a winze. Little further worthwhile work was done until 1949 when a new adit was begun on the Scranton claim. During subsequent years the adit was driven 91 metres northeasterly with a raise to the adit above, and a 23-metre winze and 44 metres sublevel below.

A new company, Scranton Mines Limited, was incorporated in British Columbia in August 1951 to acquire the 14 claim property; the company head office remained in Portland, Oregon. On the west side of Pontiac creek, on the Grandview Fr. claim, the "Sunset" drift adit, which was begun in 1950, was driven southwesterly at about the 1737-metre elevation. By the end of 1952 the workings comprised about 268 metres of drifts and crosscuts and a 23-metre winze. In 1953 diamond drilling in 11 holes totalling 548.6 metres was done to determine the vein extension on the Sunrise claim. Little further activity took place until 1960-61 when an additional 30 metres of drifting and crosscutting and 43.5 metres of underground diamond drilling was carried out in the Scranton workings. A new adit about 30 metres long was driven 15 metres below the old Pontiac workings.

Blue Star Mines Limited optioned the property in 1964 and carried out stripping and 209.3 metres of diamond drilling on the Scranton claim and extended the lower Pontiac adit an additional 79 metres.

No further activity was reported until 1967 when exploration was begun in a new adit at the 1800-metre elevation on the west side of Pontiac creek at the southeast edge of the Grandview claim. The adit was driven as a crosscut for 30.4 metres, intersecting a strong quartz vein which was drifted on. Silver Star Mines Ltd. acquired the property from Blue Star Mines and Scranton Mines through a stock transaction. A new adit was begun in 1968 at the 1737-metre elevation to explore the downward extension of mineralization in the 1800-metre level; drifting, raising and stoping was carried out on both levels. Some ore was shipped to the Blue Star mill at Ainsworth. Stopping of ore proved uneconomical and the operation was shut down in 1970.

Adit, trench, and drill indicated reserves on the 1737 and 1800-metre levels ("West Sunset") workings (082FNW113) were estimated in November 1969 by W.M. Sharp at 42,680 tons averaging 8.06 grams per tonne gold and 240 grams per tonne silver, 9.1 per cent lead, 7.6 per cent zinc, plus cadmium values. (Northern Miner, March 12, 1970). Further production was reported during 1975-79.

David Minerals Ltd. acquired the property from Silver Star Mines, and the Ainsworth mill from Blue Star Mines, in 1977. Indicated reserves (likely West sunrise, 082FNW113) were reported at 17,935 tonnes averaging 9.26 grams per tonne gold and 240 grams per tonne silver, 8.2 per cent lead, and 8.0 per cent zinc (Northern Miner, January 12, 1978, page 24).

The Scranton mine occupies the middle section of a 2.1-kilometre southwest trending vein system. The Scranton contains at least 2 veins. Attitudes range from northeast to east striking, and dips from 25 southeast at the southwest end of the vein, steepening to 60 degrees southeast towards the northeast.

Vein mineralization is predominantly pyrite, up to 35 per cent, with lesser galena and sphalerite, plus or minus chalcopyrite, in a fractured quartz gangue.

Country rock is hornblende potassium feldspar granite and potassium feldspar granite. Biotite-grade, thin-bedded siltstone, argillite and limestone outcrop on surface and quartzite was intersected underground.

Production from 1948 to 1979 totalled 25,943 tonnes yielding 3,497,850 grams silver, 117,152 grams gold, 13,875 kilograms cadmium, 1,313 kilograms copper, 1,279,129 kilograms lead, 1,210,373 kilograms zinc. Production includes Sunset (082FNW113).

CAPSULE GEOLOGY

exploration work on this vein system was done at its extremities and comprised the Pontiac workings at the northeasterly end and the Sunset workings at the southwesterly end. Following the consolidation of the property in 1930 development work was carried out at lower elevations in the mid section of the property on the Scranton claim, on the east side of Pontiac creek (known as the Lower Pontiac workings), and in the "Sunset" workings on the Grandview Fr. claim on the west side of the creek.

The first reported activity and first production from the Pontiac claim was recorded in 1898.

The first reported activity at the southwesterly end of the vein system was in 1899 when Woodbury Mines, Limited, a Spokane, Washington company, was carrying out development work on the Sunset No. 5 and Mayflower claims of the Sunset Group. The workings at that time comprised some 244 metres of drifts and crosscuts in 4 adits, and 2 shafts. Ore shipments began in 1899. Work on the property continued into 1901, the workings then comprising 7 or more adits.

Two claims, the International and Vernon, located adjoining and southwest of the Sunset group, were owned by C.F. Caldwell and associates of Salt Lake City. Assessment work in 1899 included a short adit on the International claim.

Subsequent details are lacking but apparently the Sunset and Mayflower claims lapsed and the ground was restaked as the Sunrise, Grandview and Granite claims. The Sunrise claim (Lot 5991) was Crown-granted to J.A. Poyntz in 1904. The adjacent Grandview (Lot 6279) and Granite (Lot 6278) claims were Crown-granted to W. Chaplin and A.G. Caldwell respectively in 1907.

Activities at the various workings ceased in about 1908 and some of the claims were subsequently acquired by C.F. Caldwell. In 1930 Hon. J.D. Chaplin, C.F. Caldwell, T. Doyle and J. Henry, owners of the various claim groups, gave an option to purchase the Scranton Consolidated Mining Company which was incorporated in Portland, Oregon to consolidate and develop the property. Investigation of the Scranton claim began but little was accomplished until 1939-40 when the main workings on the Scranton claim (lower Pontiac workings) were driven.

A new company, Scranton Mines Limited, was incorporated in British Columbia in August 1951 to acquire the 14 claim property; the company head office remained in Portland, Oregon. On the west side of Pontiac creek, on the Grandview Fr. claim, the "Sunset" drift adit, which was begun in 1950, was driven southwesterly at about the 1737-metre elevation. By the end of 1952 the workings comprised about 268 metres of drifts and crosscuts and a 23-metre winze. In 1953 diamond drilling in 11 holes totalling 548.6 metres was done to determine the vein extension on the Sunrise claim. Little further activity took place until 1960-61 when an additional 30 metres of drifting and crosscutting and 43 metres of underground diamond drilling was carried out in the Scranton workings. A new adit about 30 metres long was driven 15 metres below the old Pontiac workings.

Blue Star Mines Limited optioned the property in 1964 and carried out stripping and 209.3 metres of diamond drilling on the Scranton claim and extended the lower Pontiac adit an additional 79 metres.

No further activity was reported until 1967 when exploration was begun in a new adit at the 1800-metre elevation on the west side of Pontiac creek at the southeast edge of the Grandview claim. The adit was driven as a crosscut for 30.4 metres, intersecting a strong quartz vein which was drifted on. Silver Star Mines Ltd. acquired the property from Blue Star Mines and Scranton Mines through a stock transaction. A new adit was begun in 1968 at the 1737-metre elevation to explore the downward extension of mineralization in the 1800-metre level; drifting, raising and stoping was carried out on both levels. Some ore was shipped to the Blue Star mill at Ainsworth. Stopping of ore proved uneconomical and the operation was shut down in 1970.

Adit, trench, and drill indicated reserves on the 1737 and 1800-metre levels ("West Sunset") workings were estimated in November 1969 by W.M. Sharp at 42,680 tonnes averaging 8.06 grams per tonne gold and 240 grams per tonne silver, 9.1 per cent lead, 7.6 per cent zinc, plus cadmium values. (Northern Miner, March 12, 1970). Further production was reported during 1975-76.

David Minerals Ltd. acquired the property from Silver Star Mines, and the Ainsworth mill from Blue Star Mines, in 1977. Indicated reserves were reported at 17,935 tonnes averaging 9.26 grams per tonne gold and 240 grams per tonne silver, 8.2 per cent lead, and 8.0 per cent zinc (Northern Miner, January 12, 1978, page 24).

The country rock is hornblende potassium feldspar porphyritic granite and lesser hornblende diorite. The vein is less than 1.5

CAPSULE GEOLOGY

metres wide, limonite stained and sulphide-poor. The footwall granite is fractured and limonitic over 1 metre or less. The hangingwall is sharply defined and locally sericitized. Mineralization includes intergrown galena and sphalerite. Pyrite occurs as coarse aggregates and finely crystalline concentrations rimming galena. Erratic high grade gold values suggest free gold occurs in the veins. A grab sample from the Sunrise upper portal taken in 1987 assayed 32 grams per tonne gold, 310 grams per tonne silver, 21.2 per cent lead and 13.8 per cent zinc (Open File 1988-11).

Production from 1899 to 1901 totalled 145 tonnes yielding 313,269 grams silver, 2,333 grams gold and 57,494 kilograms lead. Later production is included with Scranton (082FNW112).

CAPSULE GEOLOGY

This property lies at the head of Woodbury Creek on the ridge between it and Sawtooth Creek, a tributary of Keen Creek, at the 2408-metre elevation. It may be reached by approximately 8 kilometres of trail from where the Scranton road turns up Pontiac Creek. The property is located in Kokanee Glacier Provincial Park.

The area is dominated by granitic rocks of the Middle to Late Jurassic Nelson Intrusions.

At the Silver Cup occurrence, a barren-looking quartz vein occurs in hornblende-potassium feldspar porphyritic granite of the Nelson Intrusions. The vein extends for several hundred metres with an average 015 degree strike and 70 degree easterly dip. The vein width is approximately 2.3 metres. Mineralization consists of stringers of galena, sphalerite and tetrahedrite. Brecciated clay-altered wallrock is evident in the vein.

A limonitic fracture zone less than 7 metres wide hosts the quartz and carbonate veins. Veins on surface are less than 5 centimetres wide and contain coarse sphalerite and galena within very coarse pink and white carbonate.

A grab sample of vein material assayed 950.0 grams per tonne

CAPSULE GEOLOGY

silver, 3.8 grams per tonne gold, 1.28 per cent lead and 0.99 per cent zinc (Open File 1988-11).

The E.L., Silver Cup (Lot 6507), Moonlite, Evening Star, and Sun (Lot 6955) claims extend in a northeasterly direction along the strike of the vein outcrop. These claims lie near the western edge of a more or less rectangular block of 33 claims and fractional claims that is roughly 5 claims wide and 6 claims in length. All these claims were Crown-granted to D.H. Nellis, some in 1907, and the remainder in 1911.

Very little information is available on this property and it is not known when the claims were located. A 1911 report states that 3 men worked on the Sun claim from June to December and 2 cars of ore were sacked ready for shipment. In 1917 Mr. Nellis shipped 35 tons of ore, reported to be from the Sun claim (082FNW207). The main workings are on the Silver Cup claim. Here Mr. Nellis drove a crosscut in a westerly direction, about 30 metres below the outcrop, on the Woodbury side of the divide. The crosscut is 22 metres long and intersects the vein 10 metres from the portal. A winze has been sunk on the vein, and 4.5 metres below the adit level a sublevel has been driven on the vein to the north of the shaft for 10.6 metres. About 4.5 metres back from the face the stringer of galena has been underhand mined for about a metre. The winze is reported to be 14 metres deep with a 15-metre drift to the south off the bottom. This lower level was inaccessible when the workings were examined in 1949.

In 1940 J. Flagel of Ymir shipped 31 tons of ore from the Silver Cup. Three claims, the E.L, Silver Cup, and Moonlite, owned by Mrs. C.A. Nellis, were optioned to A.G. Neiman & associates late in 1949. The only work reported at this time was done on an access road to the property.

CAPSULE GEOLOGY

Marguerite and Alice fractional claims were Crown-granted to Rene Laudi; the Apex, Crescent, Twin Lakes, and Green Lakes claims were Crown-granted to W.E. Boie.

On the east side of the southern lake, on the Tony claim, a crosscut tunnel said to be between 213 and 274 metres long was not driven far enough to reach its objective, a vein outcropping on the mountain slope above. At the 2274-metre elevation on the Joker claim an inclined shaft is said to be 29 metres deep on a 65 degree slope. On the side hill above the shaft a tunnel is said to have been driven westerly about 30 metres on a vein mineralized with pyrite, galena, and sphalerite, but the portal was later obscured by slide rock and vegetation. Open cutting was done on the Treadwell claims on the supposed extension of the shaft vein. On the northern boundary of the Treadwell claim a tunnel was driven for 20 metres along a fracture up to 55 centimetres wide and dipping 65 degrees east in which there is disseminated pyrite as well as some galena, sphalerite, and chalcopyrite; at 16.7 metres in from the portal there is a 3-metre winze. On the northern boundary of the John A claim a tunnel was driven 91.4 metres along a small quartz vein (strikes 055 and dips 85 degrees southeast) following a line of jointing in the granite. The quartz and wall rocks are both stained with secondary copper minerals and carry a little galena and tetrahedrite.

A sample of a vein taken in 1987, assayed 3.8 grams per tonne gold, 42 grams per tonne silver, 0.0057 per cent copper, 0.94 per cent lead, 0.44 per cent zinc (Open File 1988-11).

CAPSULE GEOLOGY

The Boomerang is located in Kokanee Glacier Provincial Park. The mineralized quartz vein is hosted by potassium-feldspar porphyritic granite (Middle Jurassic Nelson Intrusions). Zones of argillic alteration, limonitic weathering, and locally with silicification occur adjacent to the main fault fissure.

Mineralization is sparse but includes galena, light coloured sphalerite, pyrite, and reported native silver. A vein taken in 1987, assayed 8.0 grams per tonne silver, 0.08 grams per tonne gold, 0.025 per cent lead and 0.073 per cent zinc (Open File 1988-11).

Vein strikes north-south and dips at about 80 degrees eastward.

CAPSULE GEOLOGY

The Gold-Galena prospect is located just east of Heather Lake, in the headwater area of Enterprise Creek, 17 kilometres east of the town of Slocan. Access to the property is by trail from the Enterprise Creek road. The prospect is located in Kokanee Glacier Provincial Park.

Two adit tunnels have been driven north along a shear zone for about 30 metres. In the upper tunnel the vein, located on the footwall of the shear, is 45 centimetres wide. The mineralization consists of galena, sphalerite, and pyrite in quartz. The country rock in vicinity of the property is a coarse feldspar porphyry granite phase of the Nelson batholith. The wallrocks of the vein show argillic and limonitic alteration.

CAPSULE GEOLOGY

The Blackburn is located northwest of Kaslo Lake, in Kokanee Glacier Provincial Park.

A mineralized shear zone in coarse-grained Nelson granite. Vein quartz occurs in small irregular lenses and stringers carrying a sparse dissemination of sulphides. The lode strikes north 65 degrees west and dips steeply southwest. The hangingwall is partly defined by a narrow fine-grained basic dyke.

Two ore types: 1) sphalerite-rich with pyrite and quartz vein, 2) galena-rich carbonate vein with characteristic manganese oxide weathering.

The veins occur in fresh potassium feldspar porphyritic granite, sub-parallel to prominent northwest trending linears. A sample taken in 1987, assayed 510 grams per tonne silver, 0.155 grams per tonne gold, 0.067 per cent copper, 1.1 per cent lead and 12.1 per cent zinc (Open File 1988-11).

CAPSULE GEOLOGY

The Slocan Chief is located in Kokanee Glacier Provincial Park. Slocan Chief mineralization occurs along a structure that also hosts the Smuggler (082FNW120), and Molly Gibson (082FNW121) deposits. Mineralization exhibits characteristic manganese oxide weathering. The quartz veins are vuggy with some chalcedonic quartz. An altered zone less than 3 metres wide with limonitic fractures contains the mineralized quartz veins. Arsenopyrite is characteristic to mineralization along this structure. A sample taken in 1987, assayed 1900 grams per tonne silver, 0.54 grams per tonne gold, 0.0492 per cent copper, 2.66 per cent lead and 4.75 per cent zinc.

CAPSULE GEOLOGY

The Smuggler is located in Kokanee Glacier Provincial Park. Smuggler mineralization occurs along a northwest trending structure that hosts Slocan Chief (082FNW119) and Molly Gibson (082FNW121). The galena-sphalerite-arsenopyrite-quartz-iron carbonate veins characteristically are black (manganese oxide) weathering. The veins are unique in that they contain abundant arsenopyrite. The veins are vuggy with variable amounts of chalcedonic quartz.

A grab sample taken in 1987, assayed 1100 grams per tonne silver, 8.43 per cent arsenic, 2.2 grams per tonne gold, 0.22 per cent copper, 4.89 per cent lead and 5.4 per cent zinc (Open File 1988-11).

Production, sometime before 1928 amounted to 13 tonnes grading 9463 grams per tonne silver and 65 per cent lead.

CAPSULE GEOLOGY

Molly Gibson vein follows a northwest striking joint set in potassium-feldspar porphyritic granite. Workings explore two veins, the Florence and Aspen - they strike 145 degrees and dip 75 degrees. Ore shoots plunge to the southeast at about 45 degrees. Wallrock

CAPSULE GEOLOGY

alteration includes pervasive propylitic, argillic, and locally hematite alteration. Vein mineralization comprises galena, sphalerite, arsenopyrite, pyrite, and chalcopyrite in a gangue of brecciated manganese rock, siderite, and quartz. Vein textures and mineralogy suggest several stages of brecciation and mineralization. A grab sample taken in 1987, assayed 2300 grams per tonne silver, 0.51 grams per tonne gold, 0.205 per cent copper, 9.1 per cent lead, and 3.93 per cent zinc.

The property is located on the west side of Kokanee Peak, in Kokanee Glacier Provincial Park, some 26 kilometres northeast of Nelson.

The date of discovery is not recorded although the Report of the Minister of Mines, 1922, states that shipments of high-grade ore were made as early as 1890. The Molly Gibson, Aspen, and Florence claims were optioned to Hon. Rufus, H. Pope in 1896. The Molly Gibson Mining Company, Limited was incorporated in British Columbia in November 1898. Six claims, the Aspen (Lot 1578), Molly Gibson (Lot 1579), Florence (Lot 1716), La Plata Fr. (Lot 1719), Little Dike (Lot 4392), and Little Fraction Fr. (Lot 4393) were Crown-granted to the company in 1901. During 1902 mining operations were carried out under contract, some 1800 tonnes of ore being shipped to the Nelson smelter. A snow slide ended operations late in 1902 and work was not resumed until 1904.

A new company The La Plata Mines Company Limited, was incorporated in April 1909 to operate the property. A 100-ton per day concentrator was built on Kokanee Creek, with a mile tramline to connect with the mine. Milling began in July 1906 and continued through 1907. Due to financial difficulties the company was dissolved in 1908.

The Consolidated Mining and Smelting Company of Canada Limited acquired the property in 1910 by payment of 2,000 treasury shares. A second tramline 7.2 kilometres long was built to replace a portion of the road between the mill and the west arm of Kootenay Lake. The mine and mill were operated intermittently until early 1920. Underground development work to 1920 totalled 2743 metres of drifts, crosscuts, and raises in 5 adits, the 5th level being at 2103 metres elevation. Lessees operated the mine and mill intermittently until 1926.

The company resumed development work in 1930. A new low level crosscut adit begun at the 1792-metre elevation had been driven for 564 metres in 039 direction when work ceased in 1932.

Homestake Silver Ltd. optioned the property in 1965. Ore reserves at that time were estimated at 104,325 tonnes averaging 548.6 grams per tonne silver, 2.96 per cent lead, 3.17 per cent zinc. (Northern Miner, September 23, 1965).

In 1966 a drift was driven on what appears to be the main vein, from a point 488 metres from the portal of the 5,880 crosscut, to a point 262 metres north of the crosscut. In 1967 the drift was advanced 558 metres, the drift face being 1382 metres from the portal. This work exposed 5 mineral zones aggregating 91.4 metres of strike length on a fissure which is about on the projection of the Florence-Aspen vein system. Average width (1 metre) and grade of mineralization for the 5 zones was reported at 358.9 grams per tonne silver, 2.76 per cent lead, and 3.67 per cent zinc. The most northerly mineralized shoot was exposed for a vertical distance of 25.3 metres by 30.5 metres of raise.

Pyramid Mining Co. Ltd., in October 1967, optioned an interest in the property and provided funds for the later development work.

Molly Gibson Silver Ltd. was incorporated in December 1967 as a private company to acquire the 10 Crown-granted claims. The shares of the company were held by: Homestake Silver Ltd. (49%), Cominco Ltd. (34%), and Pyramid Mining Co. Ltd. (17%).

CAPSULE GEOLOGY

The Oro Fino workings occupy a 25-hectare claim located at the headwaters of Nilsik (Crazy Jane) Creek, south of Sunset and Outlook mountains. The property is located in Kokanne Glacier Provincial Park. Production in 1940 totalled 4 tonnes and yielded 62 grams gold, 964 grams silver, 48 kilograms lead and 112 kilograms zinc.

Development work includes two adits at the 2086-metre and 2118-metre elevations and surface trenching at 2196 metres elevation outlining a strike length of approximately 100 metres. The quartz vein occupies a tight fracture in potassium feldspar-porphyritic granite which strikes 030 degrees and dips 65 degrees southeast. Vein mineralogy comprises pyrite, sphalerite and galena: stronger mineralization is associated with smoky quartz. Wallrock is oxidized and altered to sericite and argillite assemblages up to 10

CAPSULE GEOLOGY

centimetres on either side of the vein.

A grab sample taken in 1987 of mineralized vein material stockpiled at the upper portal returned 24 grams per tonne gold, 390 grams per tonne silver, 2.8 per cent lead and 3.8 per cent zinc. Altered wallrock sampled from directly inside the lower portal returned 0.11 gram per tonne gold, 8 grams per tonne silver, trace lead and 0.01 per cent zinc (Open File 1988-11 and Paper 1989-5, page 24).

CAPSULE GEOLOGY

The Hudson Bay prospect is centred on the Fram (Lot 9273) and Nansen (Lot 9274) claims, at about 1890 metres elevation, in the Sapphire Lakes area, 17 kilometres east of Slocan City. Access is about 5 kilometres by trail from the eastern extension of the Lemon Creek road. The property is located in Kokanee Glacier Provincial Park.

The Fram and Nansen claims were Crown granted to the Hudson's Bay company in 1909. The principal development on this property are two short adits connected by a vertical raise.

The rock of the area is typical of the main phase of the Nelson granitic batholith. However, in the immediate vicinity of the showings, the granite is brown to reddish brown in contrast to the characteristic grey of the surrounding Nelson rocks. This zone is about 30 metres wide and strikes slightly east of north on the east side of a small draw beside the adits. The exact structural nature of this red granite was not determined but it appears to be a later alteration phase of the original granite that follows a general line

CAPSULE GEOLOGY

of weakness within the main granite mass. On the floor of the draw in the ordinary granite, lamprophyre dikes are exposed which vary in width from 0.5 to 1 metre and strike generally north parallel to the trend of the granite.

The lower adit was driven 060 degrees on a mostly steeply dipping quartz stringer which, at 7 metres from the portal, intersects a similar vein striking 020 degrees, dipping 35 to 50 degrees northwesterly. From the portal the original stringer gradually widens to 20 centimetres at the raise where it displays a section of well banded quartz heavily mineralized with sulphides. At the face, this vein structure, represented by 76 cm of shearing, includes a 10-centimetre width of quartz, some additional quartz stringers and almost no sulphides. However, at a point 18 metres from the portal, a short crosscut driven a short distance to the east, intercepts an additional quartz vein, enriched in sulphides, that strikes 010 degrees and dips vertically.

The vein in the upper drift adit ranges in width up to 28 cm wide, strikes almost north and dips steeply. Continuity of the vein is well maintained over the 40-metre length of the drift and sulphide mineralization is consistent, except close to the face where the vein pinches to a 3.5-centimetre quartz stringer bounded by one to several centimetres of shearing.

Sampling of weak pyrite and galena mineralization at the face of the lower adit across the 60-centimetre wide vein and accompanying shear zone yielded 3.4 grams per tonne gold and 45 grams per tonne silver.

In the upper adit, at 25 metres from the portal, a 28-centimetre wide sample of the quartz vein, well mineralized with galena and pyrite, assayed 1.4 grams per tonne gold and 290 grams per tonne silver.

A vein sample taken in 1987 assayed 2.4 grams per tonne gold, 490 grams per tonne silver, 0.26 per cent lead and 0.3 per cent zinc (Open File 1988-11).

CAPSULE GEOLOGY

The Silver Crest property is located along the precipitous
summits midway between Slocan Lake and Kootenay Lake, 18 kilometres
east of Slocan City. Access to the property is 7 kilometres by
trail proceeding easterly from the Lemon Creek road.

Formerly part of the German Group (in 1916), the property
was worked as the Silver Crest and White Heather in 1921. Work on
the Silver Crest consisted of open cuts on top of a precipitous
bluff at 2590 metres elevation. The bluff falls abruptly for 430
metres towards Lemon Creek and the workings are reached by a
roundabout route which culminates in the Sapphire Lakes glacial
basin situated below the summit of Sunset Mountain.

The mineralization occurs in a fissure vein in Nelson granite.
A basic micaceous lamprophyre dike follows close to the vein on the
hangingwall side. The strike of the vein conforms to the northeas-
southwest trend of the summit of the mountain and the dip is steep
southeasterly. The vein varies in width from 20 to 30 centimetres
where exposed in the open cut and, to about a metre depth, the wall
rocks are somewhat decomposed and rusty. The associated minerals
are pyrite and galena in quartz gangue. A sample across the vein

CAPSULE GEOLOGY

yielded 62 grams per tonne gold, 620 grams per tonne silver and 7.6 per cent lead (Annual Report, 1921, p. 141).

On the White Heather, located 430 metres below the Silver Crest, open cuts and a 45-metre cross-cut, with a 90-metre drift exposed veins with minor mineralization. A 15-centimetre sample assayed 7.54 grams per tonne gold, 315.43 grams per tonne silver and 0.1 per cent lead (Annual Report 1921, page 141).

A vein sample taken in 1987 assayed 1.9 grams per tonne gold, 46 grams per tonne silver, 0.97 per cent lead and 0.42 per cent zinc (Open File 1988-11).

CAPSULE GEOLOGY

The Soldier Boy property is on Sunset Mountain, about a kilometre southwest of Silver Crest, 18 kilometres east of Slocan City. Access to the property is about 8 kilometres by trail proceeding easterly from the Lemon Creek road. The property is located in Kokanee Glacier Provincial Park.

The target of exploration on the property is a mineralized fissure (lead) containing silver sulphides developed in Nelson granite. This fissure, of indeterminate width, strikes almost vertically down the face of a precipitous bluff and across the mountain towards the southeast, at right angles to the trend of the summits. Work has been confined to the only two accessible points, which are at the top and bottom of the bluff. The upper workings are reached by a circuitous route over the rugged ground southwest of the bluff.

At the top, at about 2400 metres elevation, stringers of ore are exposed in open cuts and a 20-metre long crosscut from the cliff face. An average sample from these cuts reportedly assayed 1.4 grams per tonne gold and 2500 grams per tonne silver (Annual Report 1921, page 141).

Below the portal the bluff falls almost vertically for 430 metres towards Lemon Creek. At the bottom of the bluff stringers of ore are exposed in another open cut. Sample from here assayed 15.8 grams per tonne gold and 2530 grams per tonne silver (Annual Report

CAPSULE GEOLOGY

The property is located west of McGuire Creek, on the east side of Mount Ruppel, in Kokanee Glacier Provincial Park.

Country rock is potassium feldspar porphyritic granite. In the vicinity of the workings the granite is well jointed.

The quartz vein, tested by 3 short adits and 450 metres of stripping, follows a flat basal jointing plane trending southwest. Quartz vein occupies an argillic altered shear zone with sericitic wallrock (less than 1.0 metre) containing sparse amounts of sulphides. Pyrite, galena and argentite are the chief sulphides. A vein sample taken in 1987 assayed 1100 grams per tonne silver, 6.9 grams per tonne gold and 0.14 per cent lead. Another vein sample, 500 metres to the east assayed 510 grams per tonne silver, 14.2 per cent lead and 0.33 per cent zinc (Open File 1988-11).

Production values are not available. However, in 1950, R.G. McLeod shipped 8 tonnes of ore from the Sara B; McLeod held the

CAPSULE GEOLOGY

The property is located at the head of Sitkum Creek, 20 kilometres north of Nelson. The location of the Noonday group, relative to the four original claims of the Alpine group, is not known but may have covered adjacent ground which was in later years

CAPSULE GEOLOGY

Crown-granted as the Alpine, Swiss and Washington Fractions (Lots 15002-15004). The Alpine group, comprising 4 claims, the Swiss, Highland Chief, Berne, and Kootenay Pass (Lots 2879-2882, respectively) were owned from 1896 or earlier by C. Faas, H. Cleaver & associates. The claims were Crown-granted to Faas & associates in 1899.

No further activity was reported in this vicinity until 1918 when the Noonday group, comprising the Noonday, Climax, Margaret, and Pearl Fraction claims, was owned by J. Radcliffe and J.S. Johnson, of Nelson. Workings included open cuts and a 55-metre adit on the Noonday claim.

By 1927 the Alpine group was owned by E. Harrop & associates. The workings included 2 adits, possibly including the adit driven on the Noonday claim. The Alpine Syndicate acquired the property in about 1936 and built a road to the property. In 1937 further trenching was done, and the No. 10 drift adit was begun. In October 1938, Alpine Gold, Limited, operated the mine and acquired the adjacent Swiss, Alpine, Washington, and Oregon Fractions and the Idaho claim. The Basin, Meadow, and Sitkum claims (Lots 14922, 14928, 14929), located to the south and at elevations of 1675 to 1980 metres on Sitkum Creek, were acquired by the company for a millsite.

In 1938 the new No. 10 level adit was extended to 80 metres. A 50 ton-per-day mill was put into operation in December 1939 and operated intermittently until 1948. In 1938 and 1939 the adjacent Gold Crown was operated and ore mine by hand steel.

Development work to 1948 included two drift adits, Nos. 7 and 10 levels, located about 235 metres apart at elevations of 2180 and 2110 metres, respectively. The lower adit was driven to a length of 345 metres. The workings comprised over 1646 metres drifts, crosscuts, and raises. Diamond drilling totalling 366 metres was carried out in 1947. Reserves were estimated in 1949 at 90,720 tons at 19.5 grams per tonne gold (Financial Post Survey of Mines 1953, p. 81).

In 1987, Cove Energy Corporation acquired an option to purchase Granges Exploration Ltd., included construction of an access road, dump sampling, cross cutting to provide underground drill stations, and diamond drilling.

Work by Cove Resources Corporation in 1988 included a drift extension on No. 10 level, and diamond drilling; this downdip for about 300 metres and widens to about 6 metres. Reserves were reported as 190,500 tonnes proven at 13.7 grams per tonne gold (George Cross News Letter, February 2, 1989). Custom ore was shipped in 1988.

The area is dominated by granitic rocks of the Middle to Late Jurassic Nelson Intrusions.

In 1989, Cominco Ltd. acquired an option on the property and drilled and tested the downdip extension of the Alpine vein. The company drilled 1745 metres in 12 holes.

Intermittent production from 1915 to 1988 totalled 16,810 tonnes containing 222,044 grams of silver, 356,360 grams of gold, 49,329 kilograms of lead and 17,167 kilograms of zinc.

At the Alpine mine, a quartz vein occurs in a discrete shear zone striking 255 degrees and dipping moderately (30 degrees) north within quartz monzonite of the Nelson Intrusions.

The vein is traceable over 400 metres on surface and projects into Kokanee Glacier Provincial Park to the north. Vein contacts with hanging wall and footwall quartz monzonite are sharp and variably sericitized and chloritic. The vein ranges from 0.6 to 2.1 metres in width but averages 1.1 metres.

Pre-mineralization aplite and pegmatite dykes are common; post-mineralization lamprophyre dykes are less abundant, range to 4.8 metres in width and strike between 310 and 010 degrees with east and west dips. Normal faults with displacements up to 6 metres offset all dykes and veins.

Mineralization comprises massive, disseminated and stringer-type electrum, unidentified silver minerals, pyrite and lesser galena, sphalerite and tetrahedrite hosted in a quartz and minor calcite gangue. Rare clots of molybdenite were identified in altered potassium feldspar granite from the mine dump (Paper 1989-5).

The quartz vein is limonitic weathering, highly jointed and fractured and sometimes brecciated. Vein textures are massive crystalline, ribboned, or banded and vuggy. Quartz is variably milky, white, grey and colourless suggesting episodic deposition (Paper 1989-5). Stevenson (Bulletin 10) refers to scheelite mineralization at the Alpine occurrence.

CAPSULE GEOLOGY

The Crusader property is located north of Lemon Creek, 10 kilometres southeast of Slocan City. In addition to the Crusader claim, the property includes the Boulder and Hidden Treasure claims. In 1902 the discovery of mineralized float led to trenching which resulted in the discovery of a weathered quartz vein in Nelson granite. The vein is reported to be 0.75 metre wide composed of cellular, coarsely crystalline quartz containing pyrite, silver sulphides, some native silver and gold. Subsequent work from 1896 through 1902 included sinking a 33-metre shaft on the vein. The Crusader claim (Lot 5985) was crown granted in 1904. In 1939, production of 5 tonnes resulted in 218 grams of gold and 12,255 grams of silver. King Jack Resources conducted surveys on the Chapleau Creek property between 1985 and 1987.

CAPSULE GEOLOGY

Cameronian claim from D. Cameron, of Vancouver. Work 1986-87 included geochemical soil, silt and rock surveys, mag, EM and HLEM surveys. Trench of anomalous targets located narrow beds of low grade zinc. Drilling in 1988 intersected stratiform massive sulphide zones of zinc (Assessment Report 17323). In 1991, Kokanee Explorations Ltd. drilled 9 holes, totalling 255.5 metres. They indicated a reserve of 13,600 tonnes grading 59.3 grams per tonne silver, 1.3 per cent lead and 3.6 per cent zinc is readily available to open pit mining with 1.7:1.0 waste to ore ratio (Assessment Report 21324).

A sample from the dump taken in 1987, assayed 320 grams per tonne silver, 0.03 grams per tonne gold, 0.0563 per cent copper, 7.8 per cent lead and 21.4 per cent zinc (Open File 1988-11). A sample taken 500 metres to the southwest assayed 0.32 per cent molybdenum, 0.024 per cent lead and 0.029 per cent zinc (Open File 1988-11).

CAPSULE GEOLOGY

The Chapleau property comprises the Chapleau and Chapleau Consolidated fraction and several other Crown granted claims centred 6 kilometres southeast of Slocan City. The Chapleau mine may be reached by a short access road about 1.5 kilometres long connected to the main road at a point about 13 kilometres from the Slocan highway. See also 082FNW131-136.

Chapleau was one of the first properties in Lemon Creek area to receive attention. In 1896 the initial shipment of ore yielded 435 grams of gold and 11,788 grams of silver. Until 1900 development was rapid and an aerial tramway and stamp mill were erected. However, in 1904 the mine was closed as a result of decreasing value of the ore and difficulties were encountered because of faulting of the vein. Until 1941, ore was shipped intermittently by lessees. In 1946 and 1947 the workings were rehabilitated and a new road was constructed to the property, but there were no shipments of ore. Intermittent production from 1896 to 1941 totalled 297 tonnes, yielding 407,604 grams of silver and 29,455 grams of gold.

The country rock is porphyritic Nelson quartz monzonite that is bounded a short distance to the north and northwest by a large pendant and other inclusions of argillaceous quartzite. The granite is cut by small dikes of fine grained granite, pegmatite, and aplite. The phenocrysts of orthoclase and microcline in the porphyritic granite are up to a centimetre long. Larger feldspar phenocrysts, up to 7 centimetres in length, occur in the pegmatite dikes, elongated parallel to the walls. Some pegmatites contain small crystals of garnet and magnetite but no mica or ferromagnesian minerals.

The vein strikes 110 degrees and dips 25 degrees northeast. Its width ranges from 7 centimetres to 0.6 metre and widths up to 1.2 metres have been reported. The gangue is quartz that in places forms drusy cavities. Pyrite is the most abundant metallic mineral followed by sphalerite and galena. Minor chalcopyrite, free gold and ruby silver (?) are also reported.

In 1981, Julia Resources Corp., Agean Resources Corp. and Galilean Resources Corp., formed a joint venture and optioned the 3 claim Chapleau property (Chapleau (Lot 4963), Seattle No. 3 (Lot 4965) and Corker No. 2 (Lot 5494)). The joint venture conducted a program of exploration which included drilling a hole to a depth of 152 metres. On July 16, 1984, Dr. A. Ross Gorrell acquired title to the Chapleau, Seattle and the Corker #3 claims. In about 1984, King Jack Resources Ltd., a private company, acquired a lease option on the claims surrounding the Chateau Mine property and initiated a modest program of exploration. In November 25, 1985, Dr. Ross Gorrell sold all of his interest in the Chapleau, Seattle and Corker #2 claims to Epic Resources (B.C.) Ltd. In 1986, King Jack Resources Ltd. entered into negotiations with Epic Resources (B.C.) Ltd. pertaining to the 3 Chapleau mine claims. They conducted surveys and drilling as part of the Chapleau Creek property in 1987.

Reserves for the Chapleau mine are reported as 80,200 tonnes grading 19.7 grams per tonne gold and 737 grams per tonne silver (CMH 1989-90, page 259). In 1989, drilling outlined a reserve of 31,026 tonnes grading 8.1 grams per tonne gold and 194 grams per tonne silver (Assessment Report 22085). Total reserves for the Chapleau properties are reported as 505,200 tonnes grading 8 grams per tonne gold and 238 grams per tonne silver (CMH 1989-90, page 259). In July 1990, King Jack became International King Jack Resources Ltd., who became Petromin Resources Ltd. in April 1996.

A vein sample taken in 1987 assayed 2.1 grams per tonne gold, 36 grams per tonne silver, 0.1 per cent lead and 0.15 per cent zinc (Open File 1988-11).

CAPSULE GEOLOGY

The Kilo property, comprising the Kilo (Lot 9328), Kilo 2 (Lot 9330), Violet No. 3 (Lot 9329), Wedge Fr. (Lot 9331), and Pansy Crown Fr. (Lot 11732) granted claims, is centred 7 kilometres southeast of Slocan City. It is accessible from the Chapleau Creek road, about 12.9 kilometres from the Slocan highway. See also 082FNW130, 132-136.

The Kilo mine operated intermittently between 1897 and 1939. During the period 1900 through 1939 a total of 2,120 tonnes was produced yielding 29,640 grams of gold, 27,060 grams of silver, 48 kilograms of lead and 21 kilograms of zinc; there is no production recorded prior to 1900.

The property is underlain by coarse-grained, porphyritic Nelson granite cut by small pegmatite dikes. The underground workings consist of five levels and one sublevel, of which all but the highest and lowest levels are connected by raises; the highest level is connected to the surface by a raise. Portal to the No. 1 level is just above the road at 1460 metres elevation.

The vein strikes 135 to 155 degrees, dips 30 to 40 degrees northeast and ranges between 7 and 60 cm wide. Reportedly, the vein has been drifted on for 90 metres but is cut off by a fault near the face on No. 3 level. The vein is mainly quartz with pyrite and accessory galena and sphalerite.

Kilo Gold Mines Ltd. rehabilitated the Kilo adit in 1985. King Jack Resources Ltd. conducted the Chapleau Creek property between 1985 and 1987.

CAPSULE GEOLOGY

The Hollinger group of claims is located on the southeast side of Chapleau Creek, 8 kilometres southeast of Slocan City. Access is from the Lemon Creek road that connects to the Slocan highway. See also 082FNW130, 131, 133-136.

The principal exposure on the property consists of a quartz vein striking 180 degrees dipping 15 degrees, with a width ranging from 0.3 to 1.2 metres. The quartz filling is strongly fractured and mineralized slightly with pyrite. The Nelson granite which hosts the vein, is badly decomposed in vicinity of the old workings. Development on this showing includes surface stripping at intervals over a length of 168 metres. Also, an adit has been driven on strike of the vein for 9 metres from a face at the southwest end of the stripping at 1620 metres elevation. A series of samples taken across the vein in the adit assay from nil to 5.5 grams per tonne gold and 6.9 grams per tonne silver.

In a southeasterly direction from these workings, and near the top of the hill, considerable amount of work was done previously. This development is scattered and shows several narrow but reportedly high grade veins in the granite. Some 180 metres southeast, a second adit has been driven southeastward for 10 metres on another vein. The vein has a width of 30 centimetres at the portal but pinches rapidly to 8 centimetres within the adit. The vein is flat lying and dips 10 to 15 degrees northwest and is down faulted repeatedly. Near the face of this adit an 8-centimetre sample of heavily oxidized vein material assayed 37 grams per tonne gold and 730 grams per tonne silver.

Another caved working, 68 metres further to the east, shows a 7- to 10-centimetre wide quartz vein in granite. It strikes due north and dips 10 to 15 east into the hill. A sample of honeycombed quartz from which much of the sulphide mineralization had been leached, assayed 32 grams per tonne gold and 390 grams per tonne silver.

King Jack Resources Ltd. conducted surveys on the Chapleau

ORE ZONE: DUMP REPORT ON: N

CATEGORY:	Assay/analysis	YEAR:	1938
SAMPLE TYPE:	Grab		
COMMODITY		GRADE	
Silver		6.8000	Grams per tonne
Gold		14.3000	Grams per tonne

COMMENTS: Assays range from 14.3 to 699.3 grams per tonne gold and 6.8 to 363.3 grams per tonne silver.

REFERENCE: Minister of Mines Annual Report 1938, page E8.

CAPSULE GEOLOGY

In 1938, the Rose Group consisted of the Rose (Lot 5979) and Louise Fraction (Lot 5980) mineral claims and owned by A.S. Johnson of Montreal, Quebec. The claims, on both sides of Chapleau Creek, adjoin the Kilo ground (082FNW131) on the east and southeast. No development on this ground is reported since 1899, and although there is evidence of that development, none is in condition for purposes of examination or is worthy of rehabilitation (Minister of Mines Annual Report 1938, page E8).

On Chapleau Creek, at an elevation of 1371 metres, there is a small pile of apparently selected vein material from irregular exposures of quartz vein in granite hostrock, evident in place in the creek bottom. The vein quartz is milky and massive, heavily fractured with healing of the fractures by later quartz. Sulphide mineralization is mainly medium to coarse grained pyrite and galena with probable sphalerite. Two grab samples taken from this ore pile assayed from 14.3 to 699.3 grams per tonne gold and 6.8 to 363.3 grams per tonne silver (Minister of Mines Annual Report 1938, page E8).

The granite host is inferred to be part of the Middle Jurassic Nelson intrusions.

King Jack Resources Ltd. conducted surveys on the Chapleau Creek property between 1985 to 1987.

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The Goldstream claim, held on location in 1938, is 7 kilometres east-southeast of Slocan City. Access to the claim is from the Chapleau Creek road, about 2.5 kilometres northeast of the Kilo mine (082FNW131). See also 082FNW130, 132, 133, 135, 136.

Initial exploratory work on the property, carried out in 1931 and 1932, consisted entirely of trenching and stripping the vein. In 1938 an adit drift was driven westward from the bank of a creek. The only ore produced at this time amounted to 36 tonnes containing 684 grams of gold and 715 grams of silver.

The country rock on the claim consists of porphyritic Nelson granite. The vein which strikes 075 degrees and dips 20 degrees north, ranges in width from 15 to 40 centimetres and has been followed underground for 15 metres and on surface for 60 metres. In many places the vein splits into two or three branches. The vein is composed of white quartz with pyrite cubes and some galena.

King Jack Resources Ltd. conducted surveys on the Chapleau Creek property between 1985 to 1987.

The Rita vein strikes 320 degrees and dips 11 degrees northeast. A 15-centimetre sample assayed 20.2 grams per tonne gold, 17.8 grams per tonne silver, 0.35 per cent lead and 0.1 per cent zinc (Santos, 1986).

COMMENTS: Indicated and possible ore, King Jack Resources Ltd.
REFERENCE: Assessment Report 22085.

CAPSULE GEOLOGY

The Tail Holt property is in the head water area of Chapleau
Creek, 7.2 kilometres east southeast of Slocan City. Access is from
the Slocan highway via the Lemon Creek road. See also 082FNW130-134,
136.

The target of exploration in this area is a gold-bearing quartz
vein 0.3 to 0.9 metre thick, dipping 20 degrees (northeast?) into
the hill. Development work on this claim consists of a short adit,
crosscut and a decline for about 20 metres down the vein. Work on
this property was done mainly in the period 1898 to 1904.

About 100 metres south of the Tail Holt adit, the King Jack
adit was driven in 1922 by the King Jack Mining Company, on an
east-west trending, 30-degree north dipping vein for about 75 metres.
A 6.4-metre chip sample assayed 14.4 grams per tonne gold and 1214
grams per tonne silver (Annual Report 1922, page 204).

Albury Resources prospected on the claim in 1982. From 1985
to 1987, the King Jack claim was surveyed and drilled as part of the
Chapleau Creek property by King Jack Resources Ltd. The King Jack
adit was rehabilitated in 1985. Resources are reported as 99,800
tonnes grading 12 grams per tonne gold and 392 grams per tonne silver
(CMH 1989-90, page 259). Indicated and possible ore for the King
Jack vein are reported in 1989 as 37,200 tonnes grading 7.85 grams
per tonne gold and 79.9 grams per tonne silver (Assessment Report

CAPSULE GEOLOGY

22085). Total reserves for the Chapleau properties are reported as 505,200 tonnes grading 8 grams per tonne gold and 238 grams per tonne silver (CMH 1989-90, page 259). In July 1990, King Jack became International King Jack Resources Ltd., who became Petromin Resources Ltd. in April 1996.

CAPSULE GEOLOGY

The area is dominated by granitic rocks of the Middle to Late Jurassic Nelson Intrusions.

At the Howard Fraction occurrence, a quartz vein striking east-west and dipping 10 to 30 degrees north is hosted in coarse-grained potassium feldspar porphyritic granite of the Nelson Intrusions. The granite is crosscut by numerous porphyritic and aplitic dykes which are spatially related to quartz veining. The main vein is from 30 to 55 centimetres wide and composed of honeycombed quartz mineralized with disseminated crystalline argentite and pyrite. Hematite and limonite oxidation products are also prevalent in the veining. At intervals along the dip of the vein, faulting has displaced it 0.9 to 2.4 metres.

A chip sample across the vein in 1987 assayed 66.0 grams per tonne silver and 1.9 grams per tonne gold (Open File 1988-11).

Past development consisted of three adits and an incline shaft. Small shipments of sorted ore were intermittently made, beginning in 1895 and ending in 1950, for a total of seven years. Production

CAPSULE GEOLOGY

totalled 162 tonnes, resulting in 166,184 grams of silver and 902 grams of gold.

Albury Resources Ltd. prospected on the claim in 1982. King Jack Resources Ltd. conducted surveys on the Chapleau Creek property between 1985 to 1987. See also 082FNW130-135.

CAPSULE GEOLOGY

The Meteor property, comprising the Meteor (Lot 2893), Ottawa No. 5 (Lot 2892) and Cultus (Lot 2891) claims and fractions, is situated at the head of Tobin Creek on the northwesterly slope of the divide between Lemon and Springer creeks, 8 kilometres east of Slocan. Access to the property from the Slocan highway is via the

CAPSULE GEOLOGY

Lemon Creek and Chapleau Creek roads.

The Meteor (Lot 2893) Crown-granted claim was staked in 1895. J.A. Finch & associates optioned the property in 1896 and the initial production of ore, amounting to about 70 tonnes, was shipped in 1897, yielding 1182 grams of gold and 466,545 grams of silver. Since this time mining continued intermittently, until 1985, achieving greatest production of 1,715 tonnes of ore in 1964. Total production from the Meteor mine is 2,659 tonnes of ore yielding 4,724,994 grams of silver, 13,177 grams of gold and a small amount of lead and zinc.

Three claims, the Cultus, Ottawa No. 5, and Meteor (Lots 2891-2893 respectively) were Crown-granted to Finch & associates in 1899. The vein was apparently not found in the lower adit and work ceased in about 1900. Lessees carried out intermittent exploration and development during the period 1905 to 1917. J.C. Buchanan acquired the property in 1919 and began driving No. 6 level adit; he continued the project in 1922 and 1923. Lessees worked the property in 1928 and intermittently from 1932 to 1940. Some ore shipments were made under the name Meteor Mining Company, which may have been an American incorporation. In the early 1930's the owners of the property were reported to be E. Murphy and M.S. Mayfield. Development work to that date comprised 6 adits, of which the three lower ones totalled over 426.7 metres of drifts and crosscuts.

Cultus Explorations Ltd. was incorporated in May 1963 to acquire the above Crown-grants, and the Deadwood claim (Lot 3576). No. 6 level was rehabilitated for 244 metres and stoping and underground diamond drilling carried out. A 50 ton-per-day mill, installed near No. 6 adit, was put into operation in 1964. Drifting, crosscutting and raising during the year totalled 123.4 metres. The mine closed in November 1964. Lessees carried out some underground exploration work in 1967 and 1970.

The area is dominated by granitic rocks of the Middle to Late Jurassic Nelson Intrusions. Host rock at the Meteor occurrence is a medium-grained potassium feldspar porphyritic granite, commonly crosscut by dykes of biotite diorite and pegmatitic granite phases. The dykes range from 10 centimetres to 3 metres in width, strike north-northeast and north-northwest with moderate to steep dips. Contacts with the granite country rock are sharp and shearing is common along these zones.

Faults, shear zones and joints are oriented predominantly in north and north-northeast directions with generally near vertical dips. North trending faults and shears commonly display strike-slip displacements, while north-northeast trending structures commonly display dip-slip displacements.

The workings of the Meteor mine consist of six adits that intersect a 5 to 50-centimetre wide vein that strikes 105 degrees and dips 35 degrees north. Vein mineralization is associated with the sheared upper contact of a 3-metre wide dike and narrow off-shoot fissures. Quartz veining is localized mainly at the sheared dyke contact but also occurs as narrow (1-2 centimetre) veinlets adjacent to the main vein. These veinlets constitute stockwork mineralization in the dyke up to 1 metre from the main vein. The dyke rock is pervasively sericitized in the zones of quartz veining and contains up to 2 per cent disseminated crystalline pyrite. Both the dyke and the quartz veining are dislocated by a series of nearly parallel vertical post-mineralization faults. Displacement along the faults is of a dip-slip nature with the southeastern side of the faulting being downdropped.

The vein is largely quartz carrying some sphalerite, galena, tetrahedrite, stephanite, argentite and native silver. Pyrite and chalcopyrite are also present and associated with significant gold values. Scheelite was discovered in the Meteor vein on No. 2 level as a wedge-shaped body approximately 3.6 metres long and 10 centimetres thick at the base. A small amount was also found on No. 4 level. Scheelite also occurs in the No. 6 level adit as disseminated grains along a moderately well-developed fracture striking 320 degrees and dipping 80 degrees northeast in the granite country rock (Assessment Report 9607). Examination of material from the Meteor dump in 1980 revealed molybdenite occurring locally within quartz stockwork hosted by sericitic granite, but was not found in the workings.

A sample of dump material taken in 1987 assayed 2300 grams per tonne silver, 4.3 grams per tonne gold, 0.135 per cent lead, 0.0317 per cent copper and 0.083 per cent zinc (Open File 1988-11). Yukon Minerals Corporation worked the property in 1987.

CAPSULE GEOLOGY

The Elk claim is located on the crest of the ridge south of Speculator Creek, 8 kilometres east of Slocan City. Access is from the Slocan highway via the Springer Creek and Tobin Creek roads. The Elk claim (Lot 5503) was Crown granted in 1902. Development work consists mainly of several open cuts along the ridge and a short adit at 2200 metres elevation. The target of exploration is a narrow oxidized quartz vein hosted by a porphyritic feldspar phase of the Nelson granitic batholith. The vein strikes 115 degrees, dips 30 degrees southwest, and varies from 20 to 30 centimetre in width. The tunnel at 9 metres from the portal encountered a fault, and a 6-metre crosscut to the southwest picked up the continuation of the vein. Assay results on a composite sample of the ore, which is oxidized quartz with sparse pyrite, show 6.9 grams per tonne gold and 340 grams per tonne silver.

CAPSULE GEOLOGY

The Alice S (Lot 12068) and Paterson (Lot 12069) Crown granted claims are located towards the head of Bettina Creek, 8 kilometres east of Slocan City. Access to the property from the Slocan highway is via the Springer and Bettina Creek roads.

The mine workings include four adits, a few small stopes, and one shallow shaft. These explore a quartz-carbonate vein in a fault zone to a depth of about 50 metres. The host rocks consist of coarse grained, porphyritic granite of the Nelson batholith.. The vein is well mineralized and strikes 095 degrees, dips 70 degrees south and varies in thickness from 0.6 to 1.5 metres. The chief vein minerals are quartz, siderite and some galena and sphalerite.

The only shipment on record was made in 1915 when 14.5 tonnes of ore yielded an average return of 2850 grams per tonne silver and 15 per cent lead.

CAPSULE GEOLOGY

The Slocan Prince property, comprising the Slocan Prince (Lot 582), Two Friends (Lot 1020), Black Prince (Lot 584), Bank of England (Lot 2214) and Moonraker (Lot 8939) Crown granted claims and fractions, is situated at the head of Crusader Creek, 10 kilometres east of Slocan. Access to the property from the Slocan highway is via the Lemon Creek and Crusader Creek roads.

This property was among the first staked in the Slocan City mining division and much work was done on it prior to 1900. The

CAPSULE GEOLOGY

first production recorded was in 1896 from the Two Friends claim and this consisted of 36 tonnes of ore averaging 10,000 grams per tonne silver and 50 per cent lead. The Slocan Prince and Black Prince had greater output, especially in the years 1901, 1905 and 1906 when ore shipments from these claims ranged to several hundred tonnes. Total ore production from the property up to 1970, amounts to 1906 tonnes containing 7,045,304 grams of silver, 128,781 kilograms of lead and 11,852 kilograms of zinc.

The property is underlain by coarse-grained, porphyritic phases of the Nelson batholith. Granite and monzonite are the most common rock but locally more basic phases of this intrusion are present. These granitic rocks are traversed by a few acid and basic dikes and many faults and shear zones, along which mineralization has occurred.

The workings comprise seven or more crosscut adits driven northerly to northwesterly and distributed from west to east across the claim group. The workings develop, principally, two fissure-vein systems referred to as the North and South lodes. The North lode outcrops on both the Bank of England and the Two Friends claims and has been traced for about 450 metres in an easterly direction, almost parallel with the north and south boundaries of these claims. The north lode is intercepted by two adits on the Bank of England claim and, farther east, by two or three adits on the Two Friends claim. The lode strikes 060 to 070 degrees and dips steeply northwest. In the Bank of England workings, the mineralization is about 0.5 metre wide, nearly continuous for about a hundred metres, and consists of quartz with some calcite carrying galena, sphalerite and probably high-grade silver minerals. The lode intersects and slightly displaces a small basic dike. The Two Friends adits are situated about 135 metres to the east of the Bank of England workings by the west boundary of the claim. These adits are crosscuts to the North lode that is 1 to 3 metres wide, containing a well defined galena-sphalerite rich ore body, varying in width from a narrow streak to 35 centimetres.

The South lode is exposed in the workings on the easterly claims of the group. A crosscut adit driven 130 metres on the Slocan Prince claim intercepts this lode which strikes 020 to 030 degrees and dips 60 degrees northwest. The lode, which is about 6 metres wide, has been drifted on for more than 120 metres. The ore occurs on both walls, but mainly along the footwall. A second adit on Black Prince ground is a crosscut for 39 metres, beyond which it follows the lode for about 120 metres. The lode is a strongly crushed zone as much as 10 metres wide. Abundant quartz partly cements and replaces the crushed rock and forms veins in places. Ore minerals occur both as disseminations and concentrations included in and associated with quartz, some siderite, and a little calcite. They comprise argentiferous galena, sphalerite, tetrahedrite, pyrite, some native silver and possibly other silver-rich minerals. No appreciable gold occurs in the ore.

In 1994, Pacific Golden Spike Resources Ltd. conducted drilling and sampling.

CAPSULE GEOLOGY

Narrow mineralized quartz vein 2.5 to 20 centimetres wide, in porphyritic granite of the Nelson Plutonic rocks contains gold, silver, lead, and zinc.

Gold and silver ores were produced for a short period (1938-1940 and 1973). A grab sample of vein material assayed 104 grams per tonne silver, 64.4 grams per tonne gold, 0.28 per cent lead and 0.18 per cent zinc (Open File 1988-11).

CAPSULE GEOLOGY

The B and R property is at the head of Arlington Basin, 10.5 kilometres east-northeast of Slocan. Access is from the Slocan highway via the Springer Creek road.

On this property quartz veins cut coarse grained, porphyritic Nelson granite. One of these veins has been explored by two adits. The lower adit, reportedly, intersects the vein at 46 metres from the portal and from there follows it for 120 metres, in which distance the vein averaged 0.6 metre in width and consisted of quartz carrying galena and sphalerite. In the upper adit the vein is 5 centimetres wide and lies between well-defined walls striking 065 degrees and dipping 45 degrees northwest. In this tunnel the vein has been drifted on for 30 metres and a small body of ore has been stoped out.

CAPSULE GEOLOGY

The Hampton property is located at the elevation of about 1675 metres in the headwater area of Springer Creek, 10 kilometres east-northeast of Slocan. Access to the property is from the Slocan highway via the Springer Creek road.

Four main adits explore a mineralized shear zone in porphyritic Nelson granite. The shear zone has a northeasterly strike, dips steeply southeast and varies from 0.3 to a few metres wide. The zone contains streaks and lenses, up to 0.6 metre thick, composed of quartz and some calcite, galena, sphalerite and high grade silver minerals including native silver.

Intermittent production from 1900 to 1940 amounts to a total of 90 tonnes of ore grading 16,817 grams per tonne silver, 2 per cent lead and ancillary zinc.

CAPSULE GEOLOGY

The Riverside property, comprising the Riverside, Almeda, Autumn and Lailey fraction Crown Granted claims, is situated on the ridge between Enterprise Creek and Arlington basin, 12 kilometres northeast of Slocan. Access is by trail from the Arlington and Springer Creek roads.

On this property three adits spaced about 60 metres vertically apart explore a quartz vein cutting coarse grained, porphyritic Nelson granite. The vein strikes northeast and dips steeply southeast. Underground work on the vein consists of about 120 metres of drifting which has exposed small pockets enriched with pyrite, sphalerite and galena associated with high silver values. A sample from a pile of 2 tonnes of ore extracted from the upper adit in 1919, assayed 3000 grams per tonne silver and 7.5 per cent zinc. In the period 1935 to 1937, production totalled 18 tonnes, yielding 27,619 grams of silver, 453 kilograms of lead and 419 kilograms of zinc.

CAPSULE GEOLOGY

The Westmont property, comprising the Westmont (Lot 8929), Eastmont (Lot 8924), Oddfellow, White Cloud, Lily G., Yankee Girl and Clipper Crown granted claims and fractions, is situated on the north slope of the valley of Enterprise Creek, 12.5 kilometres northeast of Slocan. Access to the property is from the Slocan highway via the main Enterprise Creek road. The 0.8 kilometre of

CAPSULE GEOLOGY

old road between the main road and the mine was reopened in 1958 and a 9-metre bridge was constructed over Westmont Creek.

Development work on the Westmont property began in the 1890's, although production started 1907 until 1914. Subsequent mining, until 1971, mainly by lessees, was intermittent. The mine workings consist of at least four adits, located east of Westmont Creek, ranging in elevation from 150 to 400 metres above the main road along Enterprise Creek. In 1958, the No. 4 adit was retimbered from the entry to the intersection of the main vein, a distance of 60 metres. At this time caved ground was cleared west of the intersection, for about 300 metres, to provide sufficient access to the bottom of the old stope area to re-establish natural ventilation. East of the intersection, 30 metres of drifting was done on the main vein and about 400 tonnes of ore was removed from the stope above the drift. Production from the mine to 1980 totals 3211 tonnes of ore that yielded 11,084,830 grams of silver, 2058 grams of gold, 199,781 kilograms of lead, 65,920 kilograms zinc, 54 kilograms of copper and 68 kilograms of cadmium.

The property is underlain chiefly by coarse-grained, porphyritic Nelson monzonite. The granite is traversed by basic dikes along which some renewed faulting has occurred. Faulting follows two principal directions, one striking northeast and steeply dipping, the other striking northwest and dipping steeply northeast.

The main lode, as exposed in the lower No. 3 and No. 4 adits, is mostly a steeply dipping fault-fissure zone that strikes northeast, however, at about 120 metres from the portal of these two adits the lode swings to a more easterly strike and dips 70 degrees north. It varies up to 2.4 metres in width and averages 1.2 metres wide. The lode is composed of broken and crushed rock, partly cemented by quartz which also forms veins and lenses 0.5 metre or more thick. The quartz is banded and also shows some comb structure. It carries disseminations, pockets and streaks of galena, sphalerite, pyrite, tetrahedrite, ruby silver, and native silver, intimately associated with one another in varying proportions. The richest ore was found between No. 2 and No. 3 levels. In some places high silver is associated with galena but elsewhere combinations of tetrahedrite, sphalerite and native silver yield the best silver values.

A sample taken in 1989 assayed 2300 grams per tonne silver, 0.974 grams per tonne gold, 0.247 per cent copper, 7.8 per cent lead, and 12.97 per cent zinc (Open File 1988-11).

The showings were discovered in about 1895 by F. Griffith, who in subsequent years carried out development in open cuts and an exploration adit, however, no significant amount of mineralization was discovered until 1906. In 1907 the Westmont Silver Mining Company, Limited was incorporated in Ontario to develop the property. In 1909 the Eastmont, White Cloud, Oddfellow, Eastmont Fr., Clipper, Westmont, Lily G, White Cloud Fr., and Yankee Girl Fr. claims (Lots 8924-8931 & 8935 respectively), were Crown-granted to the company. The property was acquired by The Ellis Silver Mining Company, Limited, which was incorporated in Ontario in March 1909. Development work was carried out each year from 1907 until 1914 and included over 457 metres of crosscuts and drifts in adit Nos. 3, 4 and 5. H.D. Lea & associates held a lease on the property during 1918-19 and carried out stoping between 3 & 4 levels. Further work was reported in 1927 and 1929.

No further activity was reported until 1956 when the property was owned by J.A. Cullinane & associates, of Nelson, under the name Ellis Mining Syndicate. Lessors Myers and Thickett shipped ore from No. 4 dump to the Van Roi mill at Silverton. Further shipments from No. 4 dump in 1957 were under the name Chexdeco Mining Limited, which was incorporated in July of that year.

Silver King Mines Limited was incorporated in September 1958 to acquire an option on the property. No. 4 adit was reopened and some stoping carried out; the option was abandoned in the summer of 1959. Sterling Silver Mines Ltd. held an option on the property during 1963. A new crosscut adit was driven and some 152.4 metres of diamond drilling carried out.

The 9 Crown-granted claims were optioned in October 1967 by G. Bandeen and W. Wingert, who incorporated Eastmont Silver Mines Ltd. in March 1968. Development work and stoping between Nos. 4 and 5 levels continued into 1971.

Hoko Exploration Ltd. optioned the property from J.A. Cullinane in July 1978. In October a 50-50 joint exploration agreement was reached with Alto Exploration Ltd. The purchase was completed and the title transferred to Hoko. Work during 1979 included 217 metres of diamond drilling in 4 holes.

CAPSULE GEOLOGY

The Dalhousie property is on the southern slope of the valley of Enterprise Creek, 11 kilometres northeast of Slocan. The claims are 600 to 750 metres above the Enterprise Creek road which is the main access to the area.

The workings comprise two adits, 150 metres apart vertically. The upper adit was driven on a quartz-carbonate vein striking 070 degrees, dipping 45 degrees southeast, and 20 centimetres wide by the portal. The vein contains scattered sphalerite and galena and widens to 0.75 metre at a lead enriched section. The 180-metre long lower adit is reported to have been driven as a crosscut to intersect the same vein. The vein occurs within Nelson granite.

Casco Industries Ltd. operated the Pedro, EO, JJ, Read and Wayland claims in 1972.

CAPSULE GEOLOGY

The Neepawa property comprises the Neepawa (Lot 1260), Boisevan, Edith, Mervin and Trio claims on the lower southern slope of Enterprise Creek valley, 11 kilometres northeast of Slocan. Access to the property is from the Slocan highway via the Enterprise and Neepawa Creek roads.

The Neepawa claim was located in 1895. The following year the Neepawa group, consisting of the Neepawa, Argenta, Boisevan, and Baker Fr. claims, was acquired by Messrs. Shannon and McGillvary. The property was worked intermittently either by leasers or by the owners until 1913. In 1919 Delia Mines Ltd. of Vancouver acquired the Neepawa group of 5 claims, the Trio, Biosevan, Neepawa, Edith, and Mervin Fraction. The property was worked intermittently until 1928. The name "Neepawa" was changed to "Peg Leg" in about 1923. In 1928 the property was held under option by Glasord Mining Corp. Ltd.

Terley Mining, Milling and Smelting Co. acquired the Neepawa, Mabou and Ohio claims (082FNW149) in 1946. They built a road from the Enterprise road to a camp on the Ohio claim. A crosscut was driven 12 metres toward what is considered to be the extension of the Enterprise vein, which is exposed in an adit some 40 metres higher. The Company did some diamond drilling on the Svanhild claim, which apparently was acquired in 1948. A 96-metre hole drilled in the Neepawa claim in 1949 is reported to have intersected the vein but the results have not been reported.

In 1986, Trac Resources Inc. drilled 6 holes totalling 306.2 metres on the property.

Intermittent production from 1904 to 1925 amounted to 461 tonnes of ore that averaged 4100 grams per tonne silver and about 5 per cent lead. Developments comprised extensive surface and underground work that included more than 400 metres of drifting from four adits levels

CAPSULE GEOLOGY

between 1280 to 1460 metres elevation.

The property is underlain by coarse grained, porphyritic granite and granodiorite of the Nelson batholith, cut by a few small dark coloured dikes. The claims are crossed by two or more shear zones in a belt 0.8 kilometre wide extending through the Neepawa and Enterprise mines and beyond to the northeast and southwest. On the Neepawa, the two shear zones occur on the lower two levels, separated by about 24 metres of massive granite. Each zone averages a few metres in width and consists of crushed rock, impregnated with, and partly replaced by, vein minerals. The zone strikes about 030 degrees and dip southeasterly at about 65 degrees.

The chief vein mineral is quartz that cements crushed rock and forms lenses and veins of irregular dimensions. Some siderite also occurs together with slightly visible impregnations of sulphides, chiefly pyrite and sphalerite and more rarely galena. In No. 4 adit several centimetres of banded sphalerite, galena and gangue minerals are found over lengths of less than a metre. Early operations are reported to have encountered as much as 40 centimetres of solid fine grained galena and sphalerite with from 0.9 to 1.2 metres of ancillary ore grade alongside.

CAPSULE GEOLOGY

The Enterprise mine is second only to the Ottawa mine in the quantity and total value of ore produced in the Slocan City mining camp. The property consists of the Enterprise (Lot 1014), Slocan Queen, Rainbow, Iron Horse, Sunset, Millsite, Montezuma and Sunrise Crown granted claims and fractions. The mine is on the south side of the valley near the confluence of Enterprise and Neepawa creeks, 11 kilometres northeast of Slocan. Access to the mine from the Slocan highway is via the Enterprise Creek road.

The main vein was discovered in 1894 and mined by Enterprise (B.C.) Mines Co. Ltd. until 1901 and then by lessees. In 1928 the property was purchased by Yankee Girl Consolidated Mines Ltd. which was obliged to close operations in 1930. From 1941 to 1943, the property was leased, during which time the mine tailings and dump were re-worked. In 1944 Western Exploration Co. Ltd. purchased the property and operated it until 1953. Subsequently, until 1977, there has been intermittent production from a number of mining and salvage operations. Production from the property began in 1896 and 11,067 tonnes of ore were mined by 1977 yielding 32,676,718 grams of silver, 1674 tonnes of lead, 1068 tonnes of zinc, 2041 grams of gold, 445 kilograms of cadmium and 149 kilograms of copper.

The Enterprise lode has been developed by nine adits, several intermediate levels and two shafts. One shaft was sunk on the lode about 15 metres above and 90 metres southwest of the uppermost adit,

CAPSULE GEOLOGY

and the other shaft from a point about 10 metres below and a short distance northeast of the lowest adit - the difference in elevation between the collar of the upper shaft and the bottom of the lower shaft being about 335 metres.

The rock underlying the property is a light coloured, coarse-grained porphyritic granite of the Nelson batholith. More basic phases of the batholith, found locally in the mine workings, form irregular bodies of varying size that appear to be either digested inclusions or differentiates of the granitic magma. The Nelson rocks are intruded by a few small, hornblende porphyry and olivine-pyroxene lamprophyre dikes. Some of these dikes cut across the Enterprise lode whereas others are pre-mineral and disrupted by the same faults that cut the vein.

The main vein, averaging less than 0.3 metre wide, is continuous for more than 600 metres, striking 050 degrees, dipping 60 to 85 degrees southeast. On the upper levels of the mine, the vein is filled with varying proportions of quartz and ore minerals, especially galena and tetrahedrite. On the lower levels, siderite and other carbonate gangue minerals are more abundant than quartz and sphalerite is the predominant ore mineral. Most of the silver is believed to be contained in tetrahedrite and ruby silver.

The vein is interrupted by a major fault, or fault zone, and several minor faults and slips. The major fault intercepts the vein nearly at right angles about midway between the two shafts. The zone of faulting is 6 to 9 metres wide, strikes 160 degrees and dips 90 to 75 degrees northeast. The apparent displacement of the vein is about 30 metres to the left.

Aside from the extensive developments on the main Enterprise lode, some work has been done on a second lode outcropping 115 metres to the west. In 1927, it had been drifted on for about 45 metres. It is a wide shear zone composed mostly of crushed granitic rock partly cemented by quartz gangue with some calcite. It strikes 040 degrees and dips 70 southeast. In character and width, this lode bears some resemblance to a vein at the Arlington mine (082FNW152) which may be on part of a continuous structure. It seems that both lodes at the Enterprise mine and those on adjoining properties are within a single, wide zone of fissuring, shearing and brecciation, and that to the southwest this zone passes through the Arlington, Speculator (082FNW151) and intervening properties.

The showings were discovered and staked by R. Kirkwood of New Denver and J. McKinnon of Revelstoke in 1894. The property was optioned to J.A. Finch in 1895 and development work was carried out in several adits. The Enterprise (Lot 1014) and Slocan Queen (Lot 1015) were Crown-granted to J.A. Finch in 1897. Additional claims were subsequently Crown-granted, including the Enterprise Fr. (Lot 4522), Montezuma (Lot 5405), Iron Horse No. 2 (Lot 5663), and Sunset, Sunrise and Rainbow Fractions (Lots 14541-14543).

The London and British Columbia Goldfields, Limited acquired the property and incorporated The Enterprise (British Columbia) Mines, Limited as operator in about 1899. A 50 ton-per-day gravity mill was installed, and apparently operated for a period in 1902 with unsatisfactory results. The company ceased operations and lessees worked the property intermittently from 1903 into 1918. Further work was carried out from 1924 until 1927 by Messrs. Pilcher, McGuire, and Wragge under an option agreement.

The property was acquired by Stobie, Forlong & Company, of Toronto, who incorporated Enterprise Consolidated Mining Company, Limited in February 1928; the company name was changed in September 1928 to Yankee Girl Consolidated Mines, Limited. Development work, mainly on No. 7 level, continued until June 1929 when a fire destroyed equipment housed in the old mill building and operations ceased. No further activity was reported until 1941 when S.N. Ross leased the property and installed a small flotation mill to treat dump material on a seasonal basis.

Western Exploration Company, Limited purchased the property in 1944 and disposed of the mill. Development work during 1945 to 1950 was carried out mainly between Nos. 5 and 8 levels. The No. 9 level was driven from the Iron Horse shaft in 1951-52. The company ceased operations in November 1952. At that time the workings comprised an estimated 3658 metres of drifts, crosscuts, raises and two shafts about 670 metres apart horizontally. Eight adits and several intermediate levels were driven. The lowest level (No. 9) was driven from the 18.2 metre level of the Iron Horse shaft, which was sunk on an incline to a depth of 96 metres. The mine was reopened in 1967 by J. Gates, and R.J. Forgie, who purchased the property from Western Exploration. In May 1968 Enterprise Silver Mines Ltd. was incorporated to operate the mine; some ore was shipped during the year. Lessees worked the property during 1971-77. The property was held by Enterprise Resources Inc. in 1981. Arctex Engineering Ltd.

CAPSULE GEOLOGY

carried out exploration since 1983; diamond drilling was done in 1986 and 1987.

CAPSULE GEOLOGY

The Mabou property comprises the Mabou (Lot 8399), Ohio (Lot 8769), Empress and Summit Crown granted claims and fractions on the south slope of the valley of Enterprise Creek, 10.5 kilometres northeast of Slocan. Access to the property is from the Slocan highway via the Enterprise and Neepawa Creek roads.

The Mabou property has been explored by several short adits and many open cuts on what is believed to be the southwestern extension of the Neepawa - Enterprise (082FNW147,148) vein-shear system hosted by porphyritic granite of the Nelson batholith. The largest development is a 25-metre drift from the uppermost adit. This explores the Enterprise vein which strikes 055 degrees and dips 70 to 80 degrees southeast. The ore consists of fairly coarse grained galena mixed with varying quantities of sphalerite. Assay results on a grab sample of the cleanest looking ore yielded trace of gold, 9100 grams per tonne silver, 18.5 per cent lead and 17 per cent zinc.

The Ohio claim was owned and worked by Messrs. Kirkwood & Wells in 1898. They apparently acquired the Mabou claim in about 1902 and development work was carried out intermittently on both claims through 1904. The Mabou and Riverside claims were owned and worked by Mr. R. Kirkwood in 1905.

The property lay idle until 1919 when Mr. Kirkwood and associates acquired the Mabou, Ohio, Empress Fr. and Summit Fr. claims and resumed development work. The workings at this time consisted of 3 adits, 23, 15 and 4.5 metres.

In 1946 the Mabou, Ohio and Neepawa claims were acquired by the Terley Mining, Milling and Smelting Co. Six adits on the Mabou and Ohio claims were cleaned out but apparently very little development work was done at this time.

CAPSULE GEOLOGY

The property consists of the Bondholder (Lot 1257) and Pine Log Crown granted claims, located on the ridge above the Bondholder basin, 9.5 kilometres northeast of Slocan. The property may be reached by the Little Tim mine road via the Springer Creek or Ottawa Mountain roads. The claims lie on the northeast side and the Little Tim (Graphic & Rosebud) (082FNW157) claims lie on the southwest side of the divide. Most of the workings are on the Little Tim claims at the head of Little Tim Creek.

The claims were located in 1894. The Bondholder, Pine Log, Lone Star, and Rosebud claims were under bond to the Bondholder Mining Co. of Vancouver in 1896 and development work was carried out on the east side of the divide. The Lone Star claim was Crown-granted to J.W. Swords in 1897; the Bondholder and Pine Log claims were Crown-granted to A.M. Johnson in 1899. The Bondholder was worked under lease until 1904. The Graphic and Rosebud claims were worked by the Graphic and Rosebud Mining Co. during 1905-1906. No further work was done on any of the claims for a number of years and the Crown-grants were cancelled.

In 1917 the Bondholder and Pine Log claims were Crown-granted to Ainslie and Bartlett. The following year the Little Tim group, consisting of the Little Tim, Mammoth, White Heather, and Purple Heather claims, was staked by D.B. O'Neill who worked the veins intermittently until 1947. The claims subsequently lapsed and the Victory V, V-day, Ute fraction, Radar No. 1, and Radar No. 2 claims were staked on the veins. In 1951 and 1952 the property was held under option by Harrison Drilling and Exploration Company Limited. Most of the work by the company was done on the V-day and Victory V claims, corresponding to the cancelled Graphic and Rosebud claims, respectively. The workings include three adits and a winze, giving a total depth of the mine of about 50 metres. These workings develop two nearly parallel veins about 90 metres apart, hosted by coarse grained, porphyritic Nelson granite. The veins strike 065 degrees, dip 58 degrees southeast, range from 0.3 to 1.2 metres wide and are

CAPSULE GEOLOGY

composed chiefly of quartz with paystreaks of galena or mixed galena and sphalerite with high-grade silver minerals. The galena varies from coarse to fine cubes and the sphalerite is resinous. The silver minerals are grey copper and a little native silver. The ore minerals are accompanied by some chalcedonic quartz and calcite.

During the years 1900 to 1904 inclusive, 65 tonnes of ore were shipped from this property. This averaged about 3400 grams per tonne silver and some lead.

The veins have been traced southwesterly over the divide onto the Graphic and Rosebud claims of the Little Tim mine (082FNW157).

CAPSULE GEOLOGY

The Speculator property, consisting of the Speculator (Lot 2360), Mineral Mountain (Lot 2362), Eda Fr. (Lot 2363) and Nancy (Lot 5259) Crown granted claims and fractions, is located 8.5 kilometres east-northeast of Slocan. Access from the Slocan highway is via the Springer and Speculator creek roads.

The workings consist of three adits that explore the northeast extension of the Arlington mine zone (082FNW152), which on the Speculator is crushed hornblende granite or granodiorite about 50 metres wide, within which mineralization occurs chiefly in a series of parallel fissures striking 034 degrees and dipping 65 to 70 southeast.

The ore is largely replacement of the crushed Nelson granite. The chief ore minerals are galena and lesser sphalerite, associated with disseminated stephanite, grey copper and native silver. The recorded shipments of ore in 1901, 1941 and 1951, totalled 26 tonnes that yielded 25,661 grams of silver, 5947 kilograms of lead and 413 kilograms of zinc.

A sample taken in 1987 assayed 119 grams per tonne silver, 1.55 per cent lead and 0.46 per cent zinc (Open File 1988-11). Another

CAPSULE GEOLOGY

and Stephanite Crown granted claims and fractions situated on the north slope of the valley, near the confluence of Speculator and Springer creeks, 8 kilometres east-northeast of Slocan. Access to the property from the Slocan highway is via the Springer Creek road.

The mine was developed by eight adits over a vertical range of about 200 metres. In the early years, the bulk of the ore was taken from the fifth to seventh levels and from the original discovery at surface near the shaft. In the latter years, underground work was confined to the lowest two levels.

Production between 1897 and 1979 totalled 20,592 tonnes, yielding 31,429,872 grams of silver, 861,487 kilograms of lead, 118,863 kilograms of zinc, 743 grams of gold, 834 kilograms of copper and 46 kilograms of cadmium. In 1962, 576 tonnes was used as a silica flux.

The Arlington lode is a mineralized crushed zone, about 20 metres wide, in coarse-grained hornblende granite or granodiorite of the Nelson batholith; the zone contains basic monzonite inclusions. The zone includes a number of parallel fissures and maintains a uniform strike of 040 degrees, dipping 60 to 70 degrees southeast. The sear zone is chloritic to talcose altered.

The ore is largely replacement of the country rock, occurring as scattered breccia lenses on continuous fractures. The chief ore minerals are galena and sphalerite, with associated disseminated pyrite, chalcopyrite, stephanite, tetrahedrite and native silver. A sample of the dump taken in 1987 assayed 1280 grams per tonne silver, 0.03 grams per tonne gold, 0.0215 per cent copper, 5.7 per cent lead and 11.47 per cent zinc (Open File 1988-11).

The Arlington mine was worked extensively from 1899 through 1903, then intermittently until 1979. In 1969 and 1970, Arlington Silver Mines Ltd. stopped and shipped ore, which was mainly salvages from the old workings; they also explored, by diamond drilling, what appears to be the northern extension of the vein system.

The property was staked in about 1894 and comprises the Stephanite fraction, Burlington No. 2, Arlington No. 1 fraction, and Arlington No. 2 Crown-granted claims.

The first shipment of ore was made in 1897. The property was worked extensively from 1899 to 1903, production reaching a maximum in 1901. During this period the property was developed by three tunnels over a vertical range of 46 metres. Most of the stoping was done in the upper 15 metres. In 1919 the property was owned by the Rithet Estate and leasers began shipping ore from the dump.

During 1928 the Bayview Mining Co. held an option on the property and began driving a 4th level, the direction of the tunnel being determined by a Radiore survey. In 1937 the Slocan-Arlington Mines Development Co. of Penticton made a shipment of ore from the dump. Leasers shipped from the dump in 1939 and 1948. In 1951 the Ottawa Silver Mining & Milling Co. made a small shipment from the dump.

Amaque Gold Mines Ltd. obtained an option on the property in 1961 from B.I. Nesbitt of Vancouver. The old "A" level was rehabilitated by stripping the first 24 metres, which was caved, and retimbering 73 metres of drift. The level was reopened for a length of 213 metres. The portal of "D" level was opened up and some surface stripping was done. On "A" level eight diamond drill holes were completed, with a total length of 182.8 metres. The holes were drilled along the drift at intervals to explore the shear from footwall to hanging wall. In 1962 B.I. Nesbitt made a shipment of ore from the dump.

Arlington Silver Mines purchased 16 claims including the Arlington mine in 1964. The road and two adits were reopened. In 1969, Arlington became Western Arlington Resources Ltd. and in 1986 changed its name to Lightning Creek Mines Ltd. In 1981, Svienson Way Mineral Services Ltd. purchased 50 per cent interest in the property. From previous work there were blocked out 43,114 tonnes of proven surface dump ore at 487.8 grams per tonne silver, 0.49 per cent lead and 0.39 per cent zinc; 17,470 tonnes of indicated underground at 699.4 grams per tonne silver, 1.04 per cent lead and 0.85 per cent zinc (Vancouver Stock Exchange Statement of Material Facts (#108/90, 1990). In 1988, Lightning Creek Mines Ltd. listed proven, probable and indicated resources at 62,252 tonnes averaging 396 grams per tonne silver and 0.54 per cent zinc (CMH 1988-89, page 290). During 1989 and 1990, Cazador Explorations limited purchased the property. Cazador amalgamated in 1993 to become Granduc Mining Corporation, which amalgamated in 1996 with Black Hawk Mining Inc.

CAPSULE GEOLOGY

The Lily B claim is located at about 1600 metres elevation on the south slope of the valley of Springer Creek, 7.5 kilometres east-northeast of Slocan. Access is via the Springer Creek and Bettina Creek roads from the Slocan highway.

The workings, consisting of a shaft and adit, explore a fault fissure lode cutting coarse grained Nelson granite, on a strike that varies from 075 to 105 degrees, dipping 55 degrees south. The mineralized zone consists of crushed country rock and gouge, up to 1.5 metres wide, containing small lenses of ore, up to 1 metre wide. The ore consists of galena and sphalerite accompanied by a small amount of pyrite and chalcopyrite in a quartz gangue. Some native silver occurs along the fissure planes in the ore.

Shipments of ore from this mine were intermittent beginning in 1913. Altogether up to and including 1922, this mine has produced 41 tonnes of ore yielding an average of 2748 grams per tonne silver and 5.6 per cent lead.

CAPSULE GEOLOGY

along the east shear zone for about 73 metres, at which point a crosscut 15 metres long runs to the west shear where this zone has been drifted on northerly. At about 55 metres along this drift a winze was sunk intercepting a 7-centimetre paystreak carrying tetrahedrite and native silver. Subsequently, numerous ore shoots have been encountered along the west shear zone and much stoping has been done above the level south of the winze. The ore shoots tend to cut across the shear zone from wall to wall in a northeasterly direction and en echelon style, averaging 15 metres in length, and up to 0.6 metre in width. The principal ore minerals are native silver, stephanite, tetrahedrite, some galena and sphalerite, and locally considerable chalcopyrite. Quartz is the abundant gangue mineral and occurs with some barite.

The initial shipment of ore from this mine was about 4 tonnes in 1912. Production was intermittent until 1928 then again between 1960 and 1964, when the total ore shipped amounted to 177 tonnes, averaging 5153 grams per tonne silver plus ancillary amounts of copper, lead and zinc. In 1962, 45 tonnes was used as a silica flux.

CAPSULE GEOLOGY

following year Harrison Drilling and Exploration Co. Ltd. of Vancouver held operating control under an agreement with Violamac Mines. Harrison Drilling and Exploration Co. Ltd. was reorganized in 1953 under the name of Hardex Mines Ltd. and a diamond drilling program was carried out. In 1956 the owners resumed operations. An option on the property was given to the Yukon Western Mining & Prospecting Co. Ltd. of Slocan City in 1958. In 1960 the name of this company was changed to Skylane Mines Ltd. Most of the work done at this time was confined to stoping in the West vein on No. 8 level. In 1960 Ottawa Silver Mines Ltd. bought the option from Skylane Mines Ltd. Later in the year an option was given to the Silver Buckle Mining Co. of Wallace, Idaho. This option was dropped in December after a geological examination of the property had been made. A 9th level was started at this time. In 1962 a ventilation raise was driven from No. 8 level to No. 6 level, a distance of approximately 143 metres, following the dip of the vein. In driving the raise, several lenses of very high-grade ore were opened up and subsequently stoped out. The No. 9 level drift was extended to a length of 152 metres. During 1963 and 1964 exploration and development work was carried out on No. 9 level. A 75-ton mill was built in 1963 and put into part time operation in 1964. In 1963 the company was reorganized under the name Slocan Ottawa Mines Ltd. In 1980 the mine was owned by the Slocan Development Corporation Limited and leased to C. Thickett and Memphis Mines Ltd. between 1976 and 1982.

Total recorded production between 1903 and 1984 amounts to 26,476 tonnes mined, yielding 55,940,682 grams of silver, 982 grams of gold, 360,085 kilograms of lead, 12,774 kilograms of zinc and 793 kilograms of copper.

The property is developed on nine levels, 5 of which are serviced by adits driven at vertical intervals of about 30 metres. These workings explore a broad shear/breccia zone in coarse grained, porphyritic Nelson quartz monzonite cut by felsite and lamprophyre dikes. The zone trends nearly north and dips easterly from 25 to 45 degrees. The zone comprises two rather well-defined lodes known as the West or Noble and East or Ottawa veins, respectively. Mining at the surface and underground indicates that these lodes are not exactly parallel, but approach each other towards the south and may join. On the No. 5 level the lodes are about 10 metres apart. Most of the work has been done on the East lode that is 0.6 to 6 metres wide, composed of crushed and broken granite, gouge and vein material - the latter having been stoped in places across a width of as much as 2.4 metres. The West lode is as much as 15 metres wide in places and it is reported to have produced some good ore in the uppermost workings. On No. 8 level, the stoped vein on the West lode, strikes 025 to 040 degrees and dips 20 degrees southeast. The vein is up to 0.3 metres wide - bounded by a sharply defined gouge-filled slip along the footwall and an irregular hanging wall. The East lode on the No. 8 level is strong and composed of about 1 metre of gouge and beccia cemented by quartz. It strikes 170 degrees and dips 30 to 40 degrees east.

The ore minerals consists mostly of mixture of galena, pyrite, sphalerite and a little chalcopyrite, native silver, argentite and tetrahedrite disseminations in quartz gangue. In some high grade ore, barite is reported to be predominant gangue mineral.

CAPSULE GEOLOGY

The Tamarac group comprises the Tamarack No. 2 (Lot 6054), Falls View No. 2, and Essie claims and fractions located on the north slope of the valley of Springer Creek, west of the Ottawa mine (082FNW155), 4 kilometres northeast of Slocan. Access is east from the Slocan highway along an all weather Springer Creek logging road to the Ottawa mine road which turns north. A good logging road extends from the Ottawa mine road westward to Algiers Creek and the Tamarac property.

The Tamarac mine workings are about 275 metres above Springer Creek and include three adits driven at vertical intervals of 24 metres on a shear zone cutting coarse grained, porphyritic Nelson granite following and easterly strike, dipping 25 to 35 degrees south. The principal mineralization is quartz, associated with minor amounts of calcite and barite, carrying galena, sphalerite, pyrite, chalcopyrite and tetrahedrite. Silver values in the ore are generally associated with tetrahedrite - the galena reportedly carries low silver.

The Tamarac property was worked extensively beginning in 1905. In the uppermost adit the lode was drifted on for more than 60 metres. On No. 2 level, lenses of mineralized quartz, up to 0.6 metre wide, are interspersed with barren intervals. Near the portal, the main ore shoot was followed for a length of 9 metres and was stoped to a point 14 metres above No. 1 adit. The No. 3 level is about 122 metres long where, at the face, an east dipping, metre-wide fault zone is intersected, cutting off the lode.

Although the ore zones on the Tamarac strike almost at right angles to the trend of mineralized at the Ottawa mine, the style of mineralization is similar on these adjoining properties. Total production from the Tamarac mine up to the end of 1907 amounts to 83 tonnes of ore grading 4436 grams per tonne silver and 10.2 per cent

CAPSULE GEOLOGY

Work on the property, as the Graphic and Rosebud claims, from 1905 to 1906 by the Graphic and Rosebud Mining Co. resulted in the production of 5 tonnes of ore, yielding 47,619 grams of silver and 636 kilograms of lead. The Little Tim group, consisting of the Little Tim, Mammoth, White Heather, and Purple Heather claims, was staked by D.B. O'Neill in 1918 who worked the veins intermittently until 1947. The claims subsequently lapsed and the Victory V, V-day, Ute fraction, Radar No. 1, and Radar No. 2 claims were staked on the veins. In 1951 and 1952 the property was held under option by Harrison Drilling and Exploration Company Limited (Hardex Mines Ltd.) during which time considerable drifting and diamond drilling was done. Most of the work by the company was done on the V-day and Victory V claims, corresponding to the cancelled Graphic and Rosebud claims, respectively. The Little Tim upper workings, comprising two adits and a shaft, explore the vein that is 91 metres northwest of the main vein. The main vein is developed by 4 adits that range in elevation from 2067 to 1987 metres. During 1952 No. 4 adit was extended to a total length of 134 and a raise driven to No. 3 level.

Several individuals have held leases since the early 1950's and all shipments from the property consist of hand sorted ore. Approximately 300 metres of drifts, crosscuts and raises were developed in the original mine and by 1981 a total of 339 metres of new drifts and crosscuts were added. Skagit Mining operated the property in 1984. A sample taken in 1987 assayed 4400 grams per tonne silver, 0.18 gram per tonne gold, 0.58 per cent copper, 11.3 per cent lead and 4.34 per cent zinc (Open File 1988-11).

Intermittent production from 1905 to 1984, resulted in 5116 tonnes, yielding 1,366,013 grams of silver, 26,339 kilograms of lead, 8536 kilograms of zinc, 11 grams of gold and 171 kilograms of copper.

The property is underlain by coarse-grained porphyritic granite (quartz monzonite) of the Nelson batholith. The granite is traversed by two, nearly parallel fissure vein lodes, on which considerable work has been done. The lodes are 90 metres apart and strike 055 to 070 degrees northeast, and dip 45 to 70 degrees southeast.

The mine, located just southwest and downslope from an unnamed summit, is comprised of a shaft and three adits on the northwest lode, and three adits and an intermediate level on the southeast lode - the shaft being the lowest working at an elevation of approximately 2040 metres. The shaft is reported to have followed a vein to a depth of about 15 metres. The vein, about 0.3 metre wide, consists of vuggy quartz containing disseminated galena, sphalerite, pyrite and tetrahedrite. The same vein is heavily stoped to a point about 90 metres above the shaft. On the southeast lode, the main adit is 75 metres long and follows a fissure which is strong at the face but not mineralized. The orebody on this level, about 8 metres long, was stoped through to an intermediate level 12 metres above, where the ore was exposed for a length of 15 metres and width ranging from 10 to 30 centimetres. This ore forms a streak of nearly solid galena, sphalerite, conspicuous tetrahedrite and a little chalcocopyrite. The gangue is principally quartz but some calcite and barite are also present. Some of the quartz appears to be chalcedonic. The veins are commonly flanked by a chloritic alteration envelope up to 1.2 metres wide grading into the granite. Other wallrock alteration includes argillic, silicification and hematitic-pyritic.

No further work was done on any of the claims for a number of years and the Crown-grants were cancelled.

CAPSULE GEOLOGY

The Molly claim is about 1 kilometre east of Ottawa Hill and 900 metres west of the Little Tim mine (082FNW157), 8 kilometres northeast of Slocan. Access to the area is by trail, west from the Little Tim mine road that connects with the Springer Creek road.

The workings of the Molly property one or two adits and a shaft. These explore a quartz vein cutting porphyritic Nelson granite. The vein strikes 050 degrees and dips steeply to the southeast. Samples of vuggy quartz are reported to contain considerable disseminated pyrite and silver-bearing sulphides (?) yielding good gold and silver assay results. In 1935, 8 tonnes of ore from a dump yielded 13,996 grams of silver, 160 kilograms of lead and 142 kilograms of zinc.

CAPSULE GEOLOGY

The Myrtle group of claims, consisting of the Alma (Lot 6516), McBride and Howie claims, is near the head of Memphis Creek, elevation 1650 metres, 6 kilometres northeast of Slocan City. Access is by the Memphis Creek road, 2.5 kilometres east of the Slocan highway.

The property was developed in the years 1901 to 1907, and intermittently from 1907 to 1966. Ore shipments made in 1907, 1935 and 1966 totalled 60 tonnes containing 75,425 grams of silver, 539 kilograms of lead and 907 kilograms of zinc.

The country rock is porphyritic Nelson granite that is bleached and silicified adjacent to the vein. The vein is in a sheared and brecciated zone that strikes 040 degrees and dips 35 to 40 degrees southeast. A crosscut adit driven easterly at 107 degrees on the 100 level encountered 160 metres of this zone. A small pegmatite dike, a felsic dike and several shears are also exposed in this crosscut. On the 50 level, small lenticular masses of quartz and calcite with pods of sulphides occur within a 26-metre section of the main shear. Galena, sphalerite, some chalcopyrite and a minor amount of tetrahedrite and native silver (?) are the principal ore

CAPSULE GEOLOGY

minerals.

The Alma and McBride claims were held by J.E. Tatersall in 1924; the property was held by R.F. Ainslie during the period 1935-41. Development work to this time consisted of: a 158-metre long crosscut adit and from the end of it 35 metres of drifting on the vein; a 30-metre deep shaft and from the 15-metre level a 21-metre long crosscut to the vein from which an 26-metre drift was run to the south.

Silver King Mines Ltd. began exploration work on the property in 1965. The company name was changed in November 1965 to Kirsch Silver Mines Ltd. A vein sample taken in 1987 assayed 179 grams per tonne silver, 0.0308 per cent copper, 1.53 per cent lead and 4.8 per cent zinc (Open File 1988-11).

CAPSULE GEOLOGY

The Radio claims are located at the head of Memphis Creek, 7 kilometres northeast of Slocan. Access is via a network of logging roads on the west slope of Ottawa Hill.

The only exploration work reported on this property has focused on a mineralized shear zone cutting north to northeasterly across coarse-grained porphyritic Nelson granite. The zone is a few metres wide and includes some vein quartz accompanied by sulphide mineralization.

CAPSULE GEOLOGY

The Colorado property is located at the elevation of about 1400 metres, on the northwest slope of Ottawa Hill above Memphis Creek (Twelvemile Creek), 6.5 kilometres north-northeast of Slocan. Access to the area is via 5 kilometres of switchback logging road from the Slocan highway.

A quartz vein in Nelson porphyritic granite has been explored by several open cuts and underground mining consisting of two levels connected by a raise and stoping. Intermittent mining for the periods 1904 to 1915 and 1967 to 1969 produced a total of 67 tonnes, yielding 2188 grams per tonne silver, 2.5 per cent lead, and 5.6 per cent zinc. Western Standard Silver Mines and Hyperion Silver Mines Limited worked the property between 1966 and 1970.

In 1988, Yukon Minerals Corporation conducted soil and rock sampling, and geological mapping in the area. A sample from the Colorado adit assayed 228 grams per tonne silver, 0.27 per cent lead and 0.3 per cent zinc over 0.8 metre on a quartz-galena vein (Assessment Report 18603).

CAPSULE GEOLOGY

The Coronation property is located on Memphis Creek, at the elevation of about 1100 metres, at 6.5 kilometres north-northeast of Slocan. Access is about 2 kilometres by road up Memphis Creek from the Slocan highway.

The property comprises the Coronation and Memphis claims staked in 1896. About 2 tonnes of ore are reported to have been shipped and to have carried between 19 and 20 per cent lead and as much as 13,000 grams per tonne silver. Development consists of a lower adit, 45 metres in length, and a shorter upper adit, 15 metres above, driven in easterly from the bank of the Memphis Creek. The lower tunnel is in sheared, coarse grained Nelson granite following a quartz vein, up to 0.3 metre wide, and stringers dipping 65 degrees north. The vein contains many fragments of wallrock and some galena, sphalerite, pyrite, native silver, calcite and siderite. A small basic dike forms part of the footwall. At 27 metres from the portal, two slips striking 008 degrees, dipping 80 degrees west, offset the course of the tunnel about 2 metres to the north. At this intersection of slips and quartz stringers, small clusters of highgrade ore were found. A sample of tetrahedrite-bearing ore from this location assayed 2.1 grams per tonne gold and 6000 grams per tonne silver.

In 1988, Yukon Minerals Corporation conducted soil and rock sampling, and geological mapping in the area. A sample from the Coronation dump assayed 0.4 gram per tonne gold, 2414 grams per tonne silver, 1.2 per cent lead and 10.9 per cent zinc (Assessment Report 18603).

CAPSULE GEOLOGY

The Happy Medium property is located near the head of Van Tuyl
Creek, 7 kilometres north-northeast of Slocan. Access is by road
1.5 kilometres east from the Slocan highway.

The Happy Medium property consists of the Happy Medium (Lot
5558), Velvey, International and Eclipse No. 2 Crown granted claims.
Little is known about this property other than it is underlain by
Nelson granite or mineralized crushed compositionally equivalent
units.

Shipments of ore made in 1905 and 1906 amount to 12 tonnes
grading 10 grams per tonne gold, 5,588 grams per tonne silver and
8.4 per cent lead.

CAPSULE GEOLOGY

The Senator mine, previously known as the Batchelor and Midnight, is located on the south side of Memphis Creek (formerly Twelvemile Creek) about 1.0 kilometre east of the Slocan highway, 6 kilometres north of Slocan. The Senator claim (Lot 15828) lies immediately east of the Homestake claim (Lot 15283)(082FNW213) and south of the V. & M. (Lot 4260) and Get There Eli (Lot 4261) claims (082FNW191).

The property is underlain by broken and foliated porphyritic Nelson granite. The workings consist of 2 adits, one 61 metres long, on a quartz vein averaging 1.2 metres in width. The vein strikes 030 and dips 47 degrees southeast. In 1906 and 1907, the Midnight produced 20 tonnes of ore, yielding 43,420 grams of silver and 436 grams of gold. In 1939 and 1940, the Senator produced 13 tonnes of ore, yielding 187 grams of gold and 17,947 grams of silver.

In 1948, the property was held by the Spokane Slocan Company. In 1988, Yukon Minerals Corporation conducted soil and rock sampling, and geological mapping in the area. A sample from the Senator adit assayed 6.1 grams per tonne gold and 1080 grams per tonne silver over 0.3 metre on a quartz-pyrite vein (Assessment Report 18603).

CAPSULE GEOLOGY

Senator Crown-granted claims and 6 recorded claims.

The target of exploration on the property is a narrow, locally pyritized quartz vein in granite, striking 140 degrees and dipping 50 degrees southwest. The early development consists of three main adits and several open cuts. The principal showing is on No. 2 level which has a total of 150 metres of drifts and crosscuts. The lode here is about 30 metres in length and has an average width of 25 centimetres. Most of the original ore shipments came from the upper adit which is about 25 metres long, with a raise to surface. The best part of the vein shows 5 to 15 centimetres of zinc mineralization. The lower adit is 15 metres long and exposes a wider vein section but with minor mineralization. There is another adit at the elevation of the upper adit which was driven 40 metres as a crosscut to intersect a parallel vein exposed in an open cut above, but no vein was encountered. In 1957, a new adit site was chosen to explore the vein system from a horizon about 15 metres below the lowest workings, however no worthwhile mineralization was encountered. In 1964, the workings were reopened by Western Standard Silver Mines Ltd. In 1986, Manny Consultants Ltd. surveyed the property as the JR claims.

In 1897 and 1902, a total of 12 tonnes was shipped from the Paystreak; recovery was 19,128 grams of silver and 622 grams of gold. The total intermittent production from this property from 1935 to 1964 was 81 tonnes, yielding 155 grams of gold, 25,691 grams of silver, 11,424 kilograms of lead and 11,052 kilograms of zinc.

CAPSULE GEOLOGY

and walls are well defined. Hostrocks are well brecciated and cemented with milky quartz. Mineralization hosted in quartz cement includes galena, pyrargyrite, sphalerite and pyrite. Diamond drilling in 1986 confirmed the downward dip of the shear zone up to 61 metres, along a strike length of 61 metres. Sericitic, argillic and silicification alteration were observed.

Shipments of 10 and 5 tonnes were made in 1896 and 1897, respectively. In 1975, clean-up from the dump resulted in a shipment of 36 tonnes of ore. In total 123,447 grams silver, 323 kilograms lead and 143 kilograms zinc were recovered from 51 tonnes of ore.

CAPSULE GEOLOGY

This property is located at the extreme headwater area of Scorpion Creek, at an elevation of 1300 metres, 4.5 kilometres northeast of Slocan. Access to the property is from the Slocan highway via a switchbacked logging road on the northwest slope of Ottawa Hill. The Republic (082FNW168) lies to the southwest. Adit locations are shown on Geological Survey of Canada Map 272A.

The Northern Light was located in 1902 and Crown granted (Lot 11130) in 1916. Little is known about this property other than it is underlain by coarse grained, porphyritic Nelson granite. The only development work is two short adits from which there is no known ore production.

International Cherokee Development and Manny Consultants conducted geochemical and geophysical surveys over the S and R claims between 1983 and 1986.

CAPSULE GEOLOGY

The Republic group of claims is located about 5 kilometres by gravel road northeast of Slocan City. The claims were first staked in 1895 and worked intermittently until 1952. Tandem Resources Ltd. held the property, including the Club (082FNW169) in 1972. In 1979, they conducted an IP survey and sampling.

Past production occurred from the Republic vein which is less than 75 centimetres thick. The quartz vein contains pyrite, argentite, native silver and gold with minor galena and sphalerite. Bornite are also reported. The vein is hosted in potassium-feldspar porphyritic granite. Wallrock alteration includes quartz, sericite, chlorite, and carbonate. It extends less than 1 metre from the quartz veins. There are at least 2 main quartz veins on the property. They strike west and dip moderately to gently north.

The Republic vein has been developed by an inclined shaft, collared at an elevation of 1334 metres. The incline has been sunk to a depth of some 18 metres on the vein which is approximately 1-metre wide. The vein strikes 085 degrees and dips 30 degrees to the north and is offset slightly by step-faults striking 025 degrees to 045 degrees with dips from 65 degrees to 85 degrees northwest. Short irregular drifts and slopes have been driven from the incline. Another shaft, some 244 metres west of the above shaft, has been sunk on what appears to be the extension of the Republic vein. The vein

CAPSULE GEOLOGY

is 0.6-metre wide, strikes 050 degrees and dips 35 degrees northwest. Further west 2 levels have been driven to crosscut the vein but neither one did before the work was stopped.

The Bell No. 2 adit, west of the Republic adits, follows a discontinuous vein which strikes 020 degrees and dips 45 degrees southeast. Beyond 18 metres from the portal the vein is complexly faulted. The veins in the eastern portion of the property generally strike east and dip gently north whereas the west veins strike northeasterly with a flat dip to the northwest. Ore shoots within the veins are erratically distributed and are elongated down the dip. The Crown-granted mineral claims have numerous showings and surface workings and a few claims which were previously worked on and surveyed were covered by some of the Ross claims in 1922. The Slocan Bob claim was covered by Ross No. 9 and the Ross No. 11 claims. The Club claim (082FNW169), which has two veins reported to be at right angles to one another, were covered by Ross No. 10 and Ross No. 12 claims.

R.B. Stewart prospected the Evening No. 9 claims in 1987.

CAPSULE GEOLOGY

The Club claim is situated towards the head of Scorpion Creek, 3.5 kilometres northeast of Slocan. Access is from the Slocan highway via a switchback road that crosses Scorpion Creek below the property. See also Republic (082FNW168).

The Club property was first prospected in 1904. The target of exploration was two quartz veins in crushed granitic rocks that appear to be related to the Nelson batholith. The main vein is about 0.9 metre in width, strikes northeast and dips northwest at about 30 degrees. Rich samples have reportedly been obtained from a shallow inclined shaft sunk on this vein. A shipment of 4.5 tonnes of ore from this property in 1904 produced 8367 grams of silver.

Across a small creek from these workings there is a second vein quartz, about 1.5 metres wide, striking 126 degrees.

The property was covered by the Ross claims, held in 1972 by Tandem Resources Ltd.

CAPSULE GEOLOGY

The Ruby and Mable property is located on the lower section of Scorpion Creek, 2.5 kilometres northeast of Slocan. Access is from the Slocan highway via a switchback road on the west slope of Ottawa Hill.

The workings on this property, comprising a 90-metre adit and raise, explore a quartz vein in coarse grained, porphyritic Nelson granite. A total of 10 tonnes of ore was shipped from 1903 to 1904, yielding 6656 grams of silver and 31 grams of gold.

CAPSULE GEOLOGY

The Port Hope claim is situated 1 kilometre northwest of the confluence of Scorpion and Springer creeks, 2 kilometre northeast of Slocan. Access is from the Slocan highway via a switchback road leading to the northwest slopes of Ottawa Hill.

Little is known about the Port Hope claim (Lot 5493) other than it was Crown granted in 1903 and 10 tonnes of ore was shipped the following year. Recovery was 46,530 grams of silver and 246 grams of gold. In 1935 and 1937, production from 4 tonnes, yielded 8149 grams of silver and 31 grams of gold.

The property is underlain by mineralized granitic rocks of the Nelson batholith. In 1969, work done in the area by Red Metal Mines included six open cuts and 132 metres of diamond drilling.

CAPSULE GEOLOGY

The Lakeview property is situated east of Springer Creek, at the elevation of 900 metres, and 1.5 kilometres due east of Slocan. Access is directly from Slocan via the Springer Creek gravel road.

The Lakeview property comprises the Lakeview No. 8 claim (Crown granted in 1898) and located MS claims, Selmon, Maur I and II. The property is underlain predominantly by granitic rocks of the Nelson batholith. The focus of exploration and development is a northerly trending vein exposed for a strike length of 100 metres at surface and 35 metres underground. The vein, consisting of lenses and stringers of quartz, dips 70 degrees east and is hosted by highly crushed granite. Disseminated sulphides occurring in the wall rocks and the vein system include pyrite, galena and sphalerite, together with a minor amount of chalcopyrite and pyrrhotite. At surface chalcocite and covellite occur associated with late carbonate gangue replacing chalcopyrite and cerussite replaces galena.

Development on the property consists of open cuts, an adit, a shallow shaft and a small floatation plant. The shaft, about 5 metres deep, remains from the original workings. At the south side of the shaft, the quartz vein has a width of 0.7 metre, which narrows to 40 centimetres at a point 9 metres south, where a sample taken across cellular rusty quartz assayed 17 grams per tonne gold and 410 grams per tonne silver. The adit is a crosscut for 15 metres on a course of 125 degrees to the vein, then 12 metres at 155 degrees, and further drifting for 23 metres, striking 175 degrees to the face that lies directly below the end of stripping on surface. There is an ore shoot at the second bend in the tunnel that connects to the shaft - the best mineralization is exposed in the first 15 to 18 metres of drift section of the tunnel.

Intermittent shipments of ore were made from 1937 to 1980; these totalled 4150 tonnes, yielding 132,843 grams of silver, 1504 grams of gold, 5175 kilograms of lead, 4139 kilograms of zinc, and 24 kilograms of cadmium.

CAPSULE GEOLOGY

The Dayton property is near the mouth of Dayton Creek at the elevation of 1035 metres, 3 kilometres east-northeast of Slocan. Access is from the Slocan highway via the Springer Creek road.

The Dayton claim (Lot 2419) is underlain by coarse grained, porphyritic Nelson granite. The workings consist of a crosscut adit that intercepts two vein structures. Drifting on the principal structure explores a fault fissure system that strikes 160 degrees and dips 35 degrees northeast. This contains lenses of quartz up to 46 centimetres wide, mineralized with pyrite, some galena, argentite and tetrahedrite. A second quartz vein, 15 metres further on at the face of the crosscut, strikes 025 degrees and dips 55 degrees southeast. This vein is 1.8 metres wide and contains some coarse pyrite cubes.

Intermittent production from 1903 to 1935, totalled 17 tonnes, yielding 12,224 grams of silver, 93 grams of gold and 1006 kilograms of lead.

OGG Corporation held the property in 1982.

CAPSULE GEOLOGY

The Exchange property is at 1600 metres elevation on the ridge southwest of Dayton Creek, 3 kilometres due east of Slocan. Access to the property is from a switchback mountain road that joins the Springer Creek road just east of the Slocan highway.

A quartz vein in Nelson granite has been explored by three adits, a shaft and a 30-metre winze sunk from the lowest adit. The vein is 1.5 metres wide, banded with clear and milky white quartz and pyrite accompanied by some galena, sphalerite and ancillary silver-bearing minerals.

Production from this property in 1896 amounted to 4.5 tonnes averaging 41 grams per tonne gold and 5100 grams per tonne silver. In 1940, 12 tonnes produced 25,784 grams of silver and 156 grams of gold. Total production is estimated to be more than 50 tonnes, although records are incomplete.

CAPSULE GEOLOGY

The Evening Star property is at 1675 metres elevation on the slopes east of Dayton Creek, 4.5 kilometres due east of Slocan. Access to the property is from a switchback mountain road that joins the Springer Creek road at Coldwell Creek, about 8 kilometres by road east of the Slocan highway.

The Evening Star property, which was first staked in 1894, comprises the Evening Star No. 8 (Lot 5226), Silver Crown (Lot 5227), Eclipse No. 2 (Lot 5229), Columbia No. 5 (Lot 5225), Somerset (Lot 5224) and Unknown Group (Lot 5230) Crown granted claims and fractions.

A quartz vein in Nelson granite has been explored by an adit and shaft. The vein strikes variably from 150 to 175 degrees, dips 55 to 75 degrees northeast. It is about 1 metre wide and carries some pyrite and galena.

Production of mainly hand cobbled ore from this property in 1896, 1918 and 1941 totals 42 tonnes grading 23 grams per tonne gold and 6646 grams per tonne silver.

CAPSULE GEOLOGY

The Calumet property is at about 2000 metres elevation on the ridge east of Dayton Creek, 5 kilometres due east of Slocan. Access to the property is from a switchback mountain road that joins the Springer Creek road at Coldwell Creek, about 8 kilometres by road east of the Slocan highway.

The Calumet property, first staked in 1895, comprises the Calumet No. 2, Buffalo and Hecla claims and fractions. The property was trenched by Slocan Hughes Mines Ltd. in 1963 and by Goldstream Mines Ltd. in 1970.

A quartz vein cutting granitic rocks of the Nelson batholith and a large metasedimentary xenolith (the Slocan Group ?) has been explored by an adit crosscut and drift. The vein is intercepted by the tunnel at 46 metres from the portal. It strikes about 060 degrees and dips steeply northwest and has been drifted on for 90 metres, partly in metasediment rocks and partly in the granite. In the metasedimentary rocks the vein is irregular and consists of barren quartz, however, in the granite the vein is regular, about 1.5 metres wide, and contains galena, sphalerite and barite. In this section of the tunnel the best samples grade 280 grams per tonne silver and 12 per cent lead.

CAPSULE GEOLOGY

consisted of galena and sphalerite with the latter increasing with depth. In the lower portions of the workings vein widths varied from several centimetres to 120 centimetres, containing bands of sphalerite up to 20 to 25 centimetres wide. The vein-lode is interrupted by faults which displace it to the east and divide the vein-lode into two distinct separate ore shoots. The northern ore shoot was the more extensive of the two.

Principal production was from the upper three levels of the workings which were stoped to the surface. Production records indicate 2989 tonnes were produced periodically from 1893 to 1942. From this, 10,884,805 grams silver, 311 grams gold, 913,963 kilograms lead and 183,052 kilograms zinc were recovered. Another 57 tonnes production is reported in the Minister of Mines Annual Report 1943, page A73. The ore was mined by hand and sent directly to the Trail smelter. Approximately 44 tonnes was reported mined in 1936 but was not shipped (Minister of Mines Annual Report 1936, page E52).

CAPSULE GEOLOGY

The Cliff occurrence is located at about 1067 metres elevation on the Cliff Reverted Crown grant (Lot 2606), east of Emily Creek. Silverton, British Columbia lies 2.75 kilometres to the west.

The Cliff claim was first Crown granted in 1898. Little geological information is available for the Cliff occurrence. Some general information with reference to the Cliff occurrence is given in Geological Survey of Canada Memoir 308, pages 184-185. The occurrence is described as a zinc-lead-silver fissure-filled lode deposit with silver production exceeding lead. These deposits may contain some disseminated sulphides in the adjacent wallrock. The country rocks are argillite, quartzite and limestone of the Triassic Slovan Group. Gangue minerals include quartz, calcite and siderite. Wallrock fragments are common in veins. Ore minerals are mainly sphalerite, galena and pyrite. A 60-metre adit follows part of the vein which strikes east-west and dips 50 degrees north.

Reference to production on the Cliff occurrence dates back to 1932. Production records indicate 21 tonnes was mined in 1932, 1935 and 1936. This yielded 32,098 grams silver, 2278 kilograms lead and 3542 kilograms zinc.

CAPSULE GEOLOGY

The Standard occurrence is located on the southwest flank of Idaho Peak at about 1082 metres elevation. Silverton, British Columbia is located 2.5 kilometres to the west. The Standard (Lot 564), Alpha (Lot 562) and Emily Edith (Lot 2532) claims form the nucleus the Standard claim group covering the ground hosting the Standard occurrence. These claims were initially staked under separate ownership. Production from the Alpha occurrence began almost immediately from an outcrop containing high-grade galena. The main Standard orebody was not discovered until 1919, in the No. 4 tunnel. By 1913 all the claims had been combined under ownership of the Standard Silver-Lead Mining Company and the mine operated until 1921. From 1921 to 1928 the mine continued to operate under the ownership of Western Exploration Company Limited

CAPSULE GEOLOGY

and worked by various lessees. The mine continued to operate intermittently until 1952 by Western Exploration Company Limited. Operations then ceased until 1959 when various lessees carried out salvage operations. In 1961, Loma Minerals Ltd. held a lease that included the Standard, Mammoth (082FNW060), Monarch and Enterprise (082FNW148) groups. The property was leased by Johnsby Mines Ltd. in the following year and an extensive development program was commenced on the hangingwall branch of the Standard-Mammoth lode system. Three new ore shoots were discovered during a diamond drilling program in a newly collared adit on the east-neighbouring Surprise claim. Production continued until 1966 when the new ore was exhausted. Panoil Canadian Minerals Associates optioned the property in 1967 with further development work on the Mammoth occurrence. Arjan Pacific Ltd. acquired ownership of 32 Crown grants in 1973 which included claims covering the Standard, Hecla and Mammoth lodes. In 1984, Silver Ridge Resources Inc. carried out restoration of the 7-B level on the Emily Edith claim. This included 27 metres of new drift, 183 metres of drift rehabilitation and 46 metres of crosscut rehabilitation. Development work continued from 1986 to 1988 with diamond drilling carried out.

The Alpha claim has been developed by seven adits, the lowest at 1280 metres elevation. A total of 1433 metres of adit development work were carried out. The remainder of the Standard occurrence has been developed by twelve tunnels, including the Y, and Nos. 1, 7, 7-A, 7-B, 7-C and 8. The No. 8 is the lowest at 841 metres elevation. Ore has been found over a vertical range of 610 metres with up to 90 per cent of the ore mined over 152 metres between 1021 and 1173 metres elevation.

The Standard occurrence is hosted by siliceous, carbonaceous and locally calcareous argillite, minor quartzite and limestone of the Triassic Slocan Group. These are intruded by a granodiorite stock and various quartz porphyry and biotite hornblende porphyry dikes. The dikes are highly altered to quartz, calcite and sericite, close to the Standard veins. The structure of these strata is extremely complex owing to intricate folding and faulting.

The Standard lode-fissure consists of a wide, up to 50 metres, shear zone. Underground, the lode has been followed for nearly 2.39 kilometres. While the lode is somewhat sinuous, it strikes about 065 degrees and dips 20 to 80 degrees, averaging 45 degrees. Near the main orebody the lode has a maximum width of 46 metres. The zone has many small offsets and split in north-northeast and east-northeast branches at its eastern extremity. This is where the main orebody was found. The main ore shoot, known as the Big or Million Dollar stope, extends 366 metres vertically downward from the No. 3 level to below the No. 6 level. Other orebodies, which include the I vein, 640 vein, 620 vein and Spur vein, are scattered along the structure. The ore shoots are generally at an angle to the main footwall shear and a sigmoidal shape is reported for some of them, joining the footwall and hangingwall of the structure.

The orebodies occurred generally close to the footwall of the structure and consisted of up to four metres of massive, sheared and coarse-grained galena or up to three metres of massive galena and sphalerite in veins, stringers and lenses. Breccia composed of argillite, quartzite and porphyry are common in the footwall of the structure. Other reported minerals include varying minor amounts of pyrite, chalcopyrite, tetrahedrite and rare pyrargyrite. The Big ore shoot consisted primarily of relatively clean galena. Ore mined in later years contained mixed sphalerite and galena with the former predominating. Quartz, calcite and siderite comprise the gangue mineralogy.

The controlling factors on mineralization are thought to be the extent of shearing, brecciation and faulting of hostrocks with the presence of porphyry playing a minor role.

The Standard was one the longest and most significant producers in the area. The first mill in the area was built for ore from the Standard occurrence. Production records indicate 746,235 tonnes were mined intermittently over 75 years, from 1894 to 1969. This ore yielded about 278 tonnes silver, 20 kilograms gold, 39,690 tonnes lead, 49,361 tonnes zinc and 61 tonnes cadmium. An additional 4356 tonnes of ore from the Standard occurrence were processed at the nearby Ottawa mill (National Mineral Inventory 082F14 Ag65).

CAPSULE GEOLOGY

The American Boy occurrence is situated on Crown grant Lot 571 at 1630 metres elevation above sea level, in the Slocan Mining Division. The property is on the north side of Carpenter Creek east of Mount Payne.

The American Boy and Last Chance (082FNW020) adjoin and the mine workings are on the same lode system. The principal claims making up the properties were located in 1891 and were among the first to be staked in Slocan.

Development commenced on both properties in the early 1890's and continued at a fairly steady pace until 1908 when activity ceased. Work on the American Boy was carried out by Tom McGuigan and by the American Boy Mining and Milling Company, formed in 1897, later (1918) reorganized and renamed American Boy Mining Company. Work on the Last Chance was carried out by the Last Chance Mining and Milling Company.

In 1920 work recommenced on the Last Chance property and in 1922 on the American Boy. Activity was intermittent and lasted until about 1927. From that time until 1953 nothing was done on either property. In 1951 Cody-Reco Mines Limited bought up several properties in the Slocan area including the American Boy and Last Chance. A new road system was put in connecting the workings with a new mill built at Cody in 1952.

Workings on the main vein lode comprise 11 adits and several intermediate levels aggregating about 4.8 kilometres of drift and

CAPSULE GEOLOGY

crosscut. These workings are connected by raises and explore the lode over a vertical depth of about 350 or 396 metres measured down dip. Most of the work was done on the main lode and only short crosscuts were required in any distance. Certain workings are continuous on the 2 properties and have developed the main lode a length of 823 metres.

In 1953 No. 9 adit of the American Boy was reopened and some drifting done. In 1954 about 106.6 metres of drifting to get around a cave on No. 9 adit level and raises were rehabilitated down to No. 10 and No. 11 levels. In 1960 Cody-Reco Mines Limited was reorganized and its name changed to Vespar Mines Limited.

Reco Silver Mines Limited in October 1968 acquired a lease, renewable every 4 years, on 21 claims in the Last Chance and Noble Five (082FNW037) groups. Vespar amalgamated with Lakehead Mines Limited in January 1979 under the name Parlake Resources Limited. In May 1980 Reco Silver Mines changed its name to Silvex Resources Corporation.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The American Boy occurrence is hosted by quartzite, argillaceous quartzite and calcareous argillite of the Slocan Group intruded by various dikes of quartz porphyry probably related to the Nelson intrusions. The sedimentary sequence generally strikes 120 degrees and dips 58 degrees southwest. For the most part the sedimentary rocks are well bedded and banded. The quartz porphyritic dikes, in general, tend to follow the strike of the sedimentary rocks and are 3 to 10 metres thick.

The occurrence consists of two or more fissure veins that cut across the sedimentary and intrusive rocks. The veins strike 045 degrees on the American Boy Crown grant (Lot 571) and 060 degrees on the Last Chance Crown grant. Dips are 60 to 65 degrees southeast. The veins have been explored for about 825 metres along strike and 400 metres downdip on both the American Boy and Last Chance Crown grants. The veins pinch-out to the southwest on the Chicago Crown grant (Lot 622) (082FNW020) where they cut fissile slate of the Slocan Group. The strike and dip of each fissure varies from point to point so that fissures meet and separate at irregular intervals developing a braided structure varying from a few millimetres to over 6 metres in width. The fissures are mostly filled with crushed wallrock. Argentiferous galena, sphalerite, pyrite, tetrahedrite and ruby silver (pyrargyrite) occur with quartz and siderite concentrated in narrow veinlets near the walls of the fissures. The sulphide material is usually less than 10 centimetres wide except where crossfaults cut the fissure veins and pockets of massive sulphide up to 75 centimetres wide are developed. In general, sphalerite increases with depth.

Production from the American Boy portion of the fissure vein structures amounts to about 9 tonnes of silver, 1482 tonnes of lead, 85 tonnes of zinc and 62 grams of gold from 3943 tonnes mined between 1896 and 1927.

CAPSULE GEOLOGY

The Buffalo property is situated on Avison Creek at 1585 metres elevation above sea level in the Slocan Mining Division. The underground workings are on the Buffalo Crown grant (Lot 674) (forfeited).

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The Buffalo occurrence is hosted by calcareous, mostly massive argillites and quartzites of the Slocan Group. The sedimentary rocks are cut by a granitic dike, probably related to the Nelson intrusions. The occurrence consists of a fissure vein located within a fault zone subparallel to bedding. Rocks on the hangingwall side of the fault have been horizontally displaced about 10 metres north with respect to the footwall side. The fissure strikes 050 degrees, dips 55 degrees southeast and is about 1 to 1.5 metres wide. It has been explored with three short adits over a vertical range of about 75 metres.

The Buffalo vein intersects and merges with the Mammoth vein on the No. 8 level of the Mammoth mine (082FNW060) to the northwest. The vein consists of galena, sphalerite and tetrahedrite in a gangue of quartz and crushed wallrock. The wallrock is strongly silicified

CAPSULE GEOLOGY

adjacent to the vein and sulphide mineralization appears more concentrated on the hangingwall side of the vein.

Production records for the Buffalo occurrence are incomplete because the ore was combined with that of the Mammoth (082FNW060) and the Standard (082FNW180) after 1928. Production between 1905 and 1928 yielded 480,572 grams of silver, 25,794 kilograms of lead and 13,239 kilograms of zinc from 103 tonnes mined.

CAPSULE GEOLOGY

They reported a small shipment of ore in 1895. The Carnation claim, owned by D.D. Mann was under development from 1895 or earlier. Crown-grants were issued in 1897 as follows: the Carnation (Lot 575) to D.D. Mann, the Read (Lot 1247) and Tenderfoot (Lot 1248) to E.E. Evans, the Jennie Lind (Lot 1806) and Robertson (Lot 1808) to The West Kootenay (B.C.) Exploring and Mining Company, Limited. In 1904 the Robertson and Jennie Lind claims were held as part of the adjacent Wakefield property (82FNW059) which was under lease to The Anglo-Slocan Syndicate Limited. The Read and Tenderfoot claims were worked in 1906 by M.S. Davys who shipped a small amount of ore.

During the period 1917 to the mid 1920's claims on the east side of the ridge, including the Carnation, Violet (Lot 3168) and Violet Fr. (Lot 3170) were held by G.W. Clark & associates under bond from A.R. Mann and others. During that period considerable development work was done in Nos. 2 and 3 adits. The Victoria Syndicate, Limited, of London, acquired an option on the property in 1925. Development work was carried out on both sides of the ridge, mainly in No. 2 drift adit which was driven southwesterly for 853.4 metres through the mountain to the Jennie Lind claim. A raise was driven to the old Read workings. A 3048-metre tramline was installed at the west portal of No. 2 adit at an elevation of 1967 metres. The syndicate dropped the option in 1928 and work was resumed by G.W. Clark. In January 1929 A.R. Mann & associates incorporated Carnation Silver Lead Mines, Limited to acquire the 17 claims and fractions. The claims were electrically prospected for one month by The Radiore Company of Canada, Limited. Underground work began in August in No. 3 adit on the east side of the ridge. Operations ceased in 1930.

Early exploration on the Jennie Lind and Read claims on the west side of the ridge was carried out in a series of 8 or more short adits and open cuts. On the east side of the ridge, to 1930, the main lode (Carnation lode) had been partly explored on and close to the northeast corner of the Carnation claim by 3 adits and a 6-metre shaft. A 36.5-metre drift adit was driven on the "D" vein at the 1996-metre elevation about 183 metres northwest of No. 2 adit; the latter as mentioned earlier, had been driven through the mountain at the 1966 metre elevation. A third adit, begun in 1929 at the 1920 metre elevation, was driven as a crosscut for 45.7 metres northwesterly to the lode, which was drifted on southwesterly for about 122 metres.

Kelowna Exploration Company, Limited in 1939 optioned the Carnation and adjacent claims and began an extensive geological survey. The option on the Carnation was given up in 1940 but control of the adjacent claims was retained. In August 1945 the company purchased the Carnation group of 14 Crown-granted claims and fractions. In 1948 the old No. 3 adit at 1920 metres elevation was reopened. In 1949 a new low level adit at elevation 1670 metres was begun at the south edge of the Western Fr. claim of the Minniehaha property, and a second, 1670-metre east adit, was driven the following year. Two crosscuts were driven across the lode in the old 1920-metre adit and a new adit (1859 metres) was driven westerly for 166 metres after the lode had been uncovered at that level by stripping. The new low-level 1670-metre adit was driven in search of the downward extension of the Carnation lode exposed in the 1920 adit, 243.8 metres above. The new adit was driven 70 metres southwesterly into the hill, then 420.6 metres in a south 7-degree west direction through the adjacent Evening claim (082FNW049). Two mineralized lodes, about 122 metres apart, were encountered. The first, probably related to the Minniehaha lode, was drifted on for 103.6 metres in the 1670 main adit and for 97.5 metres in the 1670 east adit. The second lode (Carnation lode) was drifted on westerly for about 548.6 metres to a point down dip from the upper levels and a crosscut was driven 100.5 metres into the hangingwall. The company name was changed in 1951 to Kelowna Mines Hedley Limited. The results of the exploration work were disappointing and operations ceased in June 1951.

Silver Standard Mines Limited, in 1961, acquired an option on 59 claims from Oil Participations Incorporated who had acquired the claims from Kelowna Mines when that company was dissolved in 1958. Drilling was done to test the Carnation lode 122 metres below the 1670 level. Subsequent exploration was on claims down dip to the east (see Silvana (82FNW050)). Silmonac Mines Limited was incorporated in 1963 to acquire the property. The company name was changed in 1977 to Silvana Mines Inc.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are

CAPSULE GEOLOGY

intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium-feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted by predominantly interbedded black argillite and medium to dark grey quartzite and argillaceous quartzite of the Slocan Group. Argillaceous limestone, limestone and slate are also found in varying proportions in the sequence. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slocan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Several fault structures are evident and host vein mineralization. Later stage normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Horizontal displacement can be several metres to over 90 metres. Drag features are also present.

The vein exposed on the Jennie property is part of a vein system that has been traced to the east through the Carnation (082FNW048) and Silvana (082FNW050) and may extend as far east as the Ruth-Hope property (082FNW052). The vein has been explored with eight short adits on the Jennie Lind property. It is about a metre wide and contains mostly crushed rock cemented by coarse calcite and quartz. The ore consists of brecciated galena and sphalerite cemented by the gangue minerals. A sample of vein material from the dump in 1926 assayed 0.68 gram per tonne gold, 1900 grams per tonne silver, 17.2 per cent lead and 14.8 per cent zinc (Minister of Mines Annual Report 1926).

Production from the Jennie Lind in 1895 and in 1906 yielded 301,264 grams of silver and 31,497 kilograms of lead from 61 tonnes mined. Some production may be included with Carnation (082FNW048).

CAPSULE GEOLOGY

The Joan claim, formerly known as the Duplex, is located about 7.5 kilometres east of Slocan City. Access is by the Chapleau Creek and Lemon Creek roads that join the Slocan highway. It joins the Fourth of July No. 6 (Lot 7295) and Teuro Crown-granted claims on the south.

The property was staked prior to 1901 and worked intermittently until 1946. Ore shipments in 1902 and 1947 totalled 9 tonnes, from which 5 kilograms of lead, 249 grams of gold and 20,000 grams of silver were recovered.

The workings consist of two short drift adits (separated vertically by 13.4 metres) and a raise to surface near the portal of the lower adit.

The property is underlain by porphyritic Nelson Granite that is sheared and fractured near the vein. The vein is encountered in the lower tunnel at about 7.6 metres from the portal where it enters the right wall. From this point it is followed in the drift for a distance of about 43 metres to a fault near the face. Along the drift, the vein is offset by three faults with slight left-hand displacements. These strike roughly north and dip 70 to 80 degrees west. The vein is 0.3 to 0.6 metre wide and strikes 130 to 140 degrees, dipping 30 to 40 degrees northeast. The vein consists of quartz (no carbonates) with narrow streaks and disseminations of galena and a minor amount of pyrite and argentite.

CAPSULE GEOLOGY

Little information is available about the early years of the Gold Cure occurrence. The claims were first located in 1898 and produced 18 tonnes of ore in 1909. Further development work was carried out in 1917, extending the main adit to 34 metres length. In 1920, the property was acquired by Marsh Mines and Development Co. and a small amount of development work was continued. In 1924, the Gold Cure and Wintrop (082FNW097) occurrences were reported to be under the same management. No work was reported at this time however. Red Hawk Gold Mines Ltd. acquired an option on the property in 1950. The old adits were reopened and a contract signed to do 610 metres of diamond drilling. Cream Minerals sampled the property in 1997; a 0.3-metre chip sample assayed 175.6 grams per tonne silver, 8.18 per cent zinc and 0.08 per cent lead (GCNL #174, 1997). An 8-metre trench sample assayed 260.4 grams per tonne silver, 0.72 per cent zinc and 0.66 per cent lead (GCNL #230, 1997). A 25 to 80-metre northeast-trending shear zone has been traced for 3.7 kilometres.

Gold Cure mineralization occurs along the same northeast-trending structure as the Bismark (082FNW096) in the Triassic Slovan Group sediments. Hornblende potassium feldspar porphyritic granite of the Nelson batholith lies 400 metres to the southwest. The Middle Jurassic Mount Carlyle stock lies to the northwest. Potassium feldspar porphyritic granite comprises the stock. The Slovan Group comprises argillite, silicic sandstone and a layer of recrystallized limestone that is over 20 metres thick.

Faults and fractures at the Gold Cure occurrence host associated replacement and vein mineralization. They are stratabound and subparallel to the contact with the Middle Jurassic Nelson batholith. Mineralization at the Gold Cure occurrence consists of galena, sphalerite and pyrite hosted in a gangue of quartz and calcite.

Eighteen tonnes of ore were mined from the Gold Cure occurrence in 1909. This ore yielded 62,206 grams silver and 9072 kilograms lead.

CAPSULE GEOLOGY

The Silver Bell occurrence is located at 1432 metres elevation between Desmond and Kyawats creeks, southeast of Keen Creek. The ground is covered by the Silver Bell claim group composed of the Silver Bell (Lot 6815), Hub (Lot 6816) and Little Bell Fraction (Lot 6817) Crown grants. Kaslo, British Columbia is located 22 kilometres to the northeast.

The first production from the Silver Bell occurrence was in 1898. Workings consisted of two main and several short subsidiary adits.

The Silver Bell occurrence occupies a narrow belt of Triassic Slocan Group metasediments within the Keen Creek reentrant. Metasediments, in order of importance, include slate, carbonaceous

CAPSULE GEOLOGY

argillite, limestone, siltstone and biotite andalusite schist. Slocan lithologies are flanked by hornblende potassium feldspar porphyritic granite of the Middle Jurassic Nelson batholith and potassium feldspar porphyritic granite of the Middle Jurassic Mount Carlyle stock.

Ore mineralization occurred in a wide crushed (shear) zone in rocks of the Slocan Group. The zone strikes to the east and dips at a low angle to the south. The lode is reported to have carried high silver near and at the surface over 61 to 91 metres length. Ore occurred in broken bands and lenses composed of quartz, calcite with galena, sphalerite, pyrite and other high-grade silver minerals. Sulphides were considerably oxidized.

Ore was mined from the Silver Bell intermittently from 1898 to 1983, with most of the production occurring between 1898 and 1925. From a total of 656 tonnes mined, 2,573,587 grams silver, 111,655 kilograms lead, 12,050 kilograms zinc and 66 kilograms cadmium were recovered.

CAPSULE GEOLOGY

The quartz veins are hosted in potassium feldspar porphyritic granite of the Middle Jurassic Nelson Intrusions. Veins are less than 5 centimetres thick at surface. Quartz is aphanitic to fine-grained, dark grey to milky. Vugs are lined with quartz crystals. Sphalerite is black to dark red. Some veins are banded and brecciated.

The Olsen (Lot 10054) was Crown-granted in 1911 to C.F. Olsen. Earlier work consisted of a 30-metre adit. The property is located on Olson Creek, a tributary of Coffee Creek, and adjacent to Kootenay Glacier Provincial Park.

In 1939, eight tonnes of ore yielded 27,868 grams silver, 31 grams gold, 906 kilograms lead, and 1050 kilograms zinc.

In 1987 a grab sample assayed 3800 grams per tonne silver, 4.9 grams per tonne gold, 0.14 per cent copper, 11.6 per cent lead and 33.7 per cent zinc (Open File 1988-11).

PBX Resources Ltd. acquired the claims in 1989.

CAPSULE GEOLOGY

The Buster occurrence is located at about 853 metres elevation,
on a small knoll one kilometre southeast of Silverton, British
Columbia.

No records could be located on work on the Buster property prior
to 1970, except for production of 2 tonnes of ore in 1935. Work done
on the claims hosting the Buster occurrence from 1970 to 1980
included trenching, one 122 metre diamond-drill hole, geochemical
soil surveys, and ground electromagnetic and magnetic geophysical
surveys. During this time two small adits were discovered in the
northwest corner of the Winona claim group, covering the Buster
occurrence.

The Buster occurrence is underlain by the Triassic Slocan Group,
consisting of slate, argillite, quartzite, limestone, conglomerate
and tuff. Porphyritic granite of the Middle Jurassic Nelson
batholith outcrops to the south.

The Buster occurrence is mentioned in silver-lead-zinc vein
deposits with or without gold and cadmium (Geological Survey of
Canada Memoir 308, page 131). It is stated sphalerite was more
abundant than galena and is classified as a fault-fissure lode.
Other ore minerals may have included tetrahedrite, pyrrargyrite,

native silver and other unidentified minerals. Gangue minerals consist of varying proportions of quartz, calcite and siderite. Production records indicate 2 tonnes of ore was mined from the Buster occurrence in 1935. This ore yielded 2364 grams silver, 31 grams gold, 173 kilograms zinc and 150 kilograms lead.

CAPSULE GEOLOGY

The Skylark (Lot 9333) and Ranger (Lot 9332) claims are at about 1950 metres elevation on the ridge north of Chapleau Creek, 6 kilometres southeast of Slocan. Access to the property is by trail from the Chapleau mine (082FNW130) which is connected to the Slocan highway via the Lemon and Chapleau creek roads.

The property, Crown granted in 1910, was first explored in 1896.

A quartz vein, cutting granitic rocks of the Nelson batholith and gneissic rocks (inclusion), has been explored by drifts from three adits. At surface the vein is traced for about 900 metres over two full claims. Three tonnes of hand cobbled ore produced in 1934 graded 41 grams per tonne gold and 3442 grams per tonne silver.

Kilo Gold Mines Ltd. sampled the claims in 1985 and surveyed in 1986. A 20-centimetre sample assayed 36.2 grams per tonne gold and 757 grams per tonne silver (GCNL #229(Nov.25), 1985).

CAPSULE GEOLOGY

The Sapphire and Champion claims are located near the Slocan highway, 6.5 kilometres north of Slocan. The claims, Lots 10813 and 10811, respectively, were Crown granted in 1912 to D.A. MacLachlan.

Little is known about the Sapphire property other than the area is underlain by cataclastic granitic rocks, typical of the boundary facies of the Nelson batholith.

Recorded production in 1903 and 1904, was 37 tonnes, yielding 52,284 grams of silver and 1026 grams of gold.

CAPSULE GEOLOGY

grams of silver). At 9 metres from the face of this second adit, a small basic dike intrudes and displaces the vein about 1 metre to the left. At a point 36 metres west of the second adit, a third adit explores another quartz vein having the same attitude as the others. Also there are several small quartz veins between the second and third adits. A fourth adit, 60 metres west of the third, is 27 metres long and investigates a parallel quartz vein ranging up to 45 centimetres in width, carrying some pyrite.

Production of about 9 tonnes of ore in 1938, from the Get There Eli, yielded 124 grams of gold and 15,925 grams of silver; 3 tonnes of ore in 1955, from the V. & M., yielded 93 grams of gold, 12,338 grams of silver, 23 kilograms of lead and 8 kilograms of zinc.

In 1988, Yukon Minerals Corporation conducted soil and rock sampling, and geological mapping in the area. A sample from the Get-There-Eli adit assayed 16.8 grams per tonne gold and 549 grams per tonne silver over 0.5 metre on a quartz-pyrite vein (Assessment Report 18603).

CAPSULE GEOLOGY

The Gold Viking property is 1 kilometre west of Scorpion Creek and 2 kilometres northeast of Slocan. The property is accessible by 5 kilometre of all weather gravel road from the town of Slocan and the Slocan highway.

The Gold Viking property comprises the Gold Viking (Lot 4850), Viking (Lot 4852), and New Phoenix (Lot 4851) reverted Crown granted claims and fractions. The property is underlain by granitic rocks near the western margin of the Nelson batholith.

The mineralization consist of quartz veins in north and northeasterly trending shear zones. On the Gold Viking claim the original development, at 957 metres elevation, consisted of an adit. On the New Phoenix claim an adit, at 926 metres elevation, follows a 015 striking and 70-degree east-dipping shear zone. Shipments from 1932 to 1936 totalled 15 tonnes, yielding 4790 grams of silver 373 grams of gold and 14 kilograms of lead. Red Metal Mines Ltd. worked and diamond drilled in the area in 1969. The property was held by Amergas Resources Ltd. in 1980.

The Gold Viking vein strikes north and dips 70 degrees east. Rusted samples of quartz contain galena, sphalerite and trace amounts of chalcopyrite and pyrite. A grab sample from the mine dump assayed 1.1 grams per tonne gold, 35 grams per tonne silver, 0.01 per cent copper, 0.07 per cent lead, and 0.25 per cent zinc. On the New Phoenix claim, another vein is exposed by a 40-metre long adit that follows a shear zone in granodiorite. The shear zone strikes 015 degrees, dips 70 degrees southeast and contains a lenticular quartz vein that ranges from 0.5 to 1.0 metre in width. The vein is slightly mineralized by galena, sphalerite and pyrite in quartz and calcite gangue. A 1-metre wide chip sample across the vein, near the face of the adit, assayed 0.1 gram per tonne gold, 8.9 grams per tonne silver, 0.01 per cent copper, 0.23 per cent lead and 0.16 per cent zinc (Assessment Report 8825).

Amergas Resources Ltd. surveyed the area in 1980.

CAPSULE GEOLOGY

The Chicago No. 2 property is situated on Crown grant Lot 2142 at 1616 metres elevation above sea level in the Slocan Mining Division. The property is on the east side of the ridge that separates Cody and Sandon creeks. The claims extend from the creek, at the 1310-metre elevation, to the summit of the north trending ridge at an elevation of about 1981 metres. The Airdrie Fraction, Freddie Lee (082FNW055), Colonial (082FNW069), and Cristein (082FNW254) claims are located from north to south near the crest of the ridge. The Chicago No. 2, Chicago Fraction, and Pullman Fraction claims cover the ground down slope from the Colonial and Freddie Lee.

The Colonial claim (Lot 5313) was owned and intermittently explored by A.D. Coplen, of Spokane, from about 1906. In 1928 the Colonial, Freddie Lee, Cristein, Airdrie Fraction, and Nellie claims were acquired under option by W.G. Wasmandorff of Vancouver. The Cristein claim (Lot 5369) had been Crown-granted to Messrs. McDonald and Taylor in 1904; the Airdrie Fraction (Lot 9832) had been Crown-granted to Messrs. McAllistar and Bigney in 1910. Colonial-Slocan Mines, Limited, was incorporated in May 1929 to acquire the claims and carry on exploration work. Work by the company ended in January 1930 and the company charter was surrendered in 1932.

The Chicago No. 2 claim (Lot 2142) was Crown-granted to A.D. Coplen in 1900. The Chicago Fraction (Lot 3310) and Pullman Fraction (Lot 3309) were Crown-granted to F.P. O'Neill in 1907. These 3 claims were held by F.P. O'Neill as the Chicago group in 1925. During the year some work was done in prospecting and in driving a short adit in the vicinity of the old workings.

The workings on these claims include 9 or more short adits and several raises and intermediate levels. The upper 4 adits explore the Freddie Lee vein down dip. The lower adits comprise the principal workings on the Colonial and Chicago No. 2 claims.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity

CAPSULE GEOLOGY

of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The property is underlain by sedimentary rocks of the Slocan Group which form a broken syncline composed chiefly of massive quartzite and limestone just west of the occurrence. To the east, the syncline is faulted against another broader syncline in which the strata dip generally to the east. The core of this syncline is occupied by slate and argillite. The occurrence is hosted within argillite of the eastern synclinal structure.

The occurrence consists of a fissure vein striking 045 degrees and dipping 45 degrees southeast. The vein has been explored with at least eight adits on the southeast portion of the Chicago No. 2 Crown grant. The fissure vein consisted mostly of crushed wallrock with a few narrow bands of galena and sphalerite.

Production from the Chicago No. 2 Crown grant in 1938 yielded 6967 grams of silver, 1947 kilograms of lead and 94 kilograms of zinc from a total of 3 tonnes mined.

CAPSULE GEOLOGY

grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted by predominantly interbedded black argillite, quartzite and limestone of the Slocan Group. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slocan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Several fault structures are evident and host vein mineralization. Later stage normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Drag features are also present.

Two separate veins are known on the Cuba Reverted Crown grant, the Jan and the Belle. The veins have been explored with two major adits and several opencuts. A 15 metre deep shaft was also sunk to investigate the Jan vein.

The Jan vein is about 5 to 15 centimetres wide but can locally widen up to 50 centimetres. The vein strikes 125 degrees and dips 50 to 70 degrees southwest. It is very oxidized and locally contains argentiferous galena and sphalerite mixed with calcite and gouge.

The Bell vein is about 30 metres below and 60 metres northeast of the Jan vein. The vein has been followed for about 120 metres in a west-northwest direction in the underground workings. The vein dips 50 to 70 degrees south and locally contains argentiferous galena. It varies from a mere fracture up to 10 centimetres in width. The vein is cut and displaced by several low angle faults subparallel to bedding. A sample collected from the vein in 1939 assayed 60 per cent lead and 3428 grams per tonne silver (Property File - Prospectus, Silver Ridge Mining Company, 1939).

Production from the Cuba property in 1938 and 1940 yielded 49,671 grams of silver, 14,124 kilograms of lead and 1459 kilograms of zinc from 24 tonnes mined.

CAPSULE GEOLOGY

renamed Carnegie Mining Corporation Limited. This company holds 52 claims in the Slocan area, of which the claims of this group form a part.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The rocks hosting the occurrence consist of massive, more or less carbonaceous argillite, quartzite and limestone of the Slocan Group. The structure is complicated by folding and faulting but in general the beds strike south to southeast and dip between 30 and 75 degrees south. The sedimentary rocks have been intruded by a fine grained and dark green olivine pyroxene lamprophyre dike less than a metre thick.

The fissure zone that hosts the Silversmith and Richmond-Eureka deposits is exposed on the northwest part of the Slocan King Crown grant. The vein has been exploited with a short adit on the Slocan King Crown grant and from the No. 6 level of the Richmond-Eureka mine. The vein consisted of quartz and siderite and varied from a few centimetres to 0.6 metre in width. It contained mostly sphalerite, galena and pyrite mixed with the gangue minerals.

Production from the Slocan King adit between 1927 and 1930 yielded 87,368 grams of silver, 10,505 kilograms of lead and 1302 kilograms of zinc from 18 tonnes mined.

done on the north side of the ridge where it has been tapped by 3 adits at depths of 61, 91.4 and 160 metres. Production to date has come from the uppermost or No. 1 shaft. Below No. 3 level there are 3 short adits from which some ore has been obtained.

The Brandon lode has been traced on the south slope by opencuts and 3 short adits over a vertical range of more than 76.2 metres. A small production is recorded from these workings. On the summit and north slope the lode appears to lie partly or entirely within the adjoining Adams group. A fourth lode nearly parallel with the Brandon lode, about 45.7 metres to the west on Adams ground, has been traced for several metres and one short adit has been driven on it from the north side. A fifth lode known as the No. 2 Canadian which intersects the fourth on the summit of the ridge has been traced down into the Canadian basin by a series of opencuts.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Canadian occurrence is hosted by limestone, argillite and quartzite of the Slocan Group that have been intruded by quartz feldspar porphyries. The rocks are folded in a synclinal structure with the limbs striking north-northwest and dipping moderately southwest and northeast.

Much confusion exists about the number and relationship of veins present on this property. At least three veins are recognized and as many as five veins may exist. From east to west, the main veins are the Canadian-Ivanhoe, the Canadian No. 1 or Adams and the Brandon or South Brandon vein. The Canadian-Ivanhoe vein is an extension of the Ivanhoe vein and extends east on the Ivanhoe Crown grant (Lot 743) (082FNW057). On the Canadian property the Canadian-Ivanhoe vein changes from a generally east to a northeast strike. The vein has been developed from the Ivanhoe workings and from two adits on the Adams Crown grant. The vein is about 3 metres wide and contains discontinuous lenses of argentiferous galena and sphalerite in a matrix of quartz, calcite and siderite mixed with crushed wallrock.

The Canadian No. 1 vein is exposed on the north side of the ridge on the Adams Crown grant. This vein has been explored with at least three adits and accounts for most of the production from the Canadian property. The vein is within a fissure zone some 10 metres wide. It occupies a major fault structure and strata north of the vein cannot be matched lithologically nor structurally with strata to the south. The vein strikes 015 to 020 degrees and dips steeply southeast. Irregular pockets of sulphide mineralization are developed within the fissure which is mostly filled with crushed rock. The ore consists of galena and sphalerite mixed with coarse calcite, quartz and minor siderite. Pyrite and limonite are also present. The relation between the Canadian No. 1 vein and the Canadian-Ivanhoe vein is not clear. The two veins appear to merge and converge into one another (Bulletin 29).

The Brandon vein is about 370 metres west of the Canadian No. 1 vein. This vein has been explored with several trenches and at least five short adits. The vein straddles the ridge on the Adams and Brandon Crown grants (Lots 750 and 751). It strikes 010 degrees and dips 70 degrees west. It is less than a metre wide and contains bands of galena and sphalerite 10 to 20 centimetres wide in a gangue of quartz and calcite.

A fourth vein lies about 45 metres west of the Brandon vein. This vein is parallel and similar to the Brandon. It has been explored with surface trenching and one short adit. The vein is intersected by a fifth vein known as the Canadian No. 2 vein. This vein strikes 070 degrees and dips 60 degrees southeast.

Production from the Canadian property between 1905 and 1942 yielded about 2439 kilograms of silver, 374,301 kilograms of lead, 17,217 kilograms of zinc and 31 grams of gold from a total of 855 tonnes mined.

CAPSULE GEOLOGY

The Daybreak property is situated near the headwaters of Howson Creek at 1920 metres elevation above sea level, in the Slocan Mining Division. The underground workings are on Reverted Crown grant Lot 1464.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted by predominantly interbedded black

CAPSULE GEOLOGY

argillite, quartzite and limestone of the Slocan Group. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slocan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Several fault structures are evident and host vein mineralization. Later stage normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Drag features are also present.

On the Daybreak property the sedimentary rocks strike 145 degrees and dip 50 degrees northeast. The occurrence consists of a calcite and sulphide-filled breccia zone striking 125 degrees and dipping near vertical. The breccia zone is about 1.5 metres wide and has been traced for about 40 metres in a southeast direction. The vein is hosted within limestone and probably follows a transverse structure between two major northeast-trending faults. The vein has been explored with several surface trenches and an adit of unknown length. A representative sample collected from the vein in 1985 assayed 954 grams per tonne silver, 29.5 per cent lead and 16.4 per cent zinc (Assessment Report 14024). Although not specifically mentioned, the sulphide minerals are probably galena and sphalerite.

folded are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The occurrence consists of a fissure vein hosted by argillite and quartzite cut by a large sill of quartz porphyry. The strata generally strike north and dip 40 to 60 degrees east. The vein strikes 085 degrees, dips almost vertical and has been explored with at least four adits and a small shaft. Within the workings the vein averaged about 40 centimetres and was continuous for about 30 metres along strike and 15 metres updip. The vein is vertically zoned with galena being more abundant in the upper levels and sphalerite being the dominant sulphide in the lower levels of the mine. Gangue minerals are quartz and siderite.

Production from the New Springfield occurrence between 1897 and 1984 yielded 303,349 grams of silver, 48,792 kilograms of lead and 29,533 kilograms of zinc from 186 tonnes mined. See also Elkhorn (082FNW042).

CAPSULE GEOLOGY

The Shady Fraction occurrence is located on Carpenter Creek at 1280 metres elevation above sea level. This claim was Crown-granted as the Gem in 1898. All production has been derived by placer methods, from float. Although attempts have been made to find the source of the float these have not been successful. In recent years the claim has apparently been renamed Shady Fraction.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Shady Fraction property is underlain by massive to slaty argillite of the Slocan Group and several small quartz porphyritic dikes probably related to the Nelson intrusions. The occurrence consists of large rounded boulders and nodules of waterworn galena that have been recovered from the gravels in Carpenter Creek, at the foot of an old landslide on the north side of the creek. The galena boulders are well rounded and probably came from eroded veins further up the slope, possibly from the Chambers Crown grant (Lot 1752),

CAPSULE GEOLOGY

(082FNW032).

Mining of galena boulders from the creek bed yielded 199,712 grams of silver, 51,787 kilograms of lead and 620 kilograms of zinc from a total of 73 tonnes mined between 1917 and 1963. Production in 1939 from the Maple Leaf Fraction, operated by M. Byrne, is possibly from this area.

CAPSULE GEOLOGY

The Vulture occurrence is located at 1646 metres elevation above sea level in the Slocan Mining Division. The occurrence lies on Reverted Crown grant Lot 4482.

Most of the underground workings on this claim were driven prior to 1900, and in 1899 the first and largest shipments of ore were made.

Two adits have been driven at elevations of 1524 and 1578.8 metres. The upper adit is 74.6 metres in length and contains about 15.2 metres of crosscuts. At a point 19 metres from the portal a raise has been put up to the surface and in addition there are 2 small stopes, and a winze of unknown depth at 26 metres from the portal. The lower adit is about 53.5 metres long, with the face located approximately under the winze in the upper adit. At 15.2 metres from the portal there is a 39.6-metre drift. No mineralization of value is reported from this adit.

In January 1951 Slocan Lode Mines Limited was formed to develop the claim. In 1952 the workings were rehabilitated, and a stope prepared near the portal. Little work was done in 1953 and there is no record of subsequent development.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson

CAPSULE GEOLOGY

intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Vulture Reverted Crown grant is underlain by quartzite, calcareous argillite and slate of the Slocan Group. The strata are folded in a northwest-trending syncline with limbs dipping at low angles to the north and south. Two adits have been driven about 55 metres apart. The upper adit is 75 metres long and follows a galena-sphalerite fissure vein less than 60 centimetres wide. The lower adit extends for 53 metres in a northerly direction along the vein but no worthwhile mineralization was intersected (Minister of Mines Annual Report 1952). The vein strikes 050 degrees and dips 40 to 50 degrees southeast. The vein is cut off by a fault that parallels a vertical east trending granite dike. The fault may have a left-lateral displacement with the major dislocation being along the bedding plane (Assessment Report 22791).

Very intermittent production between 1899 and 1953 yielded about 1624 kilograms of silver, 368,625 kilograms of lead and 208 kilograms of zinc from 531 tonnes mined.

CAPSULE GEOLOGY

The R.E. Lee occurrence is situated on the crest of the divide between Carpenter and McGuigan creeks, on the north face of Mount Payne at 2135 metres elevation on the west of the divide between Carpenter and McGuigan creeks, in the Slocan Mining Division. The underground workings are near the western boundary of the Duluth Crown grant (Lot 1019).

Development of this claim commenced in 1892. Work was first confined to investigating a well-defined fissure-vain lode on the McGuigan Creek slope at the ridge. Subsequently, (about 1898); a long crosscut tunnel was run from the Carpenter Creek slope to tap this lode at a depth about 122 metres below the lowest workings on the north slope. This crosscut is reported to have intersected the lode at a point 609.6 metres from the portal.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

CAPSULE GEOLOGY

The property is underlain by quartzite and argillaceous quartzite of the Slocan Group and several small quartz and feldspar porphyritic dikes. The sedimentary rocks generally strike 115 degrees and dip 50 degrees southwest. The occurrence consists of a fissure vein striking 072 degrees and dipping steeply southeast. The vein varies from a few centimetres up to 1 metre in width and consists mostly of crushed and brecciated wallrock cemented by quartz and siderite. Bands of galena, sphalerite and pyrite up to 50 centimetres wide are concentrated along the vein walls. The vein was strongly oxidized near the surface. The vein has been explored with at least two adits.

Production records are incomplete but past records indicate that about 1080 kilograms of silver, 176,230 kilograms of lead and 729 kilograms of zinc were produced from 280 tonnes mined between 1895 and 1981. Production between 1951 and 1956 is documented from Discovery Fraction, which is located near the summit of Mount Payne. Thus, this production is attached to this occurrence.

CAPSULE GEOLOGY

the Reco group comprising 30 claims and including in addition to the Number One property the Reco No. 2 (082FNW035), and Chambers (082FNW032).

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slovan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slovan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slovan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Crown grant is underlain by argillite of the Slovan Group and felsic dikes to mafic dikes related to the Nelson intrusions. The felsic dikes are conformable to bedding and sill-like in nature while the mafic dikes appear to be parallel to the mineralized veins. The mafic dikes are 0.3 to 15 metres wide and in places cut the felsic dikes. The southwestern portion of the claim is mostly underlain by black slate.

The occurrence consists of a fissure vein striking 040 degrees and dipping 50 to 55 degrees southeast. The vein is exposed in the northwest portion of the Crown grant, continues to the east on the Slovan Sovereign Crown grant (082FNW036) and may correlate with the Reco No. 3-Goodenough vein on the Reco property (082FNW035), one kilometre northeast.

On the Number One Crown grant, the vein varies in width from a mere fracture up to 1.5 metres. It consists mostly of broken wallrock cemented with quartz and siderite with minor calcite. Massive galena and pyrite with minor sphalerite are concentrated along the vein walls in bands usually less than 10 centimetres wide. Galena is coarse, cubic and in part distinctly gneissic. The vein has been explored with at least four short adits.

Production from the vein yielded about 1245 kilograms of silver, 284,312 kilograms of lead, 16,075 kilograms of zinc and 93 grams of gold from 553 tonnes mined between 1916 and 1946.

CAPSULE GEOLOGY

The Victor property is situated west of Shea Creek on the southwest side of Carpenter Creek. The underground workings are on Crown grant Lot 4565 at 1478 metres elevation above sea level.

Production from the Victor mine between 1923 and 1985 yielded about 129 tonnes of silver, 21,746 tonnes of lead, 14,226 tonnes of zinc, 82 tonnes of cadmium, 69 kilograms of copper and 76.8 kilograms of gold from 149,502 tonnes mined.

This property is located on the southwest side of Carpenter Creek. The original discovery here was made in 1921 by G.A. Petty as the result of trenching and ground sluicing on a hillside almost covered with overburden. No. 1 adit was driven 15.2 metres below the discovery and 4 lower adits were subsequently driven. The property was leased in 1931 by Mr. E. Doney, who worked the property in 1947. In 1948 Violamac Mines (B.C.) Limited purchased the property along with Mr. Doney's lease.

Mining commenced early in 1949 and milling operations started in December 1950, with a 50-ton mill situated at the Victor Mine. Late in 1952 the company began shipping its ore to the mill of Western Exploration Company Limited, and continued to do so until the end of 1957. In January 1958 shipments were started to the mill of the Carnegie Mining Corp. Ltd., a subsidiary company.

The Victor Mine is opened by 8 adits, situated one below the other, through a vertical distance of about 274 metres. With the exception of the lowermost adit, No. 9, these adits are completely on the Victor property. No. 9 adit was collared in 1953, 161.5 metres east and 68.5 metres lower than No. 7 portal, on the adjoining Cinderella claim (082FNW014). In 1954 this level had been driven to a point 152.4 metres in advance of the face of No. 7, some 914 metres

CAPSULE GEOLOGY

from the portal. A winze started from the No. 7 level was completed in 1955 to connect with No. 9 at a point 640 metres in from the No. 9 portal. The longest levels are No. 9, about 1280 metres, and No. 7, which is over 671 metres, and No. 5 about 366 metres in length.

In 1957, due to depletion of reserves and low metal prices, production was curtailed from a rate of 70 tons a day to 25 tons. Exploration during the next 3 years was not successful in developing a sufficient tonnage of ore, and in November 1960 the last shipment was made to the Carnegie mill. Possibilities of finding further ore in the present workings are considered remote.

During 1961 mining was done above No. 7 level and above and below No. 5 level. Total development was 79.5 metres, including 33.5 metres of drifts and crosscuts and 46 metres of raising. Violamac held the lease until 1965. Kam-Kotia Mines Limited acquired the property in 1966, and production continued under lease to E.H. Peterson until 1985.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted by predominantly black argillite and quartzite of the Slocan Group intruded by numerous dikes and sills of quartz porphyry and granite probably related to the Nelson intrusions. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slocan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Several fault structures are evident in the immediate area and host vein mineralization. Later stage normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Drag features are also present.

The Victor deposit occurs in a fracture zone, up to 35 metres wide, where various veins are found. The veins are hosted by joints or faults with relatively small oblique normal dextral movement. The fracture zone is perpendicular to the strike of the sedimentary rocks and to the axial plane of a recumbent fold suggesting that it resulted from dilation along the axis of the fold. The ore zones are developed on a system of veins that follow single or multiple fractures. The veins vary from a mere crack up to 2.5 metres in width close to crossfaults that are subparallel to bedding. The veins are slightly moved by dextral and sinistral displacements along these faults. Within the underground workings the veins averaged about 30 centimetres in width, striking 040 degrees and dipping 75 to 80 degrees northwest.

Where the veins are thin, sphalerite dominates but where the veins widen, massive galena occurs. The galena is commonly sheared at the hangingwall and coarse grained at the footwall. Pyrite, chalcopyrite and tetrahedrite occur within the galena-rich portions of the veins. The ore minerals are associated with a gangue of siderite, calcite and quartz.

The veins have been explored with at least six adits over a vertical range of 120 metres. The largest orebody occurred on the No. 5 level and was mined continuously for a strike length of about 115 metres.

CAPSULE GEOLOGY

of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted by predominantly black and locally calcareous argillite and quartzite of the Slocan Group. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slocan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Several fault structures are evident and host vein mineralization. Later stage normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Drag features are also present.

The sedimentary rocks have been folded about an axis that strikes southeast and plunges 10 to 20 degrees northwest. The Lone Bachelor vein lies in a tensional fault that resulted from the folding of the strata, and is perpendicular to the fold axis. The vein strikes 035 to 065 degrees and dips steeply southeast. It has been explored with at least four adits on the Lone Bachelor claim. The vein is 1 to 2 metres wide and comprises crushed fragments of wallrock, gouge and veinlets of galena and sphalerite mixed with calcite. The proportion of sphalerite to galena appears to increase with depth and minor amounts of pyrite, chalcopyrite and tetrahedrite are also present.

Production from the Lone Bachelor between 1905 and 1961 yielded about 4788 kilograms of silver, 615,819 kilograms of lead, 108,798 kilograms of zinc, 522 kilograms of cadmium and about 1 kilogram of gold from 1820 tonnes mined.

CAPSULE GEOLOGY

The Profit-Miller group, owned in 1919 by R. Ainslie and D. McCuaig, is situated at the head of Virgil Creek (Miller Creek).

The area is underlain by east-west layers of quartzitic siltstone of the Upper Triassic Slocan Group and granites of the Middle Jurassic Nelson Batholith. A north trending fault cuts the area. On the footwall side of a shear zone, 15 to 20 centimetres of ore occurs in a quartz vein. A sample taken in 1919 ran 2.7 grams per tonne gold, 545 grams per tonne silver, 18 per cent lead and 21 per cent zinc (Annual Report 1919, page 132). A vein sample taken in 1987, likely in the same area, assayed 400 grams per tonne gold, 120 grams per tonne silver, 0.028 per cent copper, 8.0 per cent lead and 10.05 per cent zinc. Another sample assayed higher in lead and zinc (EMPR Paper 1989-5, Table A).

CAPSULE GEOLOGY

The Sun property is located on Mount Kemball, one kilometre south of the Revenue mine (082FNW106), 25 kilometres east-northeast of Slocan City. It was part of the Silver Cup property (082FNW114). The property is located within Kokanee Glacier Provincial Park.

The Sun claim was Crown granted in 1911 and the same year two cars of a good grade silver lead ore were sacked and ready for shipment. The focus of exploration appears to be veining associated with metamorphic rocks, intruded by the Nelson batholith. In 1917, D.H. Nellis shipped 31 tonnes of ore, yielding 84,600 grams of silver and 12,338 kilograms of lead.

This property lies at the head of 'Woodbury Creek on the ridge between it and Sawtooth Creek, a tributary of Keen Creek, at the 2408 metre elevation. It may be reached by approximately 8 kilometres of trail from where the Scranton road turns up Pontiac Creek.

The E.L., Silver Cup (Lot 6507), Moonlite, Evening Star, and Sun (Lot 6955) claims extend in a northeasterly direction along the strike of the vein outcrop. These claims lie near the western edge of a more or less rectangular block of 33 claims and fractional claims that is roughly 5 claims wide and 6 claims in length. All these claims were Crown-granted to D.H. Nellis, some in 1907, and the remainder in 1911.

Very little information is available on this property and it is not known when the claims were located. A 1911 report states that 3 men worked on the Sun claim from June to December and 2 cars of ore were sacked ready for shipment. In 1917 Mr. Nellis shipped 35 tons of ore, reported to be from the Sun claim. The main workings are on the Silver Cup claim (082FNW114). Here Mr. Nellis drove a crosscut in a westerly direction, about 30 metres below the outcrop, on the Woodbury side of the divide. The crosscut is 22 metres long and intersects the vein 10 metres from the portal. A winze has been sunk on the vein, and 5 metres below the adit level a sublevel has been driven on the vein to the north of the shaft for 11 metres. About 5 metres back from the face the stringer of galena has been underhand mined for a few metres. The winze is reported to be 14 metres deep with a 15-metre drift to the south off the bottom. This lower level

was inaccessible when the workings were examined in 1949.
In 1940 J. Flagel of Ymir shipped 3 1/2 tons of ore from the Silver Cup. Three claims, the E.L, Silver Cup, and Moonlite, owned by Mrs. C.A. Nellis, were optioned to A.C. Neiman & associates late in 1949. The only work reported at this time was done on an access road to the property.

Zinc 0.4800 Per cent

COMMENTS: Grab sample from oxidized dump material (Sample DB-303).

REFERENCE: Open File 1988-11.

CAPSULE GEOLOGY

A flat dipping shear zone strikes east and dips south on the south side of Enterprise Creek, immediately west of Timber Creek. Country rock is a feldspar porphyry of the Nelson Batholith.

There are at least three subparallel clay altered shear/fault zones within potassium feldspar porphyritic granite. These faults are exposed along the access road 100 metres northwest of the portal.

Production between 1973 and 1983 totalled 53 tonnes, yielding 22,930 grams silver, 531 grams gold, 2,665 kilograms lead and 1,891 kilograms zinc. A sample taken in 1987 assayed 190 grams per tonne silver, 10 grams per tonne gold, 3.4 per cent lead and 0.48 per cent zinc (Open File 1988-11).

CAPSULE GEOLOGY

The Freddy occurrence is located adjacent to the north bank of Hasty Creek, at 823 metres elevation. Silverton, British Columbia is 2 kilometres to the north. The Freddy Reverted Crown grant (Lot 4025) covers the ground hosting the occurrence which is developed by a short winze and a level near Hasty Creek.

Hostrocks of the Freddy occurrence are coarse-grained granite of the Middle Jurassic Nelson batholith. In the vicinity, metamorphosed quartzite and massive argillite of the Triassic Slocan Group form part of a large roof pendant.

The occurrence consists of an irregular lode, striking northerly and dipping easterly. The mineralogy is unknown, however, the nearby Metallic occurrence (082FNW066) contains sphalerite, galena with inclusions of tetrahedrite and pyrargyrite and minor pyrite and chalcopyrite.

Production records for the Freddy occurrence indicate 228 tonnes of ore mined between 1962 and 1973. This ore yielded 396,345 grams silver, 715 grams gold, 1245 kilograms lead and 1023 kilograms zinc. Some of this ore was hand-sorted and shipped directly to the Trail smelter.

CAPSULE GEOLOGY

Schist, calc-silicate and gneiss (Slocan Group) form a metasedimentary remnant within granite of the Middle Jurassic Nelson Batholith. Cross fractures contain massive pyrrhotite and sphalerite. Eagle Plains Resources Ltd. and Miner River Resources Ltd. drilled 5 holes, totalling 430 metres in 1997. A 55-metre chip sample assayed 0.3 per cent zinc and a 5-metre sample assayed 2.26 grams per tonne gold (Press Release, Miner River Resources, January 28, 1997).

CAPSULE GEOLOGY

The L.H. occurrence is located at 1645 metres elevation on Fingland (Vevey of L.H.) Creek, on the east side of Slocan Lake. Silverton, British Columbia lies 6.25 kilometres to the north.

The L.H. occurrence is covered by the L.H. claim group consisting of seven Crown-granted claims and fractions including the Baby Ruth (Lot 2229), L.H. (Lot 5738), Camden (Lot 5739), C.B. (Lot 5740), St. Joe (Lot 6908), Summit (Lot 6909), Basin Fr. (Lot 6910) and Harlem (Lot 6911).

The occurrence has a long history of ownership and development but little production. The claim was first located in 1895 by R.G. McConnell. In 1896, the L.H. claim was owned by J.M. Bredendum and Associates. In 1899, the Baby Ruth claim was Crown granted to E.J. Kendall and A.R. Fingland. The Camden and C.B. claims were Crown granted to Fingland and associates in 1902. Considerable development work was carried out from 1903 to 1904 by Fingland and Brand. The L.H. claim was Crown granted in 1905 to Fingland and Brand. Subsequent Crown granting was given to the St. Joe, Summit, Basin Fraction and Harlem claims. In 1911, British Columbia Copper Company acquired an option on the property but after a careful and systematic sampling program was carried out the option, was allowed to lapse. The owners resumed development work until 1925. Pacific Mines, Petroleum and Development Company Limited carried out some work on the property in 1936. The property was leased to A.H.W. Crossley and associates in 1938. A short bucket tramline was built from the No. 2 adit to the road and a shipment of 196 tonnes of ore was shipped in the following year, under the newly incorporated Fingland Mine Limited. Consolidated Quebec Gold Mining and Metals Corporation optioned the property in 1945. The subsidiary, Kenville Gold Mines Limited, carried out 610 metres of diamond drilling from the No. 3 level to define further mineralization. A 1946 Annual Report by Consolidated Quebec reports a resource of 54,430 tonnes of 8.57 grams per tonne gold. Anderado Resources Inc. acquired the property in 1980; their name was changed to Andaurex Resources Inc. Induced polarization and geochemical surveys and geological mapping were carried out. Additional geological mapping, geochemical and geophysical surveys and sampling were carried out under an option to Hudson Bay Oil and Gas Company Limited in 1981. Noranda conducted geophysics and geochemical surveys and diamond drilling between 1985 and 1987. Goldpac Investments Ltd. drilled the property in 1988. The George Cross Newsletter (June 29, 1988) reports an indicated resource of 299,375 tonnes of 17.14 grams per tonne gold (MR 223). Goldpac changed their name to Brimstone Gold Corp. in May 1994. Andaurex held the property in 1992, when their name changed to Andaurex Capital Resources Inc.

Mine workings include three adits totalling 518 metres. Most work was carried out on the Nos. 2 and 3 levels, which are 27 vertical metres apart and connected by a raise.

The L.H. occurrence is located within a roof pendant of Lower Jurassic Rossland Group metavolcanics and Early Jurassic subvolcanic equivalents. Lithologies comprising the Rossland Group at the L.H. occurrence include augite porphyry, greenstone, quartzite, arenite, sandstone and argillite. These rocks have been tentatively correlated with the Elise Formation and are strongly contact metamorphosed at the L.H. occurrence. Subvolcanic equivalents include quartz latite porphyry and feldspar porphyry. Altered aplite dikes crosscut Rossland Group rocks at the L.H. occurrence; quartz, calcite and sericite form the major constituents. These hostrocks are enclosed by medium grained biotite hornblende diorite and fine-grained granite of the Middle Jurassic Nelson batholith. Two major fracture orientations are

CAPSULE GEOLOGY

present in hostrocks. The first follows a prominent joint plane, striking 075 to 080 degrees and dipping 50 degrees to vertical. The other strikes 025 degrees and dips 65 degrees southeast.

Mineralization follows a zone of fracturing and faulting. The zone width is 6.1 to 13.7 metres, striking nearly west and dipping north at about 55 degrees. Ore consists of native gold, arsenopyrite, pyrite and pyrrhotite with minor chalcopyrite and native arsenic. A maximum width of 13.7 metres mineralization was intersected on the No. 2 level, with the best grades on the centre and western-half of the drift over 91 metres length. A narrow sericite-altered dike occupies the fissure for most of its length on the No. 2 level. The No. 1 level parallels the hangingwall of the ore zone. Hostrocks are silicified and the limits of mineralization within this zone are poorly defined. Disseminated mineralization is hosted in quartz lens-filling fractures 30 to 60 centimetres wide. Quartz also forms many small stringers or more commonly impregnates the wallrocks and varying proportions of ore mineralization. Higher grades are generally associated with more intense silicification and arsenopyrite. Minor calcite has also been reported.

From the 196 tonnes of ore mined in 1939, 1928 grams silver and 3452 grams gold were recovered.

CAPSULE GEOLOGY

The Homestake claim (Lot 15283) is centred on Memphis Creek 1.5 kilometres east of the Slocan highway, 6.5 kilometres north of Slocan. The main workings, on the north side of the creek at the elevation of 1000 metres, are reached by a short access road from the highway. The property was previously known as the Hamilton. This claim may have also be covered by the Joyce (082FNW214).

The Homestake deposit outcrops where the mountain slope breaks over into Memphis creek valley. It has been developed, between 1968 and 1970, by two short adits and several raises. Significant gold and silver values are reportedly associated with mainly pyrite mineralization, accompanied by minor tetrahedrite, arsenopyrite, native silver and possibly argentite. These minerals are found in a narrow quartz vein which strikes northwesterly and dips steeply to the northeast. The principal structure hosting the vein is a shear zone about 3 metres wide that cuts a coarse porphyritic phase of the Nelson granitic batholith.

At the Hamilton, intermittent production from 1903 to 1915, totalled 33 tonnes of ore, yielding 115,299 grams of silver, 93 grams of gold and 1921 kilograms of lead. Production as the Homestake from 1968 to 1971 totalled 330 tonnes, yielding 861,491 grams of silver, 7370 grams of gold, 440 kilograms of lead and 503 kilograms of zinc.

CAPSULE GEOLOGY

The Joyce property is on the north side of Memphis Creek, immediately north of the Homestake claim (L. 15283)(082FNW164), 1.5 kilometres east of the Slocan highway, 7 kilometres north of Slocan. The main workings at the elevation of about 1200 metres, are reached by a short jeep road from the highway. Location of the Joyce claim is unclear; it may also cover the Homestake. See also the older workings of Coronation (082FNW162) and V. & M. (082FNW191).

The Joyce property is similar in geological setting to the Homestake workings. It has been developed by one 9-metre adit, which was driven by the early prospectors. In 1971, bulldozer stripping uncovered a pocket of high grade gold-silver ore which was subsequently mined out and shipped to the Trail smelter. Production from 1967 to 1971 was 87 tonnes, yielding 260,643 grams of silver 1773 grams of gold 138 kilograms of lead and 120 kilograms of zinc.

CAPSULE GEOLOGY

The Silver Ranch is located east of Boomerange Mountain, within Kokanee Glacier Provincial Park. Mineralization and alteration occurs along northwest trending linears. The linears comprise clay and limonite altered potassium feldspar porphyritic granite. The quartz-pyrite-limonite alteration zone is up to about 5 metres wide. Quartz veins with coarse pyrite are up to 1 metre thick within the altered zone. The veins are discontinuous, cut by anastomosing shears. Minor galena and sphalerite occur in the quartz veins. A sample taken in 1987 assayed 430 grams per tonne silver, 7.1 grams per tonne gold, 0.045 per cent copper, 7.8 per cent lead and 7.6 per cent zinc (Open File 1988-11).

CAPSULE GEOLOGY

The Gold Reef property is situated 1 kilometre west of the
confluence of Mineral and Crusader creeks, 13 kilometres east of
Slocan. Access from the Slocan highway is via the Crusader and
Lemon creek roads.

Little is known about this property other than there was an
unsuccessful attempt to set up a small mill in 1922. The claims were
worked as the Golden Wedge in 1897 and 1898, when underground
workings totalled 190 metres. H. Avis trenched the claims in 1976
and 1978.

CAPSULE GEOLOGY

The Winlaw occurrence is located on the south side of the north fork of Winlaw Creek, approximately 6 kilometres east of Winlaw.

The area is underlain by Middle to Late Jurassic Nelson Intrusions.

The Winlaw quartz body is a massive irregular pod of pegmatitic quartz exposed over an area approximately 35 by 26 metres. A perthite/quartz intergrowth, with euhedral perthite crystals reaching 15 centimetres in length, borders the quartz body on the south, west and northwest sides. Rocks surrounding the pegmatitic facies are mainly porphyritic syenites. The northeast extent of the quartz is limited by granitic rocks while the eastern margin is covered by overburden. Jointing is strongly developed in three directions within the quartz and some of the joints host fine-grained specularite and hematite staining. Large vugs, containing remnant fluorite and second generation quartz crystals, typically reach 15 by 15 by 4 centimetres in size.

In 1976, it was estimated that 100,000 tonnes of high-grade silica rock, with assays up to 99.6 per cent silica, were present (Exploration in British Columbia 1976, page 207). A small quarry (Snowdrift), 10 by 20 metres, produced 500 tonnes of silica in 1971.

CAPSULE GEOLOGY

The Alexandria No. 2 is accessible by a good logging road up Lemon Creek and Crusader Creek for 20 kilometres, thence by an old logging road on Branch 5 for 3.5 kilometres to an elevation of 1600 metres on Tagart (Tiger) Creek and a foot trail for 2 kilometres to the mine on the south slope of Mount Rappel at an elevation of 2100 metres. The Alexandria No. 2 (Lot 2886) and Delley (Lot 2887) were Crown-granted in 1898 and worked from 1895 to 1899.

The host rock for the mineralization is granite to granodiorite of the Jurassic Nelson batholith. In the mine the vein is generally measured in centimetres, but in several locations widths of 0.6 metre were seen. Economic mineralization consists of galena, argentite, silver and chalcopyrite. Massive galena occurs on the eastern side of the first stope. The shaft probably was raised on the vein and galena is present on the west wall. Here the galena forms the matrix of a breccia as compared to the rest of the vein which is normal vein filling. Development in 1976 and 1977 from 6 tonnes of hand cobbled ore totalled 23,940 grams of silver, 27 grams of gold, 9 kilograms of copper, 288 kilograms of lead, 15 kilograms of zinc and 1 kilogram of bismuth. The ore came from a surface cut at an elevation of 2100 metres. Development also consists of a 24-metre shaft and 116 metres of drifting. A shipment was reported in 1941. In 1972, Hi-Ridge Resources Ltd. conducted a geophysical and geochemical survey on the Dry Ridge property.

A sample taken in 1987 assayed 1.6 per cent lead and 1.4 per cent zinc (Open File 1988-11).

CAPSULE GEOLOGY

The Silver Queen property, comprising the Grey Wolf (Lot 2204), Red Fox, Black Fox (Lot 2206) and Black Bear Crown granted claims and fractions, is located on the ridge between Goat Creek Canyon Creek and Snow Creek, near the summit of Grey Wolf Mountain, 13 kilometres east-southeast of Burton. Access is from Burton via the Londonderry Creek road to the Tillicum mine (082FNW234) on Tillicum Mountain and thence southeast by alpine trail 3 kilometres to a point 1 kilometre southwest of the summit of Grey Wolf Mountain.

The Silver Queen Mining Company, Limited Liability was organized in 1897 to acquire 8 claims in the Grey Wolf, Red Fox, Black Fox and Black Bear groups; the claims were Crown-granted (Lots 2204-2209, 2414, 2582) to the company in 1899. Development work included open cuts, a 9-metre shaft and about 107 metres of drifts and crosscuts in one adit on the south side of the mountain at about 1981 metre elevation.

The Golden Hope claim (Lot 1797), located about 0.8 kilometre west of the Grey Wolf, was Crown-granted to M.D. Shea in 1901. The Silver Queen property was owned in 1930's and early 1940's by H. Stones and J. Gayford, of Burton; some prospecting was reported.

The discovery in 1980 of high grade gold values on the nearby Tillicum Mountain property, subsequently acquired by the Esperanza Explorations Ltd and Welcome North Mines Ltd. joint venture, led to

CAPSULE GEOLOGY

additional claim staking (Til 1-4) to include the Silver Queen ground. Welcome North terminated the joint venture in March 1982. La Teko Resources Ltd in June 1982 optioned a 50.4 per cent interest in Esperanza Explorations Ltd. A geochemical survey on the Silver Queen in 1983 indicated a strong silver anomaly over a 45.7 x 914.4 metre area.

The property is underlain by highly deformed volcanic and sedimentary rocks of Triassic and older (?) age and younger aplite and feldspar porphyry dikes, and granitic intrusions. The volcanic rocks are the oldest units and are tentatively assigned to the Slocan or Kaslo Group, while the younger sedimentary rocks are correlated with the Slocan Group.

The Silver Queen workings consist of several open cuts, an adit and shaft, southwest of the summit of Grey Wolf Mountain. The ridge running westerly from the summit consists of impure tuffs and sandy sediments, striking east to northeast and dipping steeply south, intruded by numerous dikes. An open cut at a point 50 metres down the southern slope, at an elevation of 2350 metres, exposes a carbonate band, about 1 metre wide, in these sedimentary rocks. Concentrations of pyrite and black manganese oxide (?) in the band assayed 3.4 grams per tonne gold and 960 grams per tonne silver. A 10-metre shaft at 2100 metres elevation and an adit 100 metres to the southwest develop similar occurrences. The main adit is driven northeasterly for 35 metres then turns northerly about the same distance ending in aplitic granite. The adit is principally in limy and garnetiferous greenstone. A silicified sample from the portal of the adit assayed 3.4 grams per tonne gold and 1060 grams per tonne silver.

The gold and silver mineralization is thought to be related to hornfelsing episodes, associated with various dikes and sills and the Goatcanyon granitic stock of mid-Jurassic age.

CAPSULE GEOLOGY

The Yosie property is centred 1 kilometre north of the confluence of Mineral and Crusader creeks, 14 kilometres east of Slocan. Access from the Slocan highway is via the Crusader and Lemon creek roads.

Little is known about this property other than galena occurs on small shears in Nelson granodiorite as seen in a few open cuts and pits. Structural control of the mineralization is apparently related to faults trending northeast subparallel to Mineral Creek and VLF-EM 16 anomalies. C.C. Young worked the claims in 1978 and 1979; 4 tonnes were produced in 1985, yielding 1385 grams of silver, 2 grams of gold, 1205 kilograms of lead and 170 kilograms of zinc.

CAPSULE GEOLOGY

The Black Colt property is situated on Shea Creek in the Slocan Mining Division. The underground workings are on Reverted Crown grant Lot 1721 at 1630 metres elevation above sea level.

The claim was granted in 1900 to the Hinckley and Black Colt Mining Company, Ltd. Little work was apparently done until 1919 when the first shipment of ore was made. Later work by E.J. Vandergrift was responsible for the claim being taken over in 1929 as part of the Consolidated Queen Bass holdings. From that time until 1937 development continued intermittently. A little exploratory work was done under option in 1949.

There are 2 adit levels on the claim, 31.6 metres apart at elevations of approximately 1417 and 1448 metres. The portal of the lower is on the Silver Ridge claim (082FNW011), and a third adit level on the Silver Ridge Fraction crosses into Black Colt ground. In 1949 the Black Colt levels were accessible by raises from the Silver Ridge Fraction adit (082FNW011).

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted by predominantly black and locally calcareous argillite and quartzite of the Slocan Group. The

CAPSULE GEOLOGY

sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slocan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Several fault structures are evident and host vein mineralization. Later stage normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Drag features are also present.

A low angle anticlinal structure occupies the central part of the property and the dip of the strata is extremely variable and complicated by faulting. The sedimentary rocks are cut by numerous porphyritic felsic dikes probably related to the Nelson intrusions. Mineralization at the Black Colt occurs along a fracture zone some 20 metres wide. The zone generally strikes 055 degrees and has been explored by a branching adit driven southwesterly for about 135 metres. A raise connects the No. 2 level of the Black Colt with the underground workings on the Silverite property (082FNW011). Within the underground workings, argentiferous galena, sphalerite and pyrite occur in quartz and siderite veins. Mineralization is also present as coatings on joint surfaces. The mineralized veins vary greatly in widths and the wider parts of the veins are commonly brecciated.

Production from the Black Colt between 1919 and 1948 yielded about 1328 kilograms of silver, 257,385 kilograms of lead, 126,777 kilograms of zinc and 435 grams of gold from 718 tonnes mined.

CAPSULE GEOLOGY

The Kimberly is located along Springer Creek and is assumed to be quartz vein-hosted mineralization in granite of the Middle Jurassic Nelson intrusions. In 1906, some development work was done by C. Dempster resulting in a small shipment of ore (Minister of Mines Annual Report 1906, page H146).

CAPSULE GEOLOGY

Coarse metapelitic gneisses containing abundant sillimanite and garnet are reported from the Valhalla and Passmore dome area west of Slocan Lake (Reesor, 1965). Valhalla and Passmore are two of a series of domal structures containing gneisses which form part of the core of the Shuswap Metamorphic Complex. The core of the Valhalla dome comprises orthogneisses which are mantled by hybrid gneisses predominantly metasedimentary in origin. Sillimanite locally comprises 20 to 25 per cent of sillimanite-garnet-biotite gneisses of the hybrid gneiss zone, particularly along the east flank of the Valhalla dome and may be very coarse. In the vicinity of the Passmore dome coarse sillimanite may occur in knots or groups of crystals over 2.5 centimetres long and 1 centimetre wide. These gneisses may also locally contain up to 30 per cent garnet, with an average crystal size of 0.5 centimetres or less. Garnet may also be present in interbedded amphibolitic rocks in amounts up to 40 per cent (Reesor, 1965).

CAPSULE GEOLOGY

The Silver Leaf claim adjoins the Arlington mine (082FNW152) on Speculator Creek, 8 kilometres east-northeast of Slocan. Access is from the Slocan highway via the Springer Creek road, to just east of the confluence of Springer and Speculator creeks.

The property is underlain by what is considered to be the extension of the Arlington shear. The principal workings are a 76-metre prospect crosscut adit to the shear on the Silver Leaf No. 2 and Argentite claims. The mineralization consists of small stringers that could not be extracted for a profit.

Small ore shipments for the period 1947 to 1951 were from a reserve that is reported to have been mined from the Arlington workings and dumped on the Silver Leaf No. 2 claim. Recovery from 40 tonnes of ore totalled 23,949 grams of silver, 2631 kilograms of lead and 2843 kilograms of zinc.

CAPSULE GEOLOGY

The Sunset-Trade Dollar occurrence is exposed on the Sunset and the Trade Dollar Crown grants (Lots 1164 and 1432). This property has been developed in conjunction with the Bell occurrence (082FNW028).

This property comprises a group of 6 Crown-granted claims extending across the divide at the head of Jackson Creek, between elevations of approximately 1830 and 2135 metres. Mining commenced here in the late 1890's and a considerable production, chiefly from the Sunset and Trade Dollar claims was obtained in the early years of this century. In the case of the Bell claim (082FNW028), the principal producing years were 1916, 1917 and 1918. After 1918 little work was done on any of the claims until the autumn and winter of 1926-27, when lessees shipped over 91 tonnes from old workings on the Trade Dollar.

The principal workings on the Sunset and Trade Dollar claims are 12 adits, 4 of which have been driven from the northern slope of the ridge on the Sunset claim, and the remainder from the southern slope on the Trade Dollar claim. The elevation of the main lode at the summit of the divide is 2127.5 metres, nearly 305 metres above the lowest or No. 8 Trade Dollar adit. Altogether at least 2347 metres of underground work, including drifts, crosscute and raises has been done on these claims. In 1927, these workings were partly inaccessible, particularly in what had proved the more productive sections.

Little or no work has been done on the Sunset and Trade Dollar claims since 1927. On the Bell claim, several hundred tonnes of high-grade zinc ore were recovered from old dumps, and pillar and stope remains in the underground workings during 1943, 1944 and 1945.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of

CAPSULE GEOLOGY

the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Sunset and Trade Dollar Crown grants are underlain by quartzite, calcareous argillite and slate of the Slocan Group. The strata generally strike northwest, dip 43 to 58 degrees southwest and are folded in a northwest-trending syncline. The central portion of the syncline is underlain by quartzite and calcareous argillite which host most of the ore. Beneath the core of the syncline are slate and thinly banded argillite which are cut by numerous felsic porphyritic intrusions.

The occurrence consists of a vein striking 073 degrees and dipping 60 degrees southeast. The vein varies from a few centimetres up to 2 metres in width and branches out into several subparallel veins. The vein was widest in the upper level of the mine within the more quartzitic beds and narrowed quickly within the thinly banded argillite. All veins have well-developed walls marked by gouge seams, some up to 30 centimetres thick. Sulphide minerals are crudely zoned with galena being more prominent in the upper levels of the mine and sphalerite dominating in the lower levels. Pyrite is common throughout. The main underground workings include five adits on the Sunset Crown grant and nine adits on the Trade Dollar Crown grant. At least 2350 metres of development work has been carried out on the vein in total.

Production from the Sunset-Trade Dollar between 1900 and 1927 yielded 10,737,751 grams of silver, 1,684,797 kilograms of lead and 58,114 kilograms of zinc from 2519 tonnes mined. Minor production between 1916 and 1918 was included with the Bell mine production

CAPSULE GEOLOGY

The Omega occurrence is situated on Crown grant Lot 618 at 1738 metres above sea level, in the Slocan Mining Division. The property is on the north side of Carpenter Creek about 1.5 kilometres north of the community of Cody.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Crown grant is underlain by argillite of the Slocan Group that are folded in an anticlinal structure. The beds generally strike southeast and dip 45 degrees southeast and southwest.

The occurrence is developed on a vein within a fissure zone that varies from a few centimetres up to one metre in width. The vein is the extension of the vein found on the Slocan Sovereign property (082FNW036) to the southwest and may correlate with the Reco No. 2 vein on the Reco property (082FNW035) to the northeast. The vein has been explored with one adit on the Omega Crown grant and three short adits on the Texas Crown grant (Lot 589). On the Omega property the vein consists of galena, sphalerite and pyrite usually concentrated in narrow bands, less than 10 centimetres wide, along the vein walls. The bands of massive sulphides are separated by crushed wallrock cemented by quartz, siderite and calcite. Crossfractures cutting the vein at high angles seem to have played a role in localizing the ore

CAPSULE GEOLOGY

and a number of post-mineral faults have caused small displacement of the vein.

Production from the Omega property between 1900 and 1983 yielded 246,809 grams of silver, 41,560 kilograms of lead and 14,496 kilograms of zinc from 132 tonnes mined. Production from the Twilight has been attached to this occurrence.

CAPSULE GEOLOGY

The Early Bird occurrence is situated on Reverted Crown Lot 1648 at 1220 metres elevation above sea level, on the south side of Carpenter Creek, in the Slocan Mining Division.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The occurrence consists of an adit driven on fissure veins hosted within a 60 metre wide quartz diorite body. The adit follows a narrow fissure that strikes southwest and dips 60 degrees northeast for about 25 metres from the portal. The adit then follows a fissure striking 165 degrees and dipping 60 degrees west for about 40 metres. The adit also intersects a fissure striking west and dipping 45 degrees south. All fissures are filled with gouge and calcite. Minor sphalerite and galena also occur within the fissure zones.

A total of 5 tonnes were mined from the occurrence between 1908 and 1934 to produce 20,964 grams of silver, 3920 kilograms of lead and 120 kilograms of zinc.

CAPSULE GEOLOGY

The Kaslo occurrence is located on Crown grant Lot 2432 at 1340 metres elevation above sea level, in the Slocan Mining Division. The claim is on Carpenter Creek, just east of Cody Creek.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The Kaslo property is underlain by argillite of the Slocan Group and several quartz porphyritic dikes which are probably related to the Nelson intrusions. Two narrow, north trending fissure veins have been explored on the Kaslo claim. The veins are 20 to 30 centimetres

wide and about 75 metres apart. A short adit has been excavated on the western vein and a grab sample collected from the dump near the adit portal in 1971 assayed 78 grams per tonne silver (Property File - The Potential of Reco Silver Mines Ltd.). Although not mentioned specifically, the vein is probably similar to the vein found on the Chambers Crown grant (082FNW032) and probably contains mostly galena with minor sphalerite.

CAPSULE GEOLOGY

The Smeralda property is west of the upper section of Dayton Creek, 3.5 kilometres east of Slocan. Access from the Slocan highway is via switchback jeep road that joins the Springer Creek road. The Smeralda adjoins, to the southeast, the Exchange (082FNW174).

The adjoining Smeralda (Lot 2424), Silver Plate (Lot 1524) and Exchange (Lot 1523) Crown granted claims develop a vein system in Nelson granite.

A quartz vein in Nelson granite has been explored by three adits, a shaft and a 30-metre winze on the Exchange claim near the border with the Smeralda claim. The vein is 1.5 metres wide, banded with clear and milky white quartz and pyrite accompanied by some galena, sphalerite and ancillary silver-bearing minerals.

Production from the Smeralda claim in 1934 amounted to 2.7 tonnes, yielding 18,880 grams of silver, 141 kilograms of lead and 308 kilograms of zinc. Total production including the adjoining claims is estimated to be more than 50 tonnes, although records are incomplete.

CAPSULE GEOLOGY

The Dumac property is on the east side of Bondholder Creek, a northeast flowing tributary of Enterprise Creek, 10 kilometres northeast of Slocan. It is northwest of the Enterprise (082FNW148) and Neepawa (082FNW147). Access from the Slocan highway is via the Enterprise Creek road.

The property was worked as the Royal in 1932 by R.F. Ainslie. A 2.3-metre chip sample across the vein assayed 384 grams per tonne silver, 2.8 per cent lead and 4 per cent zinc (Annual Report 1932, page 179).

In 1947, a mineralized zone was uncovered by ground-sluicing in and angling away from the bed of a small stream. The zone proved to be a strong shear, with considerable gouge, in Nelson granite. Sections of the zone are well mineralized with galena and sphalerite and some native silver. In 1948, Dumac Mines Ltd. produced 5 tonnes of ore, yielding 6469 grams of silver, 296 kilograms of lead and 660 kilograms of zinc.

Development on this property comprises open cuts and adits. In 1952 a new adit was collared about 90 metres northeast of the open cuts. It was driven 12 metres southerly as a crosscut to the shear zone then turned southwest 30 metres as a drift on the shear, but no ore was encountered. In 1956, L. Gormley worked the property as the Austin claims and produced 31 tonnes, yielding 5723 grams of silver, 585 kilograms of lead and 1135 kilograms of zinc.

CAPSULE GEOLOGY

The Ajax Fraction occurrence is situated on Crown grant Lot 1727 at 2088 metres elevation above sea level, in the Slocan Mining Division. The property is on the north side of Carpenter Creek east of Mount Payne. The property consists of the Ajax Fraction and Starlight No. 3 Crown grants (Lots 1727 and 595 respectively).

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The occurrence is hosted by quartzite and argillaceous quartzite of the Slocan Group. The sedimentary sequence generally strikes 120 degrees and dips 58 degrees southwest. For the most part, the sedimentary rocks are well bedded and banded. Southwest of the Ajax Fraction Crown grant, the quartzite and argillite that host the occurrence are overlain by black slate.

The occurrence consists of a fissure vein that strikes 025 degrees and dips steeply southeast. The vein follows a joint plane within argillaceous quartzite and is a mere crack to a few centimetres in width. It carries small amounts of silver-lead mineralization (probably as tetrahedrite and galena) sporadically concentrated along the vein.

The vein has been explored with two adits and a 15 metre deep

CAPSULE GEOLOGY

The property is located at about 2100 metres elevation on the north side of Tillicum Mountain, 11.8 kilometres east of the Lower Arrow Lake community of Burton.

The Tillicum group, comprising the Tillicum, Cultus and Valley View claims, was apparently located in this vicinity. Owners J.G. Reveler and L. Robson carried out exploration work in one or more short drift adits in the period 1917-21. Some 3.6 tons of sorted ore were stockpiled in 1921.

Metavolcanic rocks and a predominant metasedimentary succession form the highly deformed, east-trending Nemo Lakes Belt. To the north and west it is intruded by the Jurassic and/or Cretaceous Goatcanyon-Halifax Creeks quartz monzonite stock, while to the south it is invaded by the Eocene Nemo Lakes quartz monzonite stock. Supracrustal rocks of the Nemo Lakes Belt in the Tillicum Mountain area are dominated by metamorphosed siltstone, calcareous siltstone, arkose, and wacke, with lesser amounts of basalt, tuff, argillite, impure carbonate and marble layers. The supracrustal rocks underwent a post-Lower Jurassic phase of regional metamorphism and folding that predates the Middle to Upper Jurassic intrusion of the monzonitic stocks. This resulted in sillimanite grade metamorphism throughout most of the Nemo Lakes Belt, however, the metamorphic grade is lower around Tillicum Mountain and resulted in the formation of biotite, muscovite, chlorite and amphibole. In addition to the regional metamorphism, the rocks were locally subjected to two episodes of contact metamorphism. The first is associated with swarms of dioritic sills that probably accompanied the regional deformation, the second is hornfelsing related to the intrusion of the large monzonitic stocks and postdates the regional deformation.

On the Tillicum property the metamorphosed sedimentary rocks appear to correlate with the Lower and Middle Jurassic Archibald and Hall formations and the metamorphosed volcanic rocks with the older Lower Jurassic Elise Formation. All formations belong to the Lower Jurassic Rossland Group. These country rocks are intruded by swarms of deformed, often schistose feldspar porphyritic diorite to quartz diorite sills that vary from 1 to over 100 metres in width. These intrusive rocks are widely distributed and are spatially and probably genetically related to gold-rich skarn mineralization on the Tillicum property. The country rocks immediately adjacent to the sills are often weakly hornfelsed. Locally the margins of some diorite sills and country rock adjacent to them are overprinted with skarn alteration.

At the Heino-Money zone, stratabound gold-bearing siliceous calc-silicate skarn alteration is hosted in a thin, wedge-shaped package of basaltic tuff and tuffaceous sedimentary rocks which is bounded to the west by metabasalts and to the east by a large, altered feldspar porphyritic diorite body. The skarn is pinkish-green and is generally well layered with subparallel thin quartz veins and variable amounts of sulphides. The skarn assemblage includes quartz, tremolite-actinolite, clinozoisite, plagioclase, diopside, biotite, garnet and microcline, with minor amounts of sericite and carbonate. Free gold occurs as fine to coarse disseminations and fracture fillings within and along walls of the quartz sulphide veins; gold is generally associated with pyrrhotite, pyrite, galena and sphalerite. The zone is cut by north-trending, steeply dipping lamprophyre dykes which postdate both the skarn development and sulphide mineralization. A polished section study of this mineralization show that gold grains are generally free, but may also be intimately associated with pyrrhotite, arsenopyrite, sphalerite and pyrite-marcasite. Some pyrrhotite grains are rimmed with colloform pyrite-marcasite while others contain small masses of

CAPSULE GEOLOGY

hematite and graphitic material. Minor to trace amounts of tetrahedrite, chalcopyrite and possibly electrum also occur. Polished thin section studies and geochemical studies suggest that the mineralizing process at the Heino-Money zone involved two phases of precious metal deposition. The first phase included the introduction of gold, arsenopyrite and possibly sphalerite, accompanied by the crystallization of quartz, carbonate and calc-silicate minerals. This was followed by the deposition of argentiferous galena and the continued introduction of arsenopyrite and sphalerite. Gold and silver-bearing horizons are present in the skarns at the Heino-Money zone but they do not occur together. Silver is probably carried in galena.

High-grade gold was discovered in the "Money Pit" in September 1980 by Arnold and Elaine Gustafson, of Burton, on ground held as the Wolf, Hugh, Sandy and Near claim groups (12 units). Esperanza Explorations Ltd and Welcome North Mines Ltd., as a joint venture, optioned 100 per cent interest in the property from the Gustafson's by a September 20, 1980 agreement, subject to a percentage of net smelter returns. The existing claims and adjacent ground was over staked as the Til 1-4 claims (72 units). Work in 1981 included geochemical and geophysical surveys and trenching. A bulk sample of 58 tonnes shipped from the Money Pit averaged 78.8 grams per tonne gold.

Welcome North withdrew from the joint venture in March 1982. La Teko Resources Ltd., on June 23, 1982, acquired an option to purchase a 50.4 per cent share interest in Esperanza Explorations prior to December 31, 1984 for \$5,125,000. Additional staking expanded the property to some 237 units. Exploration activity in 1982 included 1128 metres of diamond drilling in 16 holes on the Heino-Money zone, 8 holes on the East Ridge zone and 1 hole on the Jenny zone. In 1983 a 60.9-metre crosscut adit was driven on the East Ridge zone and further geochemical surveys and trenching carried out. Diamond drilling was done in 18 holes on the Heino-Money zone. Drilling to date outlined a drill indicated 36,287 tonnes at 20.5 grams per tonne gold and a total inferred potential of 90,720 tonnes (George Cross News Letter, February 28, 1984). Drilling in 1983 totalled 2319 metres in 38 holes.

In 1984 a 60-metre adit was driven into the upper part of the Heino-Money zone; a 2268-tonne bulk sample was shipped to the Dankoe mill at Keremeos in 1985. Further diamond drilling was done in 5 holes on the East Ridge zone (total 25 holes to date). Based on work to date the East Zone has an inferred 4,536,000 tonnes at 1.7 grams per tonne gold (Northern Miner, November 15, 1984). La Teko provided financing of exploration to the end of 1985 (\$2.28 million) to earn a 39.6 per cent interest in Esperanza. La Teko was unable to provide further financing and the 1982 option agreement expired at the end of 1985.

The Heino-Money zone has been explored by drilling and underground exploration and has a reserve potential of 45,355 tonnes grading 34.28 grams per tonne gold. Within this reserve, a mining reserve has been calculated to be 15,874 tonnes with a diluted grade of 34.28 grams per tonne gold using a 11.99 grams per tonne gold cutoff grade. The mining reserve is outlined in four south raking shoots that occur in a near vertical gold-bearing skarn structure which averages about 2 metres in width along a strike length of approximately 200 metres and a vertical extent of 100 metres. Additional reserve potential occurs between the delineated shoots as well as along strike and depth projections of the skarn structure (Assessment Report 19437). Columbia Gold Mines (1991), formerly Esperanza, estimated reserves of the Heino-Money zone to be 13,600 tonnes grading 34.79 grams per tonne gold (Information Circular 1993-13, page 17).

The structure on the property is complex and is dominated by steep angle normal and reverse faults. Most faults have little offsets, however, several faults with major displacements divide the property into fault-bounded blocks. The metamorphic fabric of the rock closely parallels the bedding planes with minor or parasitic folding only very rarely observed. The Heino-Money zone is offset by a series of left-lateral, steep angle northeast striking faults that have displacements up to 9.0 metres. Within a 500 metre radius of the Heino-Money zone, three other significant mineralized zones have been discovered. These are the East Ridge zone, the Jenny zone and the Blue zone.

The East Ridge zone is 300 metres east of the Heino-Money zone. Gold mineralization occurs in a blanket-like zone that straddles the contact between porphyritic diorite and meta-arkose, quartzite, siltstone and minor argillite. The gold-bearing, near-vertical calc-silicate skarn structures occur within a 9.1 to 24.3 metre zone that strikes northeast and dips 70 degrees northwest. The skarn

CAPSULE GEOLOGY

structures have widths that vary from 1.5 to 4.6 metres, but average 2.1 metres. The East Ridge zone has been traced by drilling for 457 metres along strike, 365 metres down-dip at an average width of 1.5 metres. The East Ridge zone is comprised of two parallel upper skarn structures 0.9 to 1.5 metres thick and a lower skarn structure. Gold occurs in randomly distributed high grade pockets separated by areas of lower grade material. Within the zone, gold-bearing sulphide mineralization consists of pyrrhotite, pyrite-marcasite, arsenopyrite, chalcopyrite, sphalerite, galena and native gold with traces of tetrahedrite.

Exploratory underground drifting (300 metres) and drilling on the East Ridge zone has resulted in indicated reserves of 1,184,672 tonnes grading 5.82 grams per tonne gold. Within this reserve are measured geological reserves of 238,567 tonnes grading 13.36 grams per tonne gold using a minimum width of 1.5 metres and a 6.85 grams per tonne gold cutoff grade (Assessment Report 19437). Columbia Gold Mines (1991) estimated reserves of the East Ridge zone to be 440,000 tonnes grading 10.26 grams per tonne gold (Information Circular

The Jenny zone is 150 metres north and 100 metres lower in elevation than the Heino-Money zone. The Jenny zone consists of alternating bands of glassy quartz and sericitic quartzite overlain by pyritic, black, fine-grained thinly bedded argillite. Very fine-grained, galena, sphalerite and pyrite occur in the quartzite with euhedral magnetite and pyrite in the glassy quartz. Occasional cavity fillings of gold-bearing chalcedonic quartz and actinolite-rich bands are also evident. A chip sample across 0.4 metres returned 12.9 grams per tonne gold and 19.8 grams per tonne silver (Assessment Report 11161).

The Blue zone is 280 metres north-northeast of the Heino-Money zone. Three pits expose pyrite, pyrrhotite, galena and sphalerite massive stringers and lenses within a fractured and sheared thinly bedded quartz-biotite gneiss. Gold values range to 6.9 grams per tonne (Assessment Report 11161). Just above the pits, scheelite occurs disseminated in a siliceous matrix and along fractures.

As a result of mining the Heino-Money zone, a total of 5503 tonnes of ore with an estimated head grade of 24.4 grams per tonne gold was shipped to the Goldstream mill (082M 141) for processing. About 102,443 grams of gold and 149,546 grams of silver were recovered into concentrates which have been shipped to Japan for smelting (George Cross News Letter No. 237 (December 10), 1993).

In 1997, AMT Resources Ltd. worked the property. Mustang Gold is acquiring the property (Northern Miner, January 18, 1999).

COMMENTS: A grab sample from the dump near the adit.
REFERENCE: Assessment Report 13045.

CAPSULE GEOLOGY

The Empire No. 5 occurrence is situated on Reverted Crown grant Lot 1580, at 1646 metres elevation above sea level, in the Slocan Mining Division.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions, which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

CAPSULE GEOLOGY

The Empire No. 5 occurrence is underlain by argillite of the Slocan Group. The beds strike northwest and dip 45 to 60 degrees northeast. Granitic sills, up to 2 metres in width, cut the sedimentary sequence parallel to bedding. An adit was excavated on an east-trending, vertically-dipping shear within the argillite. Samples collected from the dump near the adit indicate that silver-lead-zinc mineralization is associated with pyrite. A grab sample from the dump assayed 685 grams per tonne silver, 27 per cent lead and 22 per cent zinc (Assessment Report 13045).

CAPSULE GEOLOGY

The Democrat occurrence is located at 2072 metres elevation, 1 kilometre on the east side of Idaho Peak. New Denver, British Columbia lies 6.75 kilometres to the northeast.

The Democrat claim was Crown granted in 1897 to W.B. Cash and J.G. Steel. Lessees conducted property work in 1903 with the development of three short adits and several opencuts. It was owned by P.M. Stuart in 1952. The Crown grant was forfeited February 15, 1994.

The area is underlain by folded and faulted argillites, limestones and quartzite of the Triassic Slocan Group. The Democrat showing is underlain by limestone where a large dragfold, 61 metres long, is locally shattered.

Erratic patches of galena occur in fractures in the steep limb of the dragfold.

Silver 1508.0000 Grams per tonne
Lead 37.0000 Per cent
Zinc 16.0000 Per cent
COMMENTS: Sample taken from the upper adit stockpile.
REFERENCE: Minister of Mines Annual Report 1920, page 125.

CAPSULE GEOLOGY

The Rose Marie occurrence is located on the west side of Clair Creek, 600 metres from its confluence with Carpenter Creek. New Denver is located 3 kilometres to the west. The Rose Marie occurrence was found on the former Rose Marie claim, and Crown-granted to Moran and Greenlea in 1900. In 1904, it was combined with the Mowitch claim group consisting of the Mowitch (Lot 4558), St. Clair (Lot 4559), Rose Marie (Lot 4003), Home Run, Grand Stand and Ronald Fraction claims. The Rosemarie claim apparently reverted to the Crown for it was Crown-granted to J. Cecheleco and associates in 1919. A small amount of work was done on the claim in 1920 and then it lay idle until 1949 when the upper tunnel was reopened and a small shipment of ore made. Workings consisted of four adits and explore two vein-lodes crosscutting Slocan Group metasediments, the lower referred to as the Mowitch lode (082FNW002) and the upper as the Rosemarie lode. The Rose Marie lode

CAPSULE GEOLOGY

was explored by two adits, 69 metres vertically above the upper adit of the Mowitch lode.

The Rose Marie occurrence is underlain by quartzite, limestone and interbedded argillite, predominantly massive. These strata strike northwest, dip steeply to the northeast and are intruded by feldspar porphyry dikes.

The Rose Marie lode is less well defined than the Mowitch lode but is 90 to 180 centimetres wide, crosscutting slate of the Slocan Group. It strikes about 020 degrees and dips 60 degrees southeast on average. The lode consists of bands and stringers of quartz, siderite and brecciated wallrock hosting tetrahedrite and more galena and sphalerite than the Mowitch lode. Some pyrite is also present.

Ore was intersected near the face of the 12-metre long upper adit. Production records are incomplete for the Rose Marie occurrence. Records show 10 tonnes of ore mined in 1949 with 8709 grams silver, 1144 kilograms lead and 818 kilograms zinc recovered. It is also reported that several tonnes of ore were mined from the upper adit in 1920. The ore was found to yield trace gold, 1508 grams silver, 37 per cent lead and 16 per cent zinc. Several tonnes of shipping-grade ore were also mined from the lower adit in this same year (Minister of Mines Annual Report 1920, page 125).

CAPSULE GEOLOGY

The Fairy property is situated near the headwaters of Howson Creek at 2073 metres elevation above sea level, in the Slocan Mining Division. The underground workings are on Reverted Crown grant Lot 4508.

It was Crown-granted to J.G. Steel in 1900 and to H.H. Falding in 1917 and 1925. In about 1950 the claim became a part of the holdings of Silver Ridge Mining Co. Ltd.

An adit was driven 61 metres westerly at an elevation of 2039 metres. At 58 metres the drift turns to the southwest to follow light shearing into which the mineralized fracture swings at 21.3 metres from the portal. A branch extends 20 metres to the south in limy rock. The records do not indicate when or by whom this development work was done.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Permian and/or Triassic Kaslo Group metamorphosed volcanic rocks occur to the north of the Slocan Group rocks. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic to pegmatitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

The occurrence is hosted by predominantly interbedded black argillite, quartzite and limestone of the Slocan Group. The sedimentary rocks have been folded, fractured, faulted and regionally metamorphosed to greenschist facies. The regional northwest trending asymmetric Slocan syncline is thought to be Middle Jurassic and is the first recognizable deformation in the sequence. Several fault structures are evident and host vein mineralization. Later stage

CAPSULE GEOLOGY

normal and thrust faults and shearing have chopped, deformed and remobilized the veins and mineralization. Drag features are also present.

On the Fairy property the sedimentary rocks strike 145 degrees and dip 50 degrees northeast. The occurrence consists of a narrow brecciated shear zone within black argillite. The shear contains several calcite veins 10 to 15 centimetres in width. The calcite veins carry minor disseminated sphalerite.

CAPSULE GEOLOGY

The Black Eagle property is located at the head of Woodbury Creek near Grey Eagle Lake, 25 kilometres east of Slocan City. Location of the property is uncertain and could not be confirmed in 1987 mapping. The property may include King Solomon (082FNW242). It is located in Kokanee Glacier Provincial Park.

The property comprises a group of some 35 claims and fractional claims lying on the headwaters of Woodbury and Landrum (South Fork of Woodbury) Creeks. The claims cover an area extending from Kane Peak east to Grey Eagle lake, north to Woodbury Creek at a point directly west of Sunset lake, and west to Woodbury Glacier. Three claims, the Dora, Flora, and Kotnen adjoin on the south, extending south from the east side of Kane Peak.

Seven claims and fractional claims lying along the north end of the area directly west of Sunset lake, were Crown-granted to the King Solomon Consolidated Mining Company, of Spokane, in 1904. Included among the seven claims are the Black Eagle (Lot 6266), Native Silver (Lot 6265) and Enterprise (Lot 6001). The Lucky Bill group, including the Lucky Bill (Lot 6276) claim, located just north and northwest of Grey Eagle Lake, was purchased by the company in 1901 from C.J. Johanson & associates, and Crown-granted in 1904.

Eleven other claims, mainly in the center of and to the south edge of the area were Crown-granted to D.H. Nellis, some in 1904, others in 1907 and 1911. Included among the Nellis claims are the Black Bear (Lot 6262), Glasier (Lot 6263), No. 1 (Lot 6002), North America (Lot 6269), Grey Eagle (Lot 7470), Kotnen (Lot 7472) and Dora (Lot 7473). It is not known who owned the remaining claims and fractions in the area, but probably they were held by either, or divided among both of the above parties.

There is no information on the nature of the showings or work done on the Nellis claims. It is not known if Mr. Nellis was in any way associated with the above company.

The King Solomon Consolidated Mining Company in 1904 owned about

CAPSULE GEOLOGY

60 Grown-granted claims on Woodbury Creek, a number of which were located at the mouth of the creek. The company is reported to have done considerable development work "upon some of the high-up claims". In 1902 it was reported that 76.2 metres of tunnel had been driven on the Black Eagle group. Development work was reported by the company from 1902 through 1912 and in 1910 they were reported to have considerable ore ready for shipment.

The target of exploration was quartz veining hosted by the Nelson granite.

CAPSULE GEOLOGY

The Iron Mask property is situated on the north side of Silverton Creek at 1067 metres elevation above sea level in the Slocan Mining Division. The showing is on the Iron Mask Reverted Crown grant (Lot 3520).

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

On the Iron Mask property the Slocan Group comprises massive argillite, quartzite and limestone. The strata are tightly folded and faulted but generally the beds strike southeast and dip to the

CAPSULE GEOLOGY

northeast. The showing consists of a 50 metre wide fracture zone containing narrow veinlets of quartz, calcite, siderite and sphalerite. The fracture zone strikes northeast and dips 70 degrees northwest. The zone is brecciated and in-filled with quartz veins 1 to 15 centimetres wide. Grab samples collected from the mineralized portions of the shear in 1977 assayed 170 to 340 grams per tonne silver and 20 per cent zinc (Assessment Report 16247). No production is recorded for this occurrence.

CAPSULE GEOLOGY

The Fivemile Point deposit is just east of the Troup Junction near the southeast shore of the west arm of Kootenay Lake, 5 kilometres northeast of Nelson. Access from Nelson is via the Canadian Pacific Railway line.

The mineralization was discovered in 1904 by George Huston and associates, of Sandon. A drift adit was driven about 23 metres. In the fall of 1904 Hall Mining and Smelting Company, Limited, operator of a smelter at Nelson, optioned the property and mined a bulk sample for test purposes.

The Fivemile Point fluorite deposit is a vein occupying a fissure in sheared Nelson granite. The vein strikes 120 degrees and dips 90 to 55 degrees northeast. The filling is a band of fluorite, crushed granite and gouge having a maximum thickness of 1.1 metres.

A band of bluish and purplish fluorite, up to 35 centimetres wide, occurs along and near the footwall, and smaller parallel streaks lie in the central and hangingwall parts of the vein, together with some light grey siliceous streaks. Vugs up to 0.3 metre in diameter, with concentrically banded borders are common. Barite is found locally as minute crystals and aggregates on the fluorite.

A few tonnes of fluorite were mined from an adit in 1904, but silica content proved to be higher than desirable.

CAPSULE GEOLOGY

The King Solomon property (a second occurrence of the same name in the region; see 082FNW257) is at the head of Woodbury Creek, 24 kilometres east of Slocan. Access is from the Kaslo highway on the west shore of Kootenay Lake via the Woodbury Creek road and trail to the Wolf Cascade, southeast of Moonlight Peak. Location of the property is uncertain and could not be confirmed in 1987 mapping. The property is located in Kokanee Glacier Provincial Park.

Little is known about this property other than it was Crown granted in 1904 to D.A. Nellis. See Black Eagle (082FNW239) for early history. The area is underlain by the granitic rocks of the Nelson batholith.

This property might also be confused with the King Solomon on the west shore of Kootenay Lake (082FNE141).

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

A 500-metre long, east-west trending pegmatite lens occurs in light-grey to white granite of the Jurassic/Cretaceous Nelson Plutonics. The core of the pegmatite is quartz, which analysed 98.84 per cent SiO₂, 0.42 per cent Al₂O₃, 0.04 per cent total iron, and 0.06 per cent CaO (Annual Report 1964). At the northwest limit the quartz lenses out into coarse-grained perthite. Here crystals of euxenite associated with magnetite occur in orthoclase.

The area to the south and east of the showing is high in uranium silts (over 50 parts per million) and uranium waters (up to 43.0 parts per billion) (Paper 1979-6).

CAPSULE GEOLOGY

Coarse metapelitic gneisses containing abundant sillimanite and garnet are reported from the Valhalla and Passmore dome area west of Slocan Lake (Reesor, 1965). Valhalla and Passmore are two of a series of domal structures containing gneisses which form part of the core of the Shuswap Metamorphic Complex. The core of the Valhalla dome comprises orthogneisses which are mantled by hybrid gneisses predominantly metasedimentary in origin. Sillimanite locally comprises 20 to 25 per cent of sillimanite-garnet-biotite gneisses of the hybrid gneiss zone, particularly along the east flank of the Valhalla dome and may be very coarse. In the vicinity of the Passmore dome coarse sillimanite may occur in knots or groups of crystals over 2.5 centimetres long and 1 centimetre wide. These gneisses may also locally contain up to 30 per cent garnet, with an average crystal size of 0.5 centimetre or less. Garnet may also be present in interbedded amphibolitic rocks in amounts up to 40 per cent (Reesor, 1965).

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The area is underlain by Middle Jurassic Nelson granites, with inclusions of older rocks. Copper mineralization, up to 1.67 per cent copper, occurs in the granites and inclusions. Mega Mineral Ltd. surveyed the area as the S.G., H.Y. M, V.M. and H claims in 1966. In 1968 the area, likely to the north of the Mega claims, was surveyed by Giant Explorations Limited.

CAPSULE GEOLOGY

The Iron King property, including the Iron King (Lot 9289),
Bodie (Lot 9290) and the Boston (Lot 9291) Crown granted claims, is
situated near Beasley, 12 kilometres west of Nelson. Access to the
property from the highway near Beasley is 8.5 kilometres via the
Smallwood Creek forestry road.
The claims were Crown-granted to William Moore in 1909.
Exploration at the time consisted of trenches, shafts and adits at
intervals over 600 metres. The property was investigated in 1933 by
trenching and drilling of 4 holes totalling 351 metres.
The claims are at the contact of the Nelson plutonic rocks and
a pendant of volcanic and sedimentary rocks of the Rossland Group.
The plutonic rocks, exposed on the western part of the property, are
composed of banded, medium-grained granite - granodiorite, striking
035 degrees, dipping 65 degrees northwest. The sedimentary rocks
are mostly schistose quartzites and argillites trending northeast,
dipping 45 degrees southeast. The contact between the intensely
metamorphosed sedimentary rocks is characterized by skarn

CAPSULE GEOLOGY

development, mostly garnet and epidote, that may extend a considerable distance into the lime-rich metasedimentary units.

The garnet and epidote is accompanied locally by magnetite and small amounts of pyrrhotite, pyrite, marcasite and chalcopyrite. The magnetite occurs as disseminations in the skarn or as irregular masses varying from 1 to 20 metres in width. Although iron content of the skarn can range up to 50 per cent. Good but erratic gold values have been obtained. One grab sample yielded over 80 grams per tonne gold (Starr, 1926). A 1.5-metre section of drill core assayed 1.37 grams per tonne gold and a 4.9-metre chip sample returned 46.6 grams per tonne gold (1933 Drillhole Summary (Property File)).

The strongly mineralized zone had been traced (by 1926) for well over 600 metres in length, having a maximum width of 60 metres.

CAPSULE GEOLOGY

The Kalappa occurrence is located on Enterprise Creek, approximately 500 metres from its mouth into Slocan Lake. Silverton, British Columbia lies 10 kilometres to the north-northeast. The Kalappa occurrence is hosted along the Eocene Slocan Lake fault. The east dipping normal fault separates foliated potassium feldspar porphyritic granite of the Middle Jurassic Nelson batholith from leucocratic biotite quartz monzonite to granite of the Paleocene Valhalla Complex. Locally, this granite is referred to as the

CAPSULE GEOLOGY

Ladybird granite. Younger rhyolite and andesite dikes intrude along the fault. The fault zone is 100 to 800 metres wide composed of 20 centimetre or less spaced brittle fractures and faults with lower to middle greenschist retrograde alteration. Granitic rocks of the Nelson batholith in the hangingwall are variably altered to clay-limonite, local quartz stockwork and zones of pyritization. The Ladybird granite is foliated and mylonitic. Older metasediments in the footwall show little retrograde or hydrothermal alteration.

The Kalappa occurrence consists of an altered and mineralized quartz stockwork to vein, striking 030 degrees and dipping 32 degrees to the southwest. Alteration consists of variable argillic and silicification restricted to the lode structure. The lode strikes 015 degrees and dips 35 degrees southeast.

Mineralization is composed of massive stibnite and pyrite. Ten kilometres further south along the Slocan Lake fault, sample J-74 taken from a fault-hosted quartz vein contained tetrahedrite and possibly native silver. Sample JL-200, a grab sample taken from a quartz vein on this occurrence, yielded 23.0 grams per tonne silver, 0.97 gram per tonne gold, 0.0072 per cent copper, 0.0040 per cent lead and 0.0088 per cent zinc (Open File 1988-11).

TERRANE: Kootenay

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

Granodiorite was quarried for dimension stone along the southeast side of the Canadian Pacific Railway at Three Mile Point, 2.4 kilometres northeast of Nelson.

This region, in the vicinity of the West Arm of Kootenay Lake, is underlain by plutonic rocks of the Middle to Late Jurassic Nelson Intrusions.

The quarried stone consists of medium to coarse grained porphyritic granodiorite containing scattered feldspar phenocrysts up to 2 by 4.5 centimetres, glossy grey to pink quartz grains 1 to 10 millimetres in diameter and black biotite flakes 1 to 2 millimetres. In thin section, the rock is comprised of fresh plagioclase and orthoclase, considerable quartz, minor biotite and a few grains of magnetite and sphene. The stone is of uniform texture and has a white to pink tone. Rare black knots are present. Stone used in buildings and monuments appears fresh and retains its attractive appearance.

The stone is cut by one major vertical dipping joint set striking 170 degrees and a second set striking 80 to 125 degrees and dipping 35 to 45 degrees north. Parks (1917) reports that the second joint set is spaced up to 1.2 metres apart, while White (1987) states these joints are widely spaced apart. Blocks up to 7.6 metres in length are reported to have been quarried from here. Considerable reserves of stone remain at the site. Physical properties are as follows (Parks, 1917, p. 112):

Specific gravity 2.656
Crushing strength (dry) (lbs/sq.in.) 29,406
Transverse strength (lbs/sq.in.) 1,708
Shearing strength (lbs/sq.in.) 1,790

Kootenay Granite and Monument Company Ltd. quarried granite from three sites in the early 1900's, with the largest face being 36

CAPSULE GEOLOGY

The Red Mountain claim, held by A. Ainslie and D. McCuaige, lies on the north side of Virgil Creek (Miller Creek), near Mount Revell.

The area is underlain by an east-west layer of quartzitic siltstone of the Upper Triassic Slocan Group and granites of the Middle Jurassic Nelson Batholith. Pyrritized sediments occur as inclusions in the granites. Oxidized minerals in quartz stringers carry values in silver and zinc. A sample accross 15 centimetres ran 17,623 grams per tonne silver and 1.37 grams per tonne gold. Another sample ran 1389 grams per tonne silver and 6 per cent zinc (Annual Report 1919, page 132).

CAPSULE GEOLOGY

The Al showing is located within Kokanee Glacier Provincial Park, approximately 1 kilometre south of Wheeler Lake. Chopper Mines Ltd. prospected, trenched and sampled the Al claims in 1983. Auckland Explorations Ltd. optioned the claims in 1984. The quartz veins, less than 5 centimetres thick, are hosted in potassium feldspar porphyritic granite. Two mineralized zones about 100 metres apart have been identified. The veins appear to trend northward but exposures are limited. Wallrock alteration is limited to 15 centimetres or less from the quartz veins. The veins contain galena, sphalerite and pyrite. A sample taken in 1987 assayed 26.0 grams gold, 170 grams silver, 15.9 per cent lead and 3.3 per cent zinc (Open File 1988-11).

CAPSULE GEOLOGY

The Jazmine property is located on the east side of the ridge that separates Cody and Sandon creeks at 1814 metres elevation above sea level, in the Slocan Mining Division. The property includes the Deloraine and the Silver Tip Fraction Reverted Crown grants (Lots 3156 and 4881 respectively).

The claims extend from the creek, at the 1310-metre elevation, to the summit of the north trending ridge at an elevation of about 1981 metres. The Airdrie Fraction, Freddie Lee (082FNW055), Colonial (082FNW069), and Cristein claims are located from north to south near the crest of the ridge.

In 1928 the Colonial, Freddie lee, Cristein, Airdrie Fraction, and Nellie claims were acquired under option by W.G. Wasmandorff of Vancouver. The Cristein claim (Lot 5369) had been Crown-granted to Messrs. McDonald and Taylor in 1904.

Colonial-Slocan Mines, Limited, was incorporated in May 1929 to acquire the claims and carry on exploration work. Work by the company ended in January 1930 and the company charter was surrendered in 1932.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper

CAPSULE GEOLOGY

Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

On the property, argillite and slate of the Slocan Group are folded in a broad synclinal structure in which the beds dip generally east. A mineralized shear zone has been identified on the northwestern part of the property near the eastern boundary of the Cristein Crown grant (Lot 5369).

The shear zone strikes 040 degrees, dips 70 to 80 degrees southeast and is exposed for about 3 metres in an old trench. An adit was excavated downhill from the trench, apparently to explore the downdip extension of the shear but it is not known if the shear was intersected in the underground workings. A 1 metre chip sample collected from the mineralized shear in the trench assayed 972 grams per tonne silver, 52.42 per cent lead and 1.4 per cent zinc. The sample contained galena in quartz (Assessment Report 13529).

CAPSULE GEOLOGY

The property is located at elevations of 1800 to 2200 metres on the south spur of Hailstorm Peak, 15 kilometres east of the Lower Arrow Lake community of Burton.
Three claims, the Hailstorm, Londonerry and Golden Rodd No. 2

CAPSULE GEOLOGY

(Lots 5875-5877 respectively) were held from 1899 or earlier by J.D. Jamieson and T. Matthews. The claims were Crown-granted in 1903. Exploration work was done in trenches and a short adit on the east slope of the mountain.

The Consolidated Mining and Smelting Company of Canada Limited, early in 1929, optioned the Crown-grants and 4 located claims. A crosscut adit at 2130 metres elevation on the west slope of the mountain was driven 275 metres during the year. Further crosscutting and some raising was done in 1930. This work failed to locate values similar to the main outcrop, although most of the crosscutting was from a raise directly under the outcrop; the option was abandoned.

The property was acquired by Roxwell Gold Mines Ltd. in about 1981. A geochemical survey was carried out in 1983.

Free gold has been found in the soil in a black graphitic manganese fault and in a marble. Numerous faults are present. It is suspected that where they intersect the limestone or marble that Bonanza type gold deposits will be found. A structural geology study indicates that the bearing of the limestone strikes 005 degrees, with a dip of 40 degrees west. At 400 metres and 1000 metres to the north there are gold geochemical anomalies with the following values: 550 parts per billion gold, 175 parts per billion gold and note that the Discovery Zone has 170 parts per billion gold (Assessment Report 12355). Geophysical tests using VLFEM, SP, IP and MAG have all responded positively.

Baron Gold Corp. drilled 5 holes totalling 762 metres in the area in 1997. Alex Strebchuck prospected the area since 1980 and in 1984 located bedrock mineralization, 5.35 grams per tonne gold over 2 metres (Assessment Report 18638). In 1985 and 1986, five tonnes of hardcobbed skarn ore resulted in 793 grams of gold. Esperanza Explorations Ltd. drilled 16 holes, totalling 2149 metres in 1988.

Drill indicated reserves are reported as 116,120 tonnes grading 8.57 grams per tonne gold and drill inferred as 156,040 tonnes grading 8.57 grams per tonne gold (Assessment Report 18638).

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The claims are underlain by the Mesozoic Nelson Intrusive comprised of porphyritic granite. The granite is crosscut by a series of felsite dykes and quartz veins with a network of calcite veinlets. In areas, the porphyry is slightly bleached with sericitic and argillic alteration. Minor propylitic alteration obscures the original texture with a network of calcite veinlets, abundant chlorite, some epidote, pyrite and a few fluorite veinlets.

In 1986, a diamond drill hole intersected a mineralized quartz vein hosting disseminated tetrahedrite and argentite. A sample from the vein assayed 0.07 gram per tonne gold, and 530.7 grams per tonne silver. Another drill hole intersected a weakly sericitized rhyolitic felsite dyke which assayed 0.034 gram per tonne gold and 219.08 grams per tonne silver. Trac Resources Inc. drilled the property (Assessment Report 15800).

CAPSULE GEOLOGY

The King Solomon is located 2 kilometres southwest of the Alpine (082FNW127), on the summit of the ridge between Sitkum and Duhamel creeks, some 18 kilometres north of Nelson.

The King Solomon claim (Lot 14628) was owned and operated during 1938-39 by T.L. Paris and A.D. Papazian, of Nelson. Hand steel was used to mine a small amount of ore.

Country rock is quartz monzonite, cut by pegmatitic quartz and potassium feldspar-rich dykes. A quartz vein occupies a shear zone averaging 0.15 metre in width, striking 260 degrees and dipping 35 degrees. The upper workings follow a sharp footwall; the lower workings are caved.

Ore mineralogy established from stockpiled ore comprises galena, sphalerite and lesser pyrite in a bullish white quartz gangue. The vein is moderately oxidized, minor limonite and hematite. A grab

CAPSULE GEOLOGY

sample taken in 1987 assayed 55 grams per tonne silver, 150 grams per tonne gold, 3 per cent lead and 1.1 per cent zinc (Open File 1988-11).
Vein characteristics very similar to the Alpine deposit (082FNW127). Production in 1938 and 1939, totalled 21 tonnes, yielding 622 grams of gold, 715 grams of silver and 49 kilograms of lead.

CAPSULE GEOLOGY

The Keen Creek limestone prospect is situated on Keen Creek, 8 kilometres west of Kaslo, in the Slocan Mining Division.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to lower greenschist facies.

South and west of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5).

The main outcrop is exposed for 140 metres in a westerly direction along the mountainside next to the creek. A series of partings that may represent bedding strike 100 degrees and dip 35

CAPSULE GEOLOGY

degrees northeast. A closely spaced joint set strikes 030 degrees and dips nearly vertical. The limestone is fine grained and uniform white to white with blue blotches and bands. A sample assayed 53.40 per cent CaO, 1.46 per cent MgO, 0.64 per cent insolubles, 0.15 per cent Al₂O₃, 0.15 per cent Fe₂O₃, 0.07 per cent P₂O₅, 0.25 per cent SO₃ and 43.00 per cent ignition loss (Geological Survey of Canada Memoir 173, page 54, Sample 1).

A smaller exposure further down the creek to the east displayed bluish mottled to light bluish white, fine grained limestone striking 110 degrees and dipping 40 degrees northeast.

The limestone was staked for marble by F. Archer and E. Timms sometime before 1917.

CAPSULE GEOLOGY

Outcrops with corundum are exposed in a highway cut (Highway 6) and along the railway below the highway. The corundum-bearing outcrops extend over a length of about 250 metres, and vertically from the river bank up to the highway cut between 50 and 100 metres. See also Blu Moon (082FNW263).

Hostrocks at the Blu Starr occurrence consist of metasedimentary (augen) gneisses, mainly syenitic or monzonitic in bulk composition, of the Valhalla Complex. They contain abundant crystals of corundum; in some coarser zones, the crystals are up to 1 to 2 centimetres. The association with zircon and sphene with amphibole zones suggest affinity to fenite/nepheline syenite complexes known from similar environments north of Revelstoke and in the Blue River area (D. Hora, personal communication, 1993).

The corundum crystals are extracted, shaped and polished and the resulting cabochons are marketed as untreated, natural "star sapphires", mostly of a translucent grey-blue to sky-blue colour (Geological Association of Canada Joint Annual Meeting 1993, Edmonton, Alberta - Field Trip Guidebook (A-7), page 32).

Anglo-Swiss Industries Inc. has acquired the Blu Starr property and in 1996 carried out detailed mapping and bulk sampling of its extensive land holdings. It will utilize its crushing, milling and

CAPSULE GEOLOGY

laboratory facility located at its Kenville mine property (082FSW086), 30 kilometres by road from the Blu Starr deposit (Information Circular 1996-1, page 20).

Over 50,000 carats of rough sapphires have been extracted from a select high-grade showing (George Cross News Letter No.36 (February 20), 1996).

Anglo-Swiss Industries has trucked 150,000 kilograms of sapphire-bearing material to its Kenville minesite for processing. Apparently 'the best blue sapphires occur on the hinge of a recumbent fold, directly above a pegmatite sill and within the sill's metasomatic halo. The larger crystals occur within the core of the hinge zone'. The company estimates about 500,000 kilograms of probable reserves (T. Schroeter, personal communication, 1997).

In 1998, Anglo Swiss Resources Inc. discovered a garnet deposit. The garnet crystals frequently exceed 10 centimetres in diameter. Facet grade material, located in the centres, yielded several carat gemstones displaying excellent clarity and are an intense pinkish red in colour. Compositionally, the garnets are intermediate between almandine and pyrope, possible the variety known as rhodolite. The garnets occur within feldspar-rich pegmatite sills and dikes, hosted by garnet-amphibolite. A transparent gem-grade variety of feldspar known as moonstone also occurs with the garnet. Several other zones containing megacrystic garnet have been located and are being explored (GCNL #127 (July 3), 1998). Anglo Swiss shipped 1000 carats of rough, gem quality garnets to cutting facilities in Sri Lanka.

Anglo Swiss obtained approval in September 1998 to add placer designation to the property. They will explore for gemstones in alluvial gravels along the valley floor. The property also contains showings of crystalline graphite.

In November 1998, Anglo Swiss discovered a new iolite (cordierite) gemstone, often referred to as "water sapphire". Many crystals exceed 100 carats, with some over 1500 carats. Over 50,000 carats of iolite crystals were extracted.

REFERENCE: Assessment Report 23406.

CAPSULE GEOLOGY

The Black Crystal property is a large graphite deposit located near the headwaters of Hoder Creek, approximately 74 kilometres north of the community of Trail. The prospect was discovered by a Castlegar prospector, Steve Paszty, around 1960.

The property is within the central portion of the Valhalla Complex comprised of high metamorphic grade paragneiss structurally overlain and interlayered with thick granitoid sheets. Graphite mineralization in the form of disseminated fine to coarse grained flakes is associated with a locally very coarse grained, friable, graphitic marble and/or siliceous metasedimentary rock. The graphite occurs along and parallel to the foliation planes and/or metamorphic compositional bands. The mineralized zone defined to date appears to cover an area 500 by 500 metres and have a minimum thickness of 80 to 100 metres. The geologic resource contained within this volume ranges from 50 to 62.5 million tonnes at an unknown grade (Assessment Report 23406).

Based on a total of 18 samples, 11 of which were three metre continuous channel samples, the average arithmetic grade of the deposit is 2.55 per cent graphite with a range of 0.39 to 6.95 per

CAPSULE GEOLOGY

cent graphite. The 11 channel samples had a weighted average grade of 2.55 per cent; the high grade assay of 6.95 per cent is an average of four separate samples from the same sample location (Assessment

Industrial Mineral Park Mining Corporation (IMP) mined a 3000 to 4000 tonne bulk sample and shipped it to a nearby site, where a flotation mill for the recovery of crystalline graphite will soon be built; start-up is forecast for spring 1996 (Information Circular 1996-1, page 20).

Sampling and evaluation continued at Black Crystal in 1996. IMP estimates a resource of flake graphite of over 27 million tonnes. The company stockpiled graphite at the mill which is nearing completion (Information Circular 1997-1, page 23).

In 1996, I.M.P. processed 5.5 tonnes (Information Circular 1997-1, page 23). In 1997, I.M.P. drilled 891 metres in 22 short, vertical core holes. In 1998, the company estimates 1,500,000 tonnes of graphite in an 1800 by 85 metre zone.

A 362-kilogram bulk sample was taken in 1998. Results were 5.4 per cent crystalline graphite.

Crystal Graphite Corporation was granted mining leases No. 392322 and No. 390937 and mining permit No. M-211 in June and July 2002. The mining leases are for 30 years, with an option to renew for another 30, and the mining permit allows the company to process graphite at its Kock Creek plant at a maximum rate of 250,000 tonnes per year.

In 2002 Crystal Graphite engaged AMEC E&C Services Ltd. to review the work completed to date on the property and prepare a technical report, as defined by National Instrument 43-101, to disclose the results of drilling on the project and the resource estimate. The database used to estimate the mineral resource at Black Crystal consists of samples and geological information from 64 drill holes, 176 slit trenches and 1,855 metres of linear trench. The amount of graphite mineralization has been determined indirectly by measuring the quantity of Fixed Carbon in a sample using the Leco method. Petrographic and X-ray diffraction analyses show the graphite to be very coarse by international standards, high-rank graphite with high reflectance and a high degree of crystallographic order. Upon segregation, it produces very pure coarse flake graphite and impure fine graphite. The graphite grains are mostly undeformed (PR REL Crystal Graphite Corp., August 7, 2002).

To date, most of the test work has been conducted on various composite samples of the regolith. Metallurgical performance from the pilot plant at a 20-tonne to 25-tonne per hour feed rate of screened regolith material has been 90 to 95 per cent graphite concentrate grade at 75 to 80 per cent recovery. The measured mineral resource category is only supported in the regolith unit, and at a trench spacing of about 25 metres. The indicated mineral resource category is supported by the present trench and drill grid on the regolith and calc-silicate units (about 50 metres). The mineralization of the Black Crystal Graphite project as of July 5, 2002, is classified as measured, indicated and inferred mineral resources. The classified mineral resources are shown below. The mineral resource is reported at a 0.7 per-cent Fixed Carbon cutoff grade to reflect preliminary metallurgical work and expected long-term pricing for high-purity graphite mineralization (PR REL Crystal Graphite Corp., August 7, 2002).
Black Crystal Graphite project mineral resource summary

CAPSULE GEOLOGY

The Winona property is situated on the south side of Silverton Creek about 1.5 kilometres southeast of the town of Silverton in the Slocan Mining Division. The showing is at 850 metres elevation above sea level.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by very fine grained clastic sedimentary rocks of the Upper Triassic Slocan Group that include locally weakly metamorphosed argillite, quartzite, limestone and some tuffaceous rocks. These sedimentary rocks are intruded by dikes, sills and stocks of varied composition and origin. Middle Jurassic Nelson intrusions are immediately south of the Slocan Group and are inferred to be the source of granitic sills and dikes found in the area. The Nelson intrusions comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite (Paper 1989-5).

On the Winona property the Slocan Group comprises massive to graphitic argillite, slate and quartzite. The strata are tightly folded, faulted and cut by a porphyritic granite stock probably

CAPSULE GEOLOGY

related to the Nelson intrusions. The occurrence is hosted within a shear zone that strikes east. The shear contains minor silver-lead-zinc mineralization and oxidized pyrite. It has been explored with trenches and two short adits. A grab sample collected from a trench in 1973 assayed 1.37 grams per tonne silver, 0.33 per cent lead and 0.49 per cent zinc (Assessment Report 4609). Although not mentioned specifically, the lead and zinc values are probably due to minor galena and sphalerite veins within the oxidized shear zone.

CAPSULE GEOLOGY

The Cat occurrence is situated south of Keen Creek, between Deer and Nashton creeks at 1220 metres elevation above sea level, in the Slocan Mining Division.

Regionally, the area lies on the western margin of the Kootenay Arc, in allochthonous rocks of the Quesnel Terrane. In the vicinity of the occurrence, the Quesnel Terrane is dominated by the Upper Triassic Slocan Group, a thick sequence of deformed and metamorphosed shale, argillite, siltstone, quartzite and minor limestone. Rocks of the Slocan Group are tightly and disharmonically folded. Early minor folds are tight to isoclinal with moderate east plunging, southeast inclined axial planes and younger folds are open, southwest plunging with subhorizontal axial planes. The sedimentary sequence has been regionally metamorphosed to middle greenschist facies.

About 2.5 kilometres west of the occurrence, the Slocan Group has been intruded by the Middle Jurassic Nelson intrusions which comprise at least six texturally and compositionally distinct phases ranging from diorite to lamprophyre. The most dominant phase is a medium to coarse grained potassium feldspar porphyritic granite. Several feldspar porphyritic granodiorite dikes, apparently related to

CAPSULE GEOLOGY

the Nelson intrusions, also cut the sedimentary sequence near the occurrence (Paper 1989-5). The sedimentary sequence has been affected by contact metamorphism from the emplacement of the nearby Nelson intrusions.

Rocks on the property are massive staurolite schist, argillite, quartzite, limestone and argillaceous limestone of the Slocan Group. The rocks strike between 075 and 150 degrees and dip between 40 degrees northeast to 40 degrees southeast. A large north trending quartz porphyritic dike, up to 200 metres wide, cuts the sedimentary sequence in the western part of the claims.

Lenticular quartz veins a few centimetres to more than two metres wide are common, mostly within or peripheral to the quartz porphyritic dike. Most veins are barren except for in the area east of Deer Creek. Here, disseminated argentiferous galena occurs in a vein 0.5 to 2 metres wide. The vein strikes 070 degrees and dips 40 degrees southeast. It has been exposed in a surface trench. A 1.7 metre wide chip sample collected in 1988 assayed 58 grams per tonne silver and 0.24 per cent lead (Assessment Report 17954). The vein has been exposed for 10 metres of strike length in the trench. The vein is hosted within the intrusion near its northern contact with a limestone bed of the Slocan Group.

CAPSULE GEOLOGY

Hostrocks at the Blu Moon occurrence consist of metasedimentary (augen) gneisses, mainly syenitic or monzonitic in bulk composition, of the Valhalla Complex. They contain crystals of corundum. The showing is similar to the Blu Starr (082FNW259), about 2 kilometres to the southeast.

Anglo Swiss Industries Inc. reported that United Radiant Applications of California has successfully heat treated 100 per cent of the initial test runs of rough sapphires to varying colours of blue. United Radiant will continue tests to determine the exact parameters of temperature, atmospheric conditions and time duration to maximize the percentage of gem quality sapphires. To date, Anglo Swiss has sorted over 150,000 kilograms of bulk sample material for the extraction of sapphire crystals. Select hand-cobbed samples have produced 10 to 200 carats per kilogram, including one rough crystal over 150 carats. The company is concentrating only on those crystals larger than 2 carats; to date it has recovered over 3000 carats of rough sapphires (T. Schroeter, personal communication, 1997).

A sapphire showing, named Sapphire Hill, was discovered in 1998. The sapphire-bearing zone is 400 by 50 metres. A 20-kilogram sample yielded over 6000 carats of sapphire crystals. Over 15,000 carats of rough sapphire has been extracted.

CAPSULE GEOLOGY

The Crown Point is located about 2 kilometres east northeast of the Alpine (082FNW127), on the southern boundary of Kokanee Glacier Provincial Park. The claims were Crown-granted in 1899.

The area is underlain by layers of quartzitic siltstone of the Upper Triassic Slocan Group and granites of the Middle Jurassic Nelson Batholith. Veins contain values in zinc, copper and lead. A sample taken in 1987 assayed 4.8 grams per tonne zinc, 0.094 per cent copper and 0.014 per cent lead (Paper 1989-5).

McCrory relocated and trenched an arsenopyrite showing in 1987. Rea Gold Corp. and Verdstone Gold Corp. optioned and drilled the property in 1988. Bryndon Ventures Inc. explored and drilled the property in 1989.

The area is underlain by Permian to Carboniferous paragneiss, intruded by Cretaceous granitic gneiss. An epithermal quartz vein with pyrite, arsenopyrite and barite occurs in the paragneiss. The vein, which measures about 75 metres in length and 60 metres down dip, strikes 160 degrees and dips 70 degrees west. Values in silver and gold are low.

COMMENTS: A chip sample taken across 6 metres.

REFERENCE: Starr, C.C. (1929): Report of a Brief Examination (Property File).

CAPSULE GEOLOGY

The Cariboo showing is located in porphyritic granite of the Nelson Intrusions. Several later phase granitic dikes striking around 350 degrees with near vertical dip occur. Mineralization consists of irregular disseminations of pyrite, pyrrhotite and small amounts of chalcopyrite and sphalerite throughout the dikes. Larger concentrations of these minerals also occur in numerous streaks and bunches throughout the dike rock over considerable area but separated by much larger areas of sparsely mineralized rocks.

Prior to 1929, the property had been developed by five opencuts, a 9-metre tunnel, a 30-metre tunnel (a crosscut through barren ground), and a 3.7-metre shaft. The workings are described as being an opencut about 150 metres north of an old cabin, an opencut and shaft 213 metres north of the cabin, an opencut 150 metres northwest of the cabin and a 9-metre tunnel about 365 metres south of the cabin. A 3.7-metre shaft is located about 90 metres northwest of the 9-metre tunnel. The location of the 30-metre tunnel was not reported.

A chip from the 9-metre tunnel assayed 0.69 gram per tonne gold, 30 grams per tonne silver and 0.13 per cent copper across 6 metres (Starr, 1929 (Property File)). Samples from the shaft to the

CAPSULE GEOLOGY

The Alpha (Magog) showing is poorly located, and very little is recorded about it. Minister of Mines Annual Reports for 1894 to 1898 state that the showings are on the Duck Creek trail in the Goat River area and the character of the ore is galena and tetrahedrite. The area is underlain by sedimentary rocks of the Purcell Supergroup of Middle Proterozoic age.

COMMENTS: Intersection over 2 metres.
REFERENCE: Assessment Report 20571.

CAPSULE GEOLOGY

The location of the Star prospect is centred on diamond-drill hole S90-1 (Assessment Report 20571). This prospect lies approximately 7 kilometres northeast of Kitchener, on the west side of Kid Creek.

This occurrence extends from diamond-drill hole S90-5 in the north to just south of drillhole S90-1 and includes strata contained within a structural panel bounded by the Spider and Carroll Creek faults (to the east and west).

Regionally, the area is underlain by the peri-cratonic Middle Proterozoic Purcell Supergroup, a thick succession of siliciclastic and lesser carbonate rocks. The Purcell Supergroup is well known for hosting a number of significant deposits that include the Sullivan (082FNE052) sedimentary exhalative lead-zinc deposit and the Troy copper-silver deposit in Montana.

The area of interest is underlain by the Aldridge Formation. The Aldridge Formation is the lowermost division of the Purcell

CAPSULE GEOLOGY

Supergroup and is composed of turbiditic siliciclastic rocks and numerous gabbro sills. The focus of exploration in the Aldridge Formation is the contact between the Lower Aldridge and the Middle Aldridge which corresponds to the time of deposition of the Sullivan deposit. In this particular area of the Purcell basin, the contact between the Lower and Middle Aldridge is somewhat enigmatic in that there is no recognizable facies change.

The Star prospect occurs within Middle Aldridge sedimentary rocks. Mineralization occurs below the lowermost of a group of sills (Middle Proterozoic Moyie intrusions) which are repeated by reverse faulting south of Kid Creek. Only the two lower sills are exposed in the fault block containing the mineralized zone. Dips are steep (averaging 65-70 degrees) and bedding trends north subparallel to the strike of the faults bounding this structural block.

Mineralization at surface consists of steeply dipping, east to northeast striking quartz veins in fine grained quartz wacke. Mineralization intersected in drill core includes 4.08 per cent zinc over 1 metre; and 8.52 per cent lead, 30.0 grams per tonne silver and 2.38 per cent zinc over 2 metres (Assessment Report 20571). Veins consist of quartz, galena, sphalerite and pyrrhotite with minor pyrite, chalcopyrite and arsenopyrite. Strongly altered sedimentary rocks occur within the mineralized zone. Patchy to pervasive chlorite and muscovite, locally associated with quartz-carbonate veining, overprints very fine grained biotite. Numerous lamprophyre sills, believed to be Cretaceous or Tertiary, occur in the mineralized zone. Widespread tourmalinization of argillaceous intervals were intersected in diamond drilling downdip from surface exposures.

In 1990, Kokanee Explorations Ltd. explored and drilled the property.

In 1996, Pacific Mariner Exploration Ltd. drilled one hole (152.4 metres).

Zinc 0.6800 Per cent

COMMENTS: A 4.3 metre sample. Equivalent uranium.
REFERENCE: Geology, Exploration and Mining in British Columbia 1969, page 347.

CAPSULE GEOLOGY

The Cariboo showing is located at about 1980 metres elevation at the headwaters of North Moyie Creek; it has been explored as the Zinc (Eagle) claims (Assessment Report 20936), the Gold Bar claims (Assessment Report 22493) and is mentioned in Assessment Report 16656 on the CND claims.

The Helikian Creston Formation (Purcell Supergroup) consists of quartzitic siltstone and argillaceous quartzite with a strong 025 degree trending, steeply east-dipping cleavage. The bedding, which trends northeast and dips northwest, is tightly folded on a 30 to 40 degree north-plunging axis.

The Cariboo main showing consists of an irregular mass of iron carbonate and sericite schist cut by a fine stockwork of white quartz veinlets and irregular veinlets of chlorite or serpentine. Galena and sphalerite occur in the quartz veins and scheelite occurs disseminated and in fractures. A 4.3-metre sample assayed 0.34 per cent lead, 0.68 per cent zinc, 1.17 per cent tungsten and 0.022 per

CAPSULE GEOLOGY

cent equivalent uranium. A grab sample assayed 48 grams per tonne silver, 4.58 per cent lead, 1.09 per cent zinc, 0.34 per cent tungsten and 0.025 per cent equivalent uranium (Geology, Exploration and Mining in B.C. 1969).

Assessment Reports 20936 and 23121 describe the showing as a carbonatite occurrence, consisting of a medium grained, buff coloured, rusty weathering dolomite dike striking north and dipping 70 degrees east, parallel to foliation, but lensing out along bedding. Trenching showed anomalous cobalt values to 800 parts per million but low gold; two diamond-drill holes yielded gold values up to 1000 parts per billion and 3470 parts per million molybdenum.

METAMORPHIC TYPE: Regional

RELATIONSHIP:

GRADE: Amphibolite

COMMENTS: On boundary between staurolite and kyanite-sillimanite facies.

CAPSULE GEOLOGY

The Topaz showing is located very close to Highway 3 and just west of the confluence of Topaz Creek with Summit Creek, about 19 kilometres west-northwest of Creston.

The Topaz and Toby groups, comprising 15 claims, were owned in 1969 by Magog Mining Co. Ltd. Work included magnetic and electromagnetic surveys over Topaz 1-5 and trenching.

The showing is hosted by relatively high grade metamorphic rocks (near the boundary between staurolite-kyanite facies to the west and kyanite-sillimanite facies to the east), developed from sedimentary rocks of the Aldridge Formation (Middle Proterozoic Purcell Supergroup). The original showing consisted of galena, sphalerite and cassiterite in a quartz vein; chalcopyrite and pyrrhotite are disseminated in a diorite sill. Traces of nickel and silver are reported.

This showing was covered by a magnetic and electromagnetic survey in 1968 for Magog Mining Ltd.; several magnetic anomalies were found worthy of follow-up, likely due to concentrations of pyrrhotite. The area was subjected to a geochemical survey in 1984 for Greenwich Resources, which did not locate the original showing, and disclosed only weak anomalies for copper and zinc.

Greenwich Resources Inc. held the property in 1984; a geochemical silt survey was reported.

COMMENTS: Main (west) zone tonnage is contained within a block 1.8 metres wide by 360 metres long by 61 metres deep; parts of the zone contain up to 0.5 per cent lead.

REFERENCE: Brown, D.A. and Klewchuck, P.: Northwest Geology, October, 1994.

CAPSULE GEOLOGY

The Wilds Creek (Leg, Legion, Liz B, Tag) deposit is located at about 915 metres elevation (over a range from 850 to 1250 metres elevation), mainly in the small valley of Wilds Creek that drains southwesterly into Kootenay River between Duck Lake and Wynndel, about 12 kilometres north-northwest of Creston.

The Wilds Creek deposit is one of a series of stratabound zinc-lead-barite prospects and mines in upper Purcell Supergroup stratigraphy along the western edge of the Purcell anticlinorium, typically hosted in dolomitic units of the Dutch Creek Formation near the contact of the overlying Mount Nelson Formation, intercalated with mafic volcanics of the Nicol Creek Formation. All these units are part of the Middle Proterozoic Purcell Supergroup, although the stratigraphic nomenclature and correlation varies with different workers. The rocks are all foliated and structurally complex, with the mineral occurrences lying in the hangingwall (west) of the Hall Lake fault. The occurrences have received various amounts of exploration as illustrated by the Mineral King (082KSE001) about 100 kilometres north of Wilds Creek. It produced 1.21 million tonnes of ore with an average grade of 4.12 per cent zinc, 1.76 per cent lead and 24.8 grams per tonne silver (Minister of Mines Annual Reports 1956 to 1964). Other properties with anomalous lead-zinc-silver geochemistry lie to the north (adjacent Ace or Rob claims: Assessment Reports 12919, 18834).

The first recorded exploration activity on the prospect occurred in 1924 when prospectors trenched and sank two short shafts. The first reported drilling was by Newmont in 1954 when 6 core holes were drilled, intersecting a mineralized zone about 2.0 metres thick with a strike length of approximately 335 metres. Holes S-1 and S-2 intersected greater than 5.0 per cent zinc over about 2.0 metres. Four holes drilled to the northeast of the original zone, holes S-3 to S-6, intersected 1.0 to 2.0-metres thick zones of 2.0 per cent to 4.0 per cent zinc, with up to 0.5 per cent lead. In 1961 the ground was re-staked by Sheep Creek Gold Mines Ltd. Two core holes were drilled to the southwest of the Newmont drilling. Drill hole Liz B-1 intersected 1.52 metres of 14.88 per cent zinc at a depth of 61 metres, and diamond drill hole Liz B-2 was terminated before reaching the zone penetrated in the first hole. The property was briefly examined by Canex later in 1961, and by Cominco in 1962. In 1963 evaluation of the property led to a preliminary reserve estimate. In 1964 the property was optioned to Aspen Grove Copper Mines Ltd., and exploration extended the mineralization approximately 100 metres to the south of the main showing. The entire Main Zone was trenched and 5 drill holes (A-1 to A-5) were completed by the end of 1965. Hole A-4 intersected 9.0 metres of 2.13 per cent zinc. From 1968 to 1970, VLF-EM and ground magnetic surveys were completed over the Main showing. In 1977 Cominco staked adjacent ground and in 1978 conducted a soil survey along Wilds Creek. In 1982 and 1984, Aspen Grove Mines Ltd. extended soil geochemical coverage and in 1988 line-cutting, geological mapping, geochemistry and IP geophysics were conducted. In 1989 Legion Resources Ltd. completed additional line-cutting and ground magnets, followed by diamond drilling (5 holes). From 1990 to 1992 Kokanee Explorations (Quest) completed fourteen diamond drill holes tracing mineralization for about 2.0 kilometres along strike and following the base metals down to a depth of 130 metres. In 1993 Kokanee completed soil geochemical and geophysical surveys, extending the mineralized horizon 3.5 kilometres along strike to the northeast.

The property geology has recently been described in detail by Brown and Klewchuck (Northwest Geology, October 1994; Fieldwork 1994). Two separate carbonate units contain the mineralization, known as the East zone and West zone. The carbonate units are described as dolomite and dolomitic siltstone, hosted in argillite, quartzite and sericite chlorite phyllite; minor mafic volcanics, rarely pillowed basalt, are intercalated. These rocks are intruded nearby by the Duck Lake stock, massive biotite granite (part of the middle Cretaceous Bayonne batholith, and probably responsible for the minor magnetite-epidote-diopside-tungsten-molybdenum skarn mineralization found on the property).

The Main or West mineralized zone is at least 300 metres long by 2 to 3 metres thick as defined by drilling (indicated ore reserves in 1964 of 136,000 to 150,000 tonnes of 6 per cent zinc, with up to 0.5 per cent lead and unspecified silver content, in a block 1.8 by 360 by 61 metres: Assessment Report 22771). It lies within the western dolomitic horizon and comprises at least two intervals of stratabound sulphide-rich material, 30 to 75 per cent pyrite and sphalerite. These intervals are bedding-parallel, fine grained pale yellow to red-brown sphalerite and fine to medium-grained pyrite within laminated baritic dolomite and calcareous quartzite and argillite. The semimassive and layered sulphides form narrow zones less than 25

CAPSULE GEOLOGY

centimetres thick in the silicic rock; alternating pyrite and sphalerite-rich layers may be a primary structure with a prominent, superimposed penetrative tectonic foliation. Disseminated pyrite is ubiquitous; minor galena occurs sporadically in dolomite layers. At surface, the mineralization is intensely oxidized and poorly exposed; mineralization is banded in the south and becomes more silicified and massive to the north (Assessment Report 19902).

The East zone was explored by drilling in 1989; the best intersection was 0.78 per cent zinc over 0.75 metre (Assessment Report 19902). The East zone is more intensely silicified than the Main zone, with abundant quartz veinlets and stockwork hosted within the eastern dolomitic siltstone unit. Mineralization comprises pyrite with sporadic sphalerite, galena, tetrahedrite and chalcopyrite. Minor silver (up to 23 grams per tonne, with 5.9 per cent lead and 7.1 per cent zinc) is reported over 0.6 metre in the 1992 drilling by Kokanee Explorations.

Irregular patches of pyrite with reaction rims of magnetite and associated narrow intervals of epidote and diopside occur locally in the dolomitic sediments; these patches have associated tungsten and molybdenum (up to 200 and 130 parts per million respectively), and are interpreted to be superimposed calcsilicate hornfels assemblages in the thermal aureole of the Duck Lake stock (Brown and Klewchuck, Fieldwork 1994).

The stratabound main zone at Wilds Creek is foliated and probably remobilized. The two most probable models of ore deposition are sedimentary exhalative (Sedex) or manto replacement. The stratabound zinc-lead-barite mineralization hosted by dolomite lies adjacent to mafic volcanic rocks that thicken rapidly to the north, possibly indicating synvolcanic growth faults developed during rifting. Such block faulting may have provided conduits for a hydrothermal system associated with volcanic activity that could have produced Sedex-style mineralization; the East zone could be a stringer feeder zone.

The Legion property is held by Quest International Resources Corporation (now Standard Mining Corporation) (55 per cent) and Legion Resources Ltd. (45 per cent).

CAPSULE GEOLOGY

The Leadville or Star property is on the east side of Goat River, 6 kilometres north of Kitchener. Several exposures of veins have been found extending from the river bottom up the east slope to an elevation of 1370 metres.

The veins are described as being hosted in quartzites of the Aldridge Formation intruded by gabbro of the Moyie intrusions, both units belonging to the Purcell Supergroup of Middle Proterozoic age. Thinly bedded quartzites strike east-northeast and dip 20 degrees to the north. The veins, described variously as quartz-filled fissures and quartz-calcite veinlets, are up to 0.5 metre wide and cut the sedimentary rocks on the dip but are parallel in strike, in close proximity or in places within the gabbro sill. In 1925, the vein had been exposed over a continuous length of 23 metres, dipping 72 degrees to the south.

The veins are irregularly mineralized with galena and minor amounts of sphalerite, chalcopyrite and a little pyrite. Carbonate

CAPSULE GEOLOGY

alteration of the wallrock, likely calcite, accompanies the vein in places and may account for the locally schistose character of the hostrock. Maximum assays from dump material are up to 720 grams per tonne silver, 61.1 per cent lead, 10.2 per cent zinc, 0.05 per cent copper and 1.4 grams per tonne gold (Minister of Mines Annual Report 1923, page 220).

CAPSULE GEOLOGY

The Storm King (Lot 3625) is located at 2130 metres elevation at the head of Goat River, some 3 kilometres south of the summit of White Grouse Mountain and 45 kilometres north of Creston. The Superior claim was also located in this vicinity.

The Superior claim, owned in 1901 by W.J. Garbutt, was apparently located in this vicinity. A considerable amount of work was done (in 1900?) and several tons of ore were packed out a distance of 48 kilometres in order to make a smelter test. Leech (1952) mentions a water filled shaft and trenches on the Storm King property, which may be the old Superior working. The Golden King (Lot 3624), Storm King (Lot 3625), Gem (Lot 3631), and Annie G (Lot 6339) claims were Crown-granted in 1905 to J.A. Gibson, Pugh Sutherland, H.H. Nell, and C.R. Holmes.

Hostrocks are Kitchener Formation dolomitic siltstones (Middle Proterozoic Purcell Supergroup); the sediments strike north and have moderate to steep dips to the west. The property is located 1.5 kilometres from the southeast corner of the Bayonne batholith, an Early Cretaceous granodiorite. The intrusive rocks are medium to coarse grained and contain pink feldspar and minor black tourmaline.

Regional metamorphism is biotite facies of greenschist grade; one small area of diopside, possibly a contact metamorphic effect, was noticed in recent work. Quartz veining is common on the property, occurring in large swarms which are subparallel to the stratigraphy and up to 50 metres wide. Individual veins are up to 1 metre in width and locally contain fine-grained carbonate; the mineralized veins are bounded by weathered brown sericite alteration up to 1 metre in width.

A shaft was sunk on mineralized quartz; the dump contains a small pile of sorted ore heavily mineralized with pyrite,

CAPSULE GEOLOGY

tetrahedrite, galena, and a little chalcopyrite and arsenopyrite. A selected sample rich in galena and tetrahedrite analysed 0.31 per cent tin; recent samples of such material yielded assays of up to 4.5 grams per tonne gold and 310 grams per tonne silver, but barren quartz veins, host dolomites and granodiorite contain no precious metals.

Efforts to find extensions of the zone in trenches do not appear to have been successful. The property was also explored as the Whiskey Jack by Lacana Mining in 1985 for its precious metal and tin potential; mineralization was found to be restricted to local areas within extensive quartz veining, with no interesting values obtained from either the altered wallrocks or in barren-looking quartz veins. No samples yielded positive tin assays, but local high grade antimony assays may be of further interest; furthermore, small occurrences of arsenopyrite north of the Whiskey Jack claim contain scheelite.

CAPSULE GEOLOGY

The old Columbia showing is located at an elevation of 1710 metres, on the northwest side of Perry Creek, about 300 metres above the valley floor and 1.4 kilometres northwest of Perry Creek. The old workings consisted of the Scorgie tunnel and Columbia shaft, with attendant opencuts.

The main showings consist of a large quartz zone containing irregular and low grade disseminations of pyrite on the hangingwall; to the southeast is a zone of sheared rock with narrow veinlets of quartz carrying mostly irregular lenses of pyrite with some chalcopyrite and galena. The veins are hosted in sedimentary rocks of the Creston Formation (banded quartzite with argillite partings) intruded by dioritic dikes of the Moyie intrusions. Both these units belong to the Purcell Supergroup of Middle Proterozoic age. The diorite is pervasively altered to chlorite and a stockwork of quartz veinlets in places.

Assays range from 0.35 gram per tonne gold over 1.8 metres to 27 grams per tonne gold over 0.4 metre in the Scorgie tunnel, averaging about 1.7 grams per tonne gold over 1 metre; in the Columbia shaft, assays range from 0.35 to 8.6 grams per tonne gold over widths of 1

CAPSULE GEOLOGY

The Lakeview (Lot 14277) is located on the east shore of Kootenay Lake about 0.5 kilometre south of the mouth of Sanca Creek. The old adit is driven under Highway 3A. The Crown grant was forfeited in June of 1990; the area was recently explored as the Sanka #5 claim (Assessment Report 11988).

The claims are underlain by sedimentary rocks of the Creston Formation, part of the Purcell Supergroup of Middle Proterozoic age. These rocks comprise quartzite and siliceous limestone, and form a roof pendant that is underlain at some depth by quartz diorite of the Cretaceous Bayonne batholith. A narrow porphyry dike is found with the mineralization in places.

On the old Crown grant, a lens of massive sulphide 7 metres long and 1.3 metres wide formed the main part of a system of lensy quartz and calcite veins mineralized with galena, sphalerite and minor pyrite and chalcopyrite. The veins occur in a northerly trending shear zone, some 100 to 150 metres north of the contact of the roof pendant with the surrounding batholith. The dip of the mineralization is steep to the east; the shear zone is from 3 to 6 metres wide.

Intermittent production from 1935 to 1953 resulted in 738 tonnes, yielding 136,698 grams of silver, 155 grams of gold, 231 kilograms of cadmium, 82,687 kilograms of lead and 175,185 kilograms of zinc.

COMMENTS: At boundary from chlorite to biotite-almandine facies.		

CAPSULE GEOLOGY

The Giant (Midget) showing is exposed immediately north of Nun Creek and at the west edge of the Priest River canyon, at an elevation of 1220 metres. The vein strikes northerly and dips very steeply to the west. The vein is composed chiefly of white quartz and is about 3 metres thick where exposed. Scattered grains and masses of sulphides, including pyrite, tetrahedrite and galena are present in the vein.

The wallrocks are described as schists conformable in attitude to the vein; recent mapping shows that they belong to the Mount Nelson Formation, part of the Middle Proterozoic Purcell Supergroup (see Brown et al., Fieldwork 1994). They are regionally metamorphosed to greenschist grade, near the boundary between chlorite and biotite-almandine facies (Geological Survey of Canada Map 1714A).

A small (50 tonne-per-day) mill was set up on the property in 1968, but production was limited to trial runs, and no results are available except that "the vein appeared to contain about 1 per cent each of copper and lead where mining was done" (Minister of Mines Annual Report 1968).

CAPSULE GEOLOGY

The Homestake showings are located on the west side of Perry Creek between Liverpool and Manchester creeks at about 1570 metres elevation. The old showings, first reported on in 1915, have recently been explored for gold as part of the Perry Creek property of Gallant Gold Mines Ltd. (specifically, on the Luke claims). The area is underlain by sedimentary rocks of the Middle Creston Formation intruded at their (faulted) contact with Kitchener Formation by Moyie diorite sills; all these units belong to the Purcell Supergroup of Middle Proterozoic age.

The showings consist of numerous irregular quartz veins and lenses with a little carbonate and predominantly disseminated pyrite

CAPSULE GEOLOGY

(plus minor galena and chalcopyrite), lying in a shear zone mainly in a dioritic sill or dike. The dike intersects thinly bedded slates, limy sediments and minor quartzite beds of the Middle Creston Formation and phyllitic argillites, or slate, of the Kitchener Formation. The dike is pervasively chloritized and silicified with a network of quartz veinlets in places.

Quartz veins assay up to 1.7 grams per tonne gold over a width of 3 metres, although picked material yields as much as 10 grams per tonne gold (Minister of Mines Annual Report 1915). Sampling by W.V. Smitheringale (report in Property File, dated August 1932) gives values from 0.3 to 69.6 grams per tonne gold, averaging 3.4 grams per tonne gold, over a width of 1.5 metres. Recent drilling by Gallant Gold Mines defined the silicified fault system anomalous in gold for at least 200 metres with a true width of about 7 metres; best results yielded a 1.0 metre assaying 10.3 grams per tonne gold.

CAPSULE GEOLOGY

The Kid 3 prospect is adjacent to the Star (082FSE002) on the west; regional and detailed geology are as described for the Star. On the Kid property, galena, sphalerite and pyrrhotite are disseminated in argillaceous quartzite of the Middle Proterozoic Purcell Supergroup and as lenses in quartz veins. There are also minor amounts of galena and sphalerite as replacements and fracture filling, and in quartz veins. The quartzites are bleached in proximity to the mineralization, assumed to be sericitic alteration.

CAPSULE GEOLOGY

The Golden Cap (Lot 5544) is at the extreme north end of the Iron Range fault which, as described by Stinson and Brown (1994), is closely associated with a dike or dikes of Moyie gabbro intruding quartzite, siltstone and argillite of the Aldridge Formation and with chloritic alteration. Both these rock groups belong to the Purcell Supergroup of Middle Proterozoic age.

Mineralization exposed in an adit on the Golden Cap consists of veins of hematite and quartz cutting a Moyie gabbro dike containing crystals of magnetite. Shearing along the margins of the dike is associated with chloritic alteration of both sedimentary rocks and the dike, and minor pyrite.

CAPSULE GEOLOGY

Relatively little is known about the Union Jack (Lot 5765) showings, which lie at the north end of the Iron Range fault and associated chloritic alteration. The showings are hosted in altered Aldridge Formation quartzite (Middle Proterozoic Purcell Supergroup) that contain thin veins and seams of hematite.

FIELD CHECK: N

CAPSULE GEOLOGY

Formation in the vicinity of the northern showings consists of well bedded quartzofeldspathic wacke and laminated siltstone, which develop a phyllitic sericite foliation near the fault. Locally, sericite alteration extends preferentially along specific bedding horizons. The gabbro dikes and/or sills in the area, which belong to the Middle Proterozoic Moyie intrusions, are preferentially mineralized.

Mineralization consists of massive to disseminated hematite, locally with magnetite, in steeply dipping, 0.3-0.6 metre wide veins, broader stockworks of thin veinlets, breccia matrix and disseminated grains. Gabbro hostrocks are strongly albitized and the siltstones exhibit sericitic +/- silicic alteration. Sulphide mineralization is sparse except in the area north of the American Flag occurrence where pyrite clots occur within a foliated mafic dike. The zone of mineralization pinches and swells along strike from narrow (0.5 metre wide) veins within sheared rock, to a broad (100 metres or more) zone of multiple veining and alteration. Depth and downdip extension of this system is unknown.

A sample taken across 3 metres of the American Flag shaft contained 55 per cent metallic iron (Geological Survey of Canada, Economic Geology Series 3, page 132).

Crosscutting relationships suggest multiple phases of hydrothermal fluids injected into the fault zone. Early quartz veins are commonly brecciated, with fragments enclosed in a hematite matrix. Early albitization is crosscut by hematite veining and angular albitized clasts float in later hematite veining. Later stage white and colourless quartz veinlets commonly crosscut both albite alteration and hematite veining.

CAPSULE GEOLOGY

having an irregular outcrop pattern and width of 0.3 to 1 metre. It contains abundant, rounded inclusions of carbonate, possible ultramafic lithologies, and xenoliths of Aldridge Formation. There are petrographic similarities to diatreme breccias in the Golden area, which are ultramafic lamprophyre and alnoite. One of the dikes on the northern part of the Iron Range yielded a Late Carboniferous potassium-argon date of 301 +/- 10 million years.

At this occurrence, the iron zone is 5.5 metres wide and a representative sample contained 55.2 per cent iron (Geological Survey of Canada Economic Geology Series 3). The wallrock on both sides of the mineralized zone is quartzite heavily impregnated with iron.

CAPSULE GEOLOGY

The Keepsake occurrence is part of the Iron Range showings, located near the crest of the ridge that is west of and parallel to the Goat River. The location is centred on an early 1920s opencut within the southern portion of the Keepsake claim, at the headwaters of Crackerjack Creek.

The regional geology, deposit description and local geology for this occurrence is similar to that of the American Flag occurrence (082FSE016) which lies approximately 1500 metres to the north.

The hematite is partly massive and partly a mixture of minute grains of quartz in a hematite matrix. This zone is hosted in the Middle Proterozoic Middle Aldridge Formation along the north trending, subvertical Iron Range fault zone. The Aldridge Formation in the vicinity of the showings consists of well bedded quartzofeldspathic wacke, laminated siltstone and quartzite, intruded by the Middle Proterozoic Moyie intrusions (gabbro).

At this occurrence, the iron zone is 2.4 metres wide at the north end and 1.2 metres at the south end. A sample taken across 2.4 metres of iron mineralization contained 46 per cent iron (Geological

CAPSULE GEOLOGY

The Rhodesia occurrence is part of the Iron Range showings, located near the crest of the ridge that is west of and parallel to the south flowing portion of the Goat River. The location is centred on an early 1920s trench at the headwaters of Crackerjack Creek.

The regional geology, deposit description and local geology for this occurrence is similar to that of the American Flag occurrence (082FSE016) which lies approximately 2000 metres to the north.

The hematite is partly massive and partly a mixture of minute grains of quartz in a hematite matrix. This zone is hosted in the Middle Proterozoic Middle Aldridge Formation along the north trending, subvertical Iron Range fault zone. The Aldridge Formation in the vicinity of the showings consists of well bedded quartzofeldspathic wacke, laminated siltstone and quartzite, intruded by Middle Proterozoic Moyie intrusions (gabbro).

This occurrence consists of two trenches that reveal mineralized rock along strike of the Keepsake occurrence (082FSE019).

CAPSULE GEOLOGY

The La Grande occurrence is part of the Iron Range showings, located near the crest of the ridge that is west of and parallel to the south flowing portion of the Goat River. The location is centred on a mineralized zone a couple of metres thick at the headwaters of Crackerjack Creek.

The regional geology, deposit description and local geology for this occurrence is similar to that of the American Flag occurrence (082FSE016) which lies approximately 2750 metres to the north.

The mineralization occurs as a zone of siliceous hematite that is a couple of metres thick and has an outcrop length of 76 metres. This zone is hosted in the Middle Proterozoic Middle Aldridge Formation along the north trending, subvertical Iron Range fault zone. The Aldridge Formation in the vicinity of the showings consists of well bedded quartzofeldspathic wacke, laminated siltstone and quartzite, intruded by the Middle Proterozoic Moyie intrusions (gabbro).

CAPSULE GEOLOGY

The Cracker Jack occurrence is part of the Iron Range showings, located near the crest of the ridge that is west of and parallel to the south flowing portion of the Goat River. The location is centred on mineralization at the headwaters of Crackerjack Creek.

The regional geology, deposit description and local geology for this occurrence is similar to that of the American Flag occurrence (082FSE016) which lies approximately 3000 metres to the north.

The mineralization occurs as several small exposures of quartzite impregnated with vein quartz and hematite. The hematite forms seams up to 18 centimetres thick. This zone is hosted in the Middle Proterozoic Middle Aldridge Formation along the north trending, subvertical Iron Range fault zone. The Aldridge Formation in the vicinity of this showing consists of well bedded quartzofeldspathic wacke and laminated siltstone intruded by Middle Proterozoic Moyie intrusions (gabbro).

CAPSULE GEOLOGY

The Dakota occurrence is part of the Iron Range showings, located near the crest of the ridge that is west of and parallel to the south flowing portion of the Goat River. The location is centred on an opencut at the headwaters of Crackerjack Creek.

The regional geology, deposit description and local geology for this occurrence is similar to that of the American Flag occurrence (082FSE016) which lies approximately 4200 metres to the north.

The opencut exposes altered rock veined with quartz and bearing films and seams of hematite. This zone is hosted in the Middle Proterozoic Middle Aldridge Formation along the north trending, subvertical Iron Range fault zone. The Aldridge Formation in the vicinity of this showing consists of well bedded quartzofeldspathic wacke, laminated siltstone and quartzite. Gabbroic sills and dikes of the Middle Proterozoic Moyie intrusions also occur in the area.

CAPSULE GEOLOGY

The Idaho occurrence is part of the Iron Range showings, located near the crest of the ridge that is west of and parallel to the south flowing portion of the Goat River. The location is centred on an open cut on the eastern slope, near the ridge between Crackerjack Creek and Six Mile Creek.

The regional geology, deposit description and local geology for this occurrence is similar to that of the American Flag occurrence (082FSE016) which lies approximately 4500 metres to the north.

Hematite mineralization occurs within a quartz-seamed zone that outcrops for a length of 30 metres in a north-south direction. This zone is hosted in the Middle Proterozoic Middle Aldridge Formation along the north trending, subvertical Iron Range fault zone. The Aldridge Formation in the vicinity of the showings consists of well bedded quartzofeldspathic wacke, laminated siltstone and quartzite. Gabbroic sills and dikes of the Middle Proterozoic Moyie intrusions also occur in the area.

CAPSULE GEOLOGY

The Niagara occurrence is part of the Iron Range showings, located near the crest of the ridge that is west of and parallel to the south flowing portion of the Goat River. The location is centred on a showing of hematite-bearing igneous rocks on the eastern slope of the ridge, south of Six Mile Creek and north of Highway 3. The regional geology, deposit description and local geology for this occurrence is similar to that of the American Flag occurrence (082FSE016) which lies approximately 8 kilometres to the north. Iron mineralization occurs as hematite within gabbroic sills and dikes of the Middle Proterozoic Moyie intrusions. This zone is hosted in the Middle Proterozoic Middle Aldridge Formation along the north trending, subvertical Iron Range fault zone. The Aldridge Formation in the vicinity of the showings consists of well bedded quartzofeldspathic wacke, laminated siltstone and quartzite.

CAPSULE GEOLOGY

The Constellation occurrence is part of the Iron Range showings which are located near the crest of the ridge that is west of and parallels the south flowing portion of the Goat River. This occurrence is centred on a narrow open-cut with hematite mineralization, located on the eastern slope of the ridge, south of Six Mile Creek and north of Highway 3.

The regional geology, deposit description and local geology for this occurrence is similar to that of the American Flag occurrence (082FSE016) which lies approximately 8300 metres to the north.

Iron mineralization occurs as massive hematite within siliceous country rocks. This zone is hosted in the Middle Proterozoic Middle Aldridge Formation along the north trending, subvertical Iron Range fault zone. The Aldridge Formation in the vicinity of the showings consists of well bedded quartzofeldspathic wacke, laminated siltstone and quartzite with gabbroic sills and dikes belonging to the Middle Proterozoic Moyie intrusions.

CAPSULE GEOLOGY

The Prospector's Dream is an old showing discovered in 1898 and recently re-examined for its gold potential. It is located in an area of known placer gold production and lode gold showings (e.g. the David, 082FSE108; Weaver, 082FSE116; and the Perry Creek area 10 kilometres to the northwest).

Hostrocks are Middle Proterozoic Aldridge Formation argillite and quartzite of the Purcell Supergroup, intruded by gabbro sills and dikes of Middle Proterozoic Moyie intrusions.

Showings consist of one or more veins of vuggy white quartz containing a little pyrite (partly oxidized to limonite) and free gold. The quartz is rusty and broken (sheared) in places.

In the shaft area, a quartz vein assayed 9.5 grams per tonne gold over a width of 0.33 metre (grab samples assayed up to 46 grams per tonne gold) (Assessment Report 22052).

In the decline area, a shear zone in Moyie gabbro contains quartz veins of variable thickness up to 1 metre; grab samples assayed up to 73 grams per tonne gold, and chip samples assayed up to 13.5 grams per tonne gold over a width of 1 metre (Assessment Report 22052). Float from other veins discovered on the property assayed from 0.1 to 35.3 grams per tonne gold (Assessment Report

CAPSULE GEOLOGY

to Harrison and Risdon for 10 claims, the Bayonne, Oxford, Maryland (Lots 5083-5085 respectively), Delaware, Columbus, Ohio (Lots 5960-5962), Kentucky (Lot 5966), New Jersey (Lot 5967), Virginia (Lot 6887) and Illinois (Lot 6888).

During 1904 the property was acquired by a syndicate of Butte Montana interests who formed Bayonne Gold Mines, Limited. Intermittent development work to 1911 included an upper drift adit on the Bayonne claim, a drift adit on the Ohio claim, and a low-level crosscut driven from the Virginia claim; the workings totalled about 509 metres. The Skookum claim (Lot 9360), located in 1902 and surrounded by the Bayonne and Echo groups, was Crown-granted to J. Campbell in 1913. No further activity was reported until the 1921-23 period when J.B. White & associates of Spokane held an option and carried out further underground work.

From incomplete records it appears that a new company, The Bayonne Gold Mines, Limited was organized in the 1920's in the USA to acquire the property. Development work during 1929-30 was financed by J.B. Gerrard, of New York; by 1930 the workings totalled about 1000 metres of drifts and crosscuts. In 1934 the property was under option to A.C. Frost, of Seattle.

Bayonne Consolidated Mines, Ltd., incorporated April 1935, purchased the Bayonne property for \$100,000 payable out of production; the adjoining Echo group was acquired by the company in about 1936. The Echo group was owned in 1904 by W. Maher, H. Anderson, and J. Baugh, of Nelson. Trenching, ground sluicing, and at least 250 feet of underground work was done in one or more adits during the initial period of exploration. In 1922 the Echo group of 6 claims, the Echo, Echo Fr., Ontario, Portland, St. Elmo, and Idaho (Lots 13014-13019 respectively) were Crown-granted to Harris Ginsberg.

By a December 1935 agreement Grull-Wihksne Gold Mines, Limited acquired a half interest in the Bayonne Consolidated properties. Grull supplied mill equipment from a Bridge River area property and a 50 ton per day cyanide mill was installed and put into operation on November 3, 1936. Development work failed to locate additional ore and depletion of the known reserves led to the closing of the mill on October 31, 1938.

Underground exploration and development during 1939-40 outlined additional reserves at depth and milling operations were resumed in April 1940; the mine closed August 1, 1942 for the duration of the war. Work resumed on the property in August 1945 when shaft sinking from No. 8 level was begun. Milling operations were resumed in May 1946 and continued until July of that same year when the mine closed due to labour and material shortages. The workings at that time comprised 7 adit levels at vertical intervals of about 30 metres, connected by raises.

An internal shaft was sunk 170 feet from the lowest adit (No. 8 level) and No. 9 level established at a depth of 30 metres in the shaft. Underground work during the period 1936 included approximately 2396 metres of drifting and crosscutting, and 229 metres of raising. Lessees worked the property intermittently between 1947 and 1951, removing about 1,000 tons of ore from the workings. The property reportedly reverted to the Crown in 1957.

The construction of the Salmo-Creston highway up Summit Creek, about 6.4 kilometres to the south of the property, led to renewed interest in the area in the 1960's. Bayonne Mine Ltd., incorporated July 1962, acquired 17 Crown-grants of the Bayonne and Echo groups, and 25 recorded claims. During 1963 the company carried out rehabilitation work in No. 8 adit, underground sampling, and site preparation for the installation of a flotation mill. Reserves were reported at 11,000 tons valued at \$50 per ton (Northern Miner, Oct. 17, 1963).

The property was held for a short period in 1968 by Liberty Mines Ltd. but no work was done and the option was later terminated.

In 1975 R.A. Sostad acquired the Bayonne, Columbia, Ohio, New Jersey, Virginia, and Skookum Crown-grants, and 11 reverted Crown-grants comprising the Bayonne and Echo groups. In February 1980 the claims were transferred to Goldrich Resources Inc. Reserves were estimated at approximately 17,200 tons (G.L. Mill, 04/01/80 in VSE AL 213/80, Goldrich Mines L.). Work began on the property in 1980.

The Bayonne mine is a small historic producer (80,903 tonnes averaging 16.1 grams per tonne gold and 38.4 grams per tonne silver) from small (0.1-0.5 metre) quartz-filled fissure veins. The veins occur in biotite hornblende granodiorite of the Bayonne batholith which is altered to a talc-carbonate rock for 0.5-1.0 metre on either side of the fissure. The fissure contains one or more quartz veins with mineralization in well-defined shoots. An oxidized zone extends down the veins for 137 metres where it is abruptly truncated by unoxidized primary sulphides. Mineralization consists of pyrite,

CAPSULE GEOLOGY

galena, sphalerite, chalcopyrite, tetrahedrite with minor free gold, hessite and petzite.

Recent work included rehabilitation by Goldrich Resources over the period 1980-1987. A shipment of 39 tonnes averaging 5.1 grams per tonne gold, 41.1 grams per tonne silver, 0.4 per cent lead, 0.2 per cent zinc and 78.3 per cent silica was made to the Cominco smelter at Trail. Further geochemical, geophysical (VLF-EM) and trenching work was done under an option agreement with Terra Mines Ltd. over the 1987-1990 period.

Reserves calculated in 1983 were 28,186 tonnes proven, 28,186 tonnes possible and 45,000 to 63,500 tonnes inferred. Proven and possible ore averages 15 and 25.7 grams per tonne gold and silver, respectively, over 0.5 metre width (GCNL May 27, 1983).

CAPSULE GEOLOGY

The Echo property adjoins the Bayonne (082FSE030) on the south; the main vein lies about 0.75 kilometre south of the Bayonne vein, at an elevation of about 2000 metres on the southwest flank of John Bull Mountain. It is one of a group of showings that collectively comprise the Bayonne mine area.

Bayonne Consolidated Mines, Ltd., incorporated April 1935, purchased the Bayonne property for \$100,000 payable out of production; the adjoining Echo group was acquired by the company in about 1936. The Echo group was owned in 1904 by W. Maher, H. Anderson, and J. Baugh, of Nelson. Trenching, ground sluicing, and at least 250 feet of underground work was done in one or more adits during the initial period of exploration. In 1922 the Echo group of 6 claims, the Echo, Echo Fr., Ontario, Portland, St. Elmo, and Idaho (Lots 13014-13019 respectively) were Crown-granted to Harris Ginsberg. See Bayonne (082FSE030) for additional exploration and development details.

Hostrock to the veins is biotite hornblende granodiorite of the Mine stock, belonging to the Nelson intrusions of Middle Jurassic age. The main Echo quartz vein strikes east-west, dips 85 degrees south and has been exposed over a horizontal distance of at least 50 metres and a vertical distance of 16 metres in underground workings; surface workings expose this vein, which is 1 metre wide, for at least 300 metres, subparallel to the Bayonne vein. A subsidiary vein strikes 060 degrees and is approximately 25 centimetres thick. The vein is followed by a light-coloured felsic dike, about 1 metre thick, in the hangingwall; this dike, which is shattered, is reported to carry low gold values of about 1.5 to 2 grams per tonne. Alteration of the footwall comprises silicification, pyritization, and possibly argillization (described variously as "altered" and "talcy gouge"). Galena and pyrite are the only sulphides present.

CAPSULE GEOLOGY

The Spokane showings are located on the southeast slope of Wall Mountain at about 2000 metres elevation, near the upper end of Next Creek. The veins are on a steep hillside of 35 to 40 degrees, and trend across it obliquely at an angle of about 45 degrees to the headwaters of Next Creek or about east-west; the dip is steep to the southwest. A series of three adits exposes the main vein over a vertical distance of 50 metres and a strike length of 120 metres.

The initial work on the property was done on a vein located at a lower elevation several hundred metres south of the main vein, and included open cutting and 2 adits 7.6 and 18 metres in length. This ground was reportedly staked in 1902 but allowed to lapse in 1909.

The main vein was discovered in 1911 by R.Y. and K.K. Laib of Salmo and 4 claims were staked. An additional 2 claims were staked in 1913, the property then comprising the Spokane, Spokane No. 1, International, Continental, Granite, and Timberline claims.

A claim adjacent to the Spokane group, and owned in 1915 by a Mr. Harris, was located on the westerly extension of the Spokane vein. This ground was apparently in part held as the Hilltop and Sitka claims, owned in 1937 by John Bull. See Harris (082FSE078) and Hilltop (082FSW232).

The Laib Bros. carried out development work in open cuts and 2 adits from 1911 until the fall of 1915 when an option was given to W.R. Salisbury of Salmo and I.G. Nelson and associates of Nelson, who comprised the Spokane Mines Syndicate. Development work and the mining of some ore was carried out in 1916 but the option was

CAPSULE GEOLOGY

subsequently given up.

The Laib Bros. resumed work on the property in 1917 and continued intermittently until 1941, apparently residing at the mine permanently for a portion of that period. In 1918 they built an arretre near the creek but the ore was found to be unamenable to amalgamation. Development work was severely handicapped by the lack of transportation and much of their efforts through the 1920's and 1930's was directed towards the construction of a road (Bayonne Road) some 29 kilometres from the railroad at Tye on Kootenay Lake.

By 1937 the workings comprised 5 adits (Nos. 1-5) totalling about 295 metres of crosscuts and drifts and a 17-metre raise. The lower adit (No. 5) consisted of a 24-metre drift. In 1939 a 533-metre tramline was built from the Main (No. 4 adit) portal and a road was completed to connect the lower tram-terminal with the Bayonne road. Subsequent ore shipments included considerable dump material.

No activity was reported from 1941 until 1948 when K.K. Laib resumed work on the property. Kootenay Central Mines Limited optioned the property in 1949. The raise from No. 4 adit was extended to the No. 3 adit level. A new crosscut adit, also called No. 5, was driven 36.5 metres before work ceased for the winter. The option was subsequently abandoned. The owner resumed work in 1950 and continued through 1954. Dennis G. White of Nelson optioned the property in 1956, extended the new No. 5 crosscut to intersect the vein at a total length of 52.4 metres, and drifted 3.6 metres to the east. The option was subsequently abandoned.

Rimrock Mining Corporation, Limited acquired the property in 1957 and extended the No. 5 crosscut an additional 1.8 metres, intersecting another vein, which was drifted on to the south. This vein, an oxidized fissure 30 inches wide containing mostly decomposed wallrock, is reported to contain high gold values in a narrow soft oxidized zone adjacent to both walls. No further work was carried out. The company planned to install a 35-ton per day mill but this was not done.

The main vein is a well defined and persistent fissure that varies in size from 5 centimetres to 1 metre wide and may be traced for over 600 metres onto the adjacent Harris (082FSE078) property to the west. The vein is hosted in biotite granodiorite of the Wall stock, assumed to be one of the Nelson intrusions of Middle Jurassic age. However, the vein is close to the southern contact of the stock with surrounding metasediments (grit and quartzite) of the Three Sisters Formation, part of the Upper Proterozoic Horsethief Creek Group.

The vein consists of quartz and sheared or altered granodiorite since the vein or veins vary from fine stringers enclosing wallrock to a single vein the full width of the fissure. Alteration is to kaolin and pyrite in the wallrock adjacent to the vein. Biotite minette (lamprophyre) dikes cut and offset the vein along the hangingwall; the strike of these dikes is perpendicular to the vein.

Much of the vein is narrow and barren, but some well-mineralized shoots contain pyrite, galena, sphalerite, chalcopyrite (minor copper stain, assumed to be malachite), limonite, and rarely free gold. These minerals are developed as lenses, stringers and disseminations in the vein. Variable values in gold (up to 20.5 grams per tonne) and silver (up to 1405 grams per tonne) are associated with the sulphides, which assay up to 48.9 per cent lead and 1.6 per cent zinc (Minister of Mines Annual Report 1915, page 173).

Recorded production over the period 1915 to 1956 was 1733 tonnes from which 570,988 grams of silver, 29,639 grams of gold, 304,046 kilograms of lead and 12,943 kilograms of zinc were recovered. The vein is oxidized to a depth of 50 metres.

Extensions to the vein were sought in 1981 by Nugget Resources Ltd. by magnetic, electromagnetic and geochemical surveying; anomalies found in the surveying suggest the presence of two veins extending both east and west off the Spokane property (Assessment Reports 10841, 13393).

REFERENCE: Property File (Special report by H. Sargent, 1937, 2 pages).

CAPSULE GEOLOGY

The Montana claim (Lot 10778) is located at an elevation of 2075 metres across the southeast ridge of John Bull Mountain, at the head of Bluebird Creek. It is about 2 kilometres southeast of the Bayonne mine (082FSE030) and 2 kilometres southwest of the Summit Bell (082FSE034) occurrence.

The Montana claim was owned from about 1902 by P. Casey and F. Aikens. Work was done in open cuts and a shallow shaft. The claim was at times grouped with the Summit Bell property held by the same owners. The Montana claim was Crown-granted to Casey and Aikens in 1917. In 1937 the claim was held by the Estate of P. Casey, of Spokane.

Bayonne Consolidated Mines, Ltd. optioned the claim in 1939. Following some development work the option was given in 1941.

The claim lies within the Mine stock, part of the Nelson intrusions of Middle Jurassic age, near the contact with a small inlier of quartzite, assumed to be part of the Monk Formation (Horsethief Creek Group of Upper Proterozoic age) that is the nearest metasedimentary rock. Metamorphic grade in the granodiorite pluton is upper amphibolite. The showing consists of a quartz vein, up to 1

CAPSULE GEOLOGY

metre thick, striking 280 degrees and dipping 58 degrees southerly. Surface workings expose the vein over a strike length of 150 metres; selected ore from a dump assayed 3.4 grams per tonne gold, 150 grams per tonne silver and 24.5 per cent lead; other samples contain up to 1.4 per cent zinc (Minister of Mines Annual Report 1937, part E, page 45, Special Report by H. Sargent). The vein is sparsely mineralized with galena and pyrite; microscopically, galena and sphalerite occur in large irregular masses and contain minor pyrite, rare minute blebs of chalcopyrite and tetrahedrite. Copper stain (malachite) is evident in places. The quartz vein has been traced from sheared granodiorite into the quartzite.

Geophysical surveying (very low frequency electromagnetic) conducted in 1990 by Goldrich Resources Inc. did not reveal any conductors considered worthy of follow-up (Assessment Report 20198).

CAPSULE GEOLOGY

No. 1 adit.

The property remained idle for many years, possibly due to the complex nature of the ore. The Porcupine Goldfields Development & Finance Company, Limited examined the property in 1926. Interior Mine-Development Company, Limited was incorporated in May 1928 by O. Frith and associates, of Nelson, to acquire a lease on the property. An electrical survey was carried out late that year by the Radiore Company of Canada. Eastern Canadian Interests examined the property in 1930. A Spokane company, General Mining, Milling & Leasing Company, reportedly held the property for a short period. Vancouver interests, under the name Lucky Strike Mining Syndicate, in 1933 carried out trenching, sampling and about 305 metres of diamond drilling in 3 holes.

In 1935 A.C. Frost and associates, of Seattle, acquired a lease on the property from the owners, C. Hussey and A. Fleming, of Spokane, and the H. Stambaugh Estate, of Youngston Ohio. Sixteen adjacent located claims in 3 groups were acquired; the Aerielle and Belkap groups by staking and the Strathcona group by lease from E.C. Wragge & associates, of Nelson. Work to mid 1937 included deepening the winze to 49 metres and drifting on the 46-metre level. Samples were sent to Mines Branch, Ottawa for tests.

A lease on the property was acquired in about 1939 by E. McQuade, of Ymir, apparently under the name Vendors, Limited. Canadian Exploration, Limited optioned the property in 1940 and carried out 76 metres of drifting and 55 metres of crosscutting on No. 1 level. The workings to date included numerous open cuts, a 34-metre shaft, and 5 adits. Number 1 adit comprised about 192 metres of drifts and crosscuts and a 49-metre winze; about 229 metres of drifting and crosscutting was done from the winze 46-metre level. Adit No. 3 comprised about 296 metres of drifts and crosscuts. Adit Nos. 2, 4 and 5 comprised about 61 metres of drifts and crosscuts; No. 4 adit is located to the northwest, on the other side of the ridge.

Esperanza Explorations Ltd. optioned the property in 1980 from owners Fleming, Stambaugh and associates. Work that year included geological and geochemical surveys. In 1984 BP Selco Inc. optioned the property. Work in 1984-85 included geological mapping, an electromagnetic survey over 24 kilometres and 2618 metres of diamond drilling in 14 holes. Dutch Creek Resources Ltd., under an option agreement with Esperanza Explorations in 1988 carried out diamond drilling.

The Wisconsin property is located near the southern end of the Kootenay Arc, a generally north trending, west dipping arcuate zone of metavolcanics and metasediments. The area is underlain by successively younger strata from east to west, ranging from the Helikian Purcell Supergroup in the east (by Kootenay Lake), through the Hadrynian Windermere Supergroup and Hadrynian-Lower Cambrian strata of the Hamill Group, Badshot and Mohican formations, and the Lower Cambrian and younger Lardeau Group to the west. All successions are cut by middle to late Mesozoic intrusive rocks.

The base of the Windermere assemblage unconformably overlies the Purcell Supergroup and is marked by a distinctive polymict conglomerate of the Toby Formation. Conformably overlying the Toby Formation are mafic volcanics of the Irene Volcanic Formation consisting of green mafic tuffs and massive to schistose greenstone. The upper Windermere succession, in conformable contact with the Irene Volcanic Formation, is made up of the Horsethief Creek Group consisting predominantly of argillite "grit" and phyllite with interbeds of grey limestone, quartzite and conglomerate or diamictite. Some workers divide the Horsethief Creek Group into two formations: the Monk Formation, the basal formation, consisting of two phyllitic units divided by a grey limestone member is overlain conformably by the Three Sisters Formation consisting of grits, quartzite and conglomerate. An upper grit unit of the Three Sisters Formation is thought to be the top of the Horsethief Creek Group locally marking the boundary to the conformably overlying Hamill Group (Assessment Report 14265).

The Wisconsin property is host to a stratabound sulphide horizon, occurring within the basal Horsethief Creek Group (Monk Formation) at the gradational contact between it and the underlying upper part of the Irene Volcanic Formation, a couple of hundred metres below the postulated fault contact with the Hamill Group. Hamill Group quartzites appear to be in fault contact with the lower Horsethief Creek Group immediately to the west of the Main zone sulphide horizon. Previous work shows the property to contain five or more arsenical base metal massive sulphide zones enriched in gold and silver. The mineralization shows evidence of recrystallization and local shearing, and in the Main zone area is located within, or at the contact between granodiorite and metasediments of the

CAPSULE GEOLOGY

Horsethief Creek Group.

The Main zone is characterized by the presence of minor limestones, on the sulphide footwall, combined with a thicker and more extensive ankerite-dolomite-barite horizon at the southern extension of the sulphide horizon. The hangingwall to the sulphides are quartzites and sillimanite muscovite schists. The central portion of the sulphide zone has been extensively recrystallized and remobilized by a lobe of intrusive granodiorite which lies east of the main showings. In the vicinity of the sulphide horizon, at the main showing, the granodiorite exhibits crosscutting relationships both to the sulphides and host sediment-volcanic stratigraphy. All rock types are cut by late-state quartz veining. The granodiorite close to the main lobe of the intrusion has been incorporated as a complex system of sills within the host quartzites and volcanics. The footwall of the Main zone sulphides is formed by an interbedded sequence of quartzitic sediments and basaltic volcanics of the Irene Volcanic Formation.

The mineralization varies from massive to semimassive with varying proportions of arsenopyrite and pyrite making up the majority of the sulphides and lesser amounts of barite, galena, sphalerite, chalcopyrite, pyrrhotite and valleriite. Metallurgical examinations indicate that most gold is found as inclusions in chalcopyrite or with galena fracture fillings in pyrite and arsenopyrite. Thin section study of drill core indicates that alteration of the metasedimentary hostrock comprises muscovite, chlorite, sericite and carbonate. Further evidence in drill core shows at least two phases of mineralization, one of which consists of massive arsenopyrite-pyrite mineralization and the second consisting of lesser amounts of galena, sphalerite, arsenopyrite, pyrite and pyrrhotite associated with quartz veining (Assessment Report 14265).

Certain aspects of the Wisconsin deposit bear a striking similarity to the J & L "Sedex" deposit (082M 003) north of Revelstoke, including mineralogy, structure and roughly similar position within the Horsethief Creek-Hamill sedimentary pile. It is probable that the Wisconsin deposit is a Sedex (sedimentary exhalative) type which has been remobilized in the vicinity of the later granodioritic intrusion and re-deposited along shears developed along the granodiorite-metasediment contact (Assessment Report 14265).

Mineralization at Wisconsin has been extended by drilling 300 metres along strike and approximately 200 metres downdip on the Main zone with indication of increased grade and thickness to the north (Assessment Report 14265).

Inferred reserves at the Wisconsin property are 136,065 tonnes grading 11.99 grams per tonne gold and 171.4 grams per tonne silver (Northern Miner, November 1, 1984).

Ronald Granger conducted geochemistry, geological work and prospecting on the DI claims in 1997.

CAPSULE GEOLOGY

The Iva Fern showing is located near the top of the ridge between Cultus and Laib creeks; the veins strike northerly up the slope from Cultus Creek, with the main discovery at about 1905 metres elevation on Lot 12656. The main #2 vein has been traced for over 600 metres along strike; the #1 vein lies 100 metres to the east and is subparallel in strike and has been traced for over 50 metres. Vein widths vary between 0.6 and 2 metres.
Hostrocks belong to the Upper Proterozoic Horsethief Creek Group intruded on the claims just to the west by a small stock of Middle Eocene Coryell biotite monzonite-syenite. Rocks underlying

CAPSULE GEOLOGY

the property have been recently mapped as belonging to the Irene volcanics (greenstone); however, descriptions in old reports mention only slates and shales. The Horsethief Creek Group is known to comprise phyllites, quartzites and grits; regional strike is 010 degrees, dipping 60 degrees west. A basic lamprophyre dike accompanying the vein in places is also described as "hornblende dyke rock", which might be part of the Coryell intrusions.

Two main fissure veins, containing quartz, siderite, calcite and tourmaline, occur in variably silicified phyllite and slate. Mineralization is in two forms: either coarse galena with pyrite, chalcopyrite and sphalerite, or streaks and bunches of galena and sphalerite. There is significant development of limonite due to oxidation at the surface; outcrops are few, with abundant overburden about 1-2 metres deep covering most of the property.

Grab samples of dump material assayed up to 3.5 per cent copper, 26 per cent lead, 9 per cent zinc, 144 grams per tonne silver and 1.4 grams per tonne gold (Minister of Mines Annual Report 1919).

Mapping for Agincourt Explorations Ltd. in 1985 discovered three additional mineralized zones over a total width of 200 metres, concordant with and near the top of the Irene volcanics; the possibility exists that syngenetic sulphides deposited within siliceous sinter zones have been remobilized during metamorphism and nearby intrusion, but this is speculative (Assessment Report 14053). A geochemical survey described in Assessment Report 14053 suggests further mineralization may be buried below overburden to the north, although magnetic and electromagnetic surveys of this area failed to show any significant anomalies/conductors.

Recent work by Yukon Revenue Mines Ltd. resampled old trenches where the best reported sample assayed 1.52 per cent copper, 24 grams per tonne silver and 2 grams per tonne gold across a width of 7.3 metres (George Cross News Letter No. 47, 1994).

REFERENCE: Assessment Report 10811.

CAPSULE GEOLOGY

The Valparaiso (spelled Vallparaso in the Crown grant listings) (Government) showings are located on Lots 4907 and 4908 respectively, just north of the steep headwaters of Ginol Creek that flows into Kootenay Lake about 1.5 kilometres south of Columbia Point. The property was originally discovered in the early 1900s and has recently been re-explored by Dobrana Resources Ltd. and drilled by Inco Ltd. in the late 1980s.

The principal deposit is a persistent, quartz-filled fissure in a lobe of the middle Cretaceous Bayonne batholith near its contact with sediments. Nowhere has the vein been traced into the sediments. In this locality the batholith consists of biotite granite and granodiorite, locally altered to chlorite and sericite along the vein walls. Mineralization consists of pyrite, arsenopyrite, wolframite, galena, sphalerite and chalcopyrite, in approximate order of abundance. The first three of these minerals occur together; wolframite and arsenopyrite tend to be restricted to the margins of the veins, and occur in the sheared and altered footwall, or ribbons near the vein margins. Gold and silver values are proportional to the amount of sulphides present, which occur as bands, blebs and

CAPSULE GEOLOGY

disseminations in the quartz. A biotite lamprophyre dike is found adjacent to the Valparaiso vein.

The vein occupies a fault that strikes 350 degrees and dips 40 degrees east, parallel to the Sarah 2nd or Imperial vein (082FSE055) to the east and 200 metres above the Valparaiso. Additional quartz veins have been reported to occur between these two veins. The vein has been exposed by 160 metres of drifting in the Government workings, 200 metres of drifting in the Valparaiso workings, and by pits, trenches and outcrop for about 650 metres to the north of the Valparaiso workings, for a total strike exposure of approximately 1000 metres. The vein varies between 0.3 and 7.6 metres, averaging about 1.25 metres wide.

Shipments from this property were made in 1900 and 1901 by Valparaiso Gold Mining Co. Ltd. A trial shipment of 293 tonnes in 1933 assayed 11.7 grams per tonne gold and 120 grams per tonne silver (Minister of Mines Annual Report 1933, pages 239-240). Tungsten concentrate was produced in 1955. Extensive sampling, assaying and compilation was done by Custom Mining Inc. in 1980-1981 (Assessment Report 10811).

CAPSULE GEOLOGY

surface from the adits are reported. The vein was exposed on surface for about 100 metres strike length, where it occupies a strong fracture in the granite hostrock and varies from 1 to 2.5 metres thick. The quartz is milky white and contains scattered galena, chalcopyrite and pyrite; some orange-yellow scheelite is present. Gold values are reported associated with the sulphides, which occur in irregular bands, patches and clustered in vugs, commonly along the margins of the vein. There is slight chloritization and sericitization of the wallrock, accompanied by disseminated pyrite. Assays by Dobrana Resources Ltd. on quartz vein material ranged up to 39.7 per cent lead, 366 grams per tonne silver and 3.4 grams per tonne gold (Assessment Report 17527).

CAPSULE GEOLOGY

The Empire State occurrence is located approximately 3 kilometres north of Kitchener, on the west side of the south flowing portion of the Goat River.

Regionally, the area is underlain by the peri-cratonic Middle Proterozoic Purcell Supergroup, a thick succession of siliciclastic and lesser carbonate rocks. The Purcell Supergroup is well known for hosting a number of significant deposits that include the Sullivan (082FNE052) sedimentary-exhalative lead-zinc deposit and the Troy copper-silver deposit in Montana.

More locally, the area of interest is underlain by Middle Proterozoic sedimentary rocks of the Aldridge Formation and by penecontemporaneous intrusive sills and dikes of the Moyie intrusions. The Aldridge Formation is the lowermost division of the Purcell Supergroup and is composed of turbiditic siliciclastic rocks, quartzofeldspathic wacke and siltstone, and numerous gabbro sills. The focus of exploration in the Aldridge Formation is the contact between the Lower Aldridge and the Middle Aldridge which corresponds

CAPSULE GEOLOGY

to the time of deposition of the Sullivan deposit. In this particular area of the Purcell basin, the contact between the Lower and Middle Aldridge is somewhat enigmatic in that there is no recognizable facies change.

This occurrence lies to the east of the Iron Range fault and to the west of the Carroll Creek/Kid fault. The strata within this structural block belongs to the eastward-dipping limb of the Goat River anticline. The strata strikes north-south with dips ranging from less than 15 degrees (near the core of the axis) to 25-30 degrees (near the Carroll Creek/Kid fault).

This mineralization is exposed in a number of opencuts which follow a steep-dipping fracture in a dioritic dike (possibly a sill) that is bounded within Middle Aldridge quartzites. The fracture appears to disappear to the southwest and is associated with the presence of pyrrhotite and chalcopyrite disseminated through unaltered diorite. In the main opencut, the fracture appears as a network of small quartz-calcite veinlets. The width of the mineralized zone is 1.2 to 1.5 metres. The change to totally unmineralized diorite is abrupt.

A sample of almost pure pyrrhotite analysed 0.52 per cent nickel (Geological Survey of Canada Memoir 228). No copper grade is reported.

CAPSULE GEOLOGY

The Creston Hill occurrence is located about 3 kilometres southwest of Kitchener.

Regionally, the area is underlain by the peri-cratonic Middle Proterozoic Purcell Supergroup, a thick succession of siliciclastic and lesser carbonate rocks. The Purcell Supergroup is well known for hosting a number of significant deposits that include the Sullivan (082FNE052) sedimentary-exhalative lead-zinc deposit and the Troy copper-silver deposit in Montana.

More locally, the area of interest is underlain by the Aldridge Formation. The Aldridge Formation is the lowermost division of the Purcell Supergroup. It is composed of turbiditic siliciclastic rocks, quartzofeldspathic wacke and siltstone and numerous gabbro sills and/or dikes of the Middle Proterozoic Moyie intrusions. The focus of exploration in the Aldridge Formation is the contact between the Lower Aldridge and the Middle Aldridge which corresponds to the time of deposition of the Sullivan deposit. In this particular area of the Purcell basin, the contact between the Lower and Middle Aldridge is somewhat enigmatic in that there is no recognizable facies change.

This occurrence includes a 122-metre adit and opencuts within about 100 vertical metres upslope from the adit. Upslope, 100 vertical metres, there is a shallow shaft that was sunk on a well mineralized quartz-calcite vein 1.2 to 1.5 metres wide (Geological Survey Of Canada Memoir 228). Near the top of a gabbro sill the vein is well mineralized with chalcopyrite and pyrrhotite. The mineralization continues at depth for a distance of approximately 15 metres, where the vein becomes sulphide poor.

CAPSULE GEOLOGY

The May-Bee property is located on the south end of the Iron Range Mountain fault at about 1000 metres elevation, about 4.5 kilometres west of Kitchener.

The main vein, varying from 0.3 to 1.5 metres in width, is hosted in a diorite sill belonging to the Middle Proterozoic Moyie intrusions. The sill and a lamprophyre dike that adjoins the vein are hosted in sedimentary rocks of the Middle Proterozoic Purcell Supergroup (Middle Aldridge Formation). In the area, these sediments are described as quartzitic wackes and argillaceous siltstones (Fieldwork 1994, pages 111-125).

The mineralization consists of chalcopyrite in the quartz vein which strikes 324 degrees and dips vertically. Assays range up to 1.81 per cent copper, 1 gram per tonne gold and 17 grams per tonne silver over 0.7 metre; the main vein was developed on two levels 55 metres apart vertically (Minister of Mines Annual Report 1957, page 61). It is reported that five other veins were also exposed by stripping on the property.

INVENTORY

ORE ZONE: SAMPLE REPORT ON: N

CATEGORY: Assay/analysis YEAR: 1956
SAMPLE TYPE: Chip
COMMODITY GRADE

Silver	263.0000	Grams per tonne
Lead	13.4000	Per cent
Zinc	14.9000	Per cent

COMMENTS: Average of three samples over a width of 0.5 metre and strike length of 20 metres.

REFERENCE: Minister of Mines Annual Report 1956, page 87.

CAPSULE GEOLOGY

The Hope or Hope of Discovery showing is located on a steep mountainside 0.5 kilometre east of Dark Canyon Creek, the first south-flowing tributary of Akokli Creek east of its mouth. The showing lies at about 1450 metres elevation, 4 kilometres east of Boswell on Kootenay Lake; the exact location is shown on a map in Assessment Report 17527.

Hostrocks consist of thinly bedded, white to blue-grey limestone of the Middle Proterozoic Dutch Creek Formation (Purcell Supergroup); in the vicinity of the showing, these rocks are tightly folded. A galena bearing quartz-calcite vein ranges in width from 2.5 to 70 centimetres over an exposed length of 60 metres. The vein strikes 348 degrees and dips 77 degrees east; at the north end the vein pinches to a fracture, where the white limestone merges with the less thinly bedded blue-grey limestone. Galena occurs as bands and pockets in the quartz and in minor concentrations in the bedding planes of the limestone adjacent to the vein; scattered

CAPSULE GEOLOGY

disseminations of galena occur in the blue-grey limestone beyond the end of the vein. Assays indicate that sphalerite is likely present. The description in Assessment Report 17713 of malachite and azurite (plus manganese staining) indicates copper may be present. This report also suggests the hostrock may be dolomite.

The best sample over 0.7 metre assayed 387 grams per tonne silver, 19.0 per cent lead and 18.7 per cent zinc; an average of three samples over a width of 0.5 metre and strike length of 20 metres was 263 grams per tonne silver, 13.4 per cent lead and 14.9 per cent zinc. All assays for gold are nil or trace. A shipment of 11 tonnes in 1957 yielded only 302.5 grams per tonne silver, 16.2 per cent lead, and 8.95 per cent zinc (Minister of Mines Annual Report 1957). Recent work by Forbes Resources Ltd. in 1990 confirmed recorded assays ranging from 0.14 to 0.47 gram per tonne gold (this would have been nil to trace in earlier assays), 77.5 to 1213 grams per tonne silver, 2.04 to 71.2 per cent lead and 1.83 to 18.1 per cent zinc.

CAPSULE GEOLOGY

The MB property is at the north end of Iron Range Mountain, 13 kilometres northwest of Kitchener. The claims are at the head of a small creek basin on the south side of Hall Creek, a tributary of Goat River, at an elevation of 1400-1500 metres. The occurrence is a strong quartz-calcite vein containing minor amounts of galena, chalcopyrite and pyrite. The vein has an average width of 1.4 metres and has been exposed at intervals over a distance of 300 metres across the nose of the ridge west to the creek basin; the strike is 315 degrees and the dip 85 degrees southwest. The southeast end of the vein is approximately 150 metres west of the Iron Range Mountain fault. The vein is hosted in grey quartzite of the Aldridge Formation, and in one instance cuts across a diorite sill of the Moyie intrusions. Both these units are of Middle Proterozoic age, and belong to the Purcell Supergroup. Two samples are reported; one across 0.9 metre width of mineralized vein assayed 0.25 per cent copper and 0.65 per cent lead (Minister of Mines Annual Report 1956, page 107).

CAPSULE GEOLOGY

The Otto vein strikes northeasterly and dips vertically. The narrow, discontinuous vein carries scattered bunches of argentiferous galena in a quartz gangue. Hostrocks belong to the Middle Aldridge Formation of the Middle Proterozoic Purcell Supergroup, intruded by gabbro sills of the Moyie intrusions (also of Middle Proterozoic age). The sedimentary rocks are described as quartzofeldspathic and quartz wacke with lesser argillite, mainly turbidites, by Brown and Stinson (Fieldwork 1994, page 115). Regional strike is 010 degrees with dips from 30 to 80 degrees west.

NORTHING: 5449146
EASTING: 511940

LOCATION ACCURACY: Within 1 KM

COMMENTS: Located at the head of Shaw Creek at an elevation of 1830 metres
(Minister of Mines Annual Report 1902).

COMMODITIES: Copper Gold

MINERALS

SIGNIFICANT: Chalcopyrite
ASSOCIATED: Quartz Calcite
COMMENTS: Calcite may be more abundant than quartz.
MINERALIZATION AGE: Unknown

DEPOSIT

CHARACTER: Vein
CLASSIFICATION: Hydrothermal Epigenetic
TYPE: I06 Cu±Ag quartz veins I01 Au-quartz veins
COMMENTS: Described as a wide zone, 30 to 100 metres wide and 1000 metres along strike.

HOST ROCK

DOMINANT HOSTROCK: Plutonic

STRATIGRAPHIC AGE	GROUP	FORMATION	IGNEOUS/METAMORPHIC/OTHER
Middle Jurassic			Nelson Intrusions

LITHOLOGY: Biotite Amphibole Granodiorite

HOSTROCK COMMENTS: Located in the Mine stock (Nelson intrusions) just outside of the Bayonne batholith.

GEOLOGICAL SETTING

TECTONIC BELT: Omineca PHYSIOGRAPHIC AREA: Selkirk Mountains
TERRANE: Ancestral North America
METAMORPHIC TYPE: Regional Contact RELATIONSHIP: Pre-mineralization GRADE: Amphibolite
COMMENTS: Staurolite-kyanite-sillimanite regional metamorphism is pre-mineral.

CAPSULE GEOLOGY

The Lost Mine (Copper Ridge, Copper Peak) showings were described in the Minister of Mines Annual Report for 1902 as situated at the head of Shaw Creek, at an elevation of 1830 metres. The vein matter is composed of quartz and calcite, with chalcopyrite, and can be traced for over 1 kilometre with widths of 30-100 metres (sic) and values at the surface averaging 8.6 grams per tonne gold (translated from \$5 values, at \$20 per ounce) and 4 per cent copper (Minister of Mines Annual Report 1902). A tunnel on the vein was driven for 75 metres in the mineralization.

Hostrocks are mapped as biotite amphibole calcic-granodiorite by Geological Survey of Canada Map 603A (1941), now considered to be part of the Nelson intrusions of Middle Jurassic age and metamorphosed to staurolite-kyanite-sillimanite amphibolite facies. The property is located a short distance to the west of the contact with the middle Cretaceous Bayonne batholith.

It is hard to see how such extensive, high-grade mineralization could escape the attention of later explorationists; it lies just off the western boundary of the Sherpa claim, staked in 1982 and stream silt sampled by Brinco Mining Ltd.; their survey showed nothing of interest (Assessment Report 11028).

INVENTORY

ORE ZONE: DUMP	REPORT ON: N
CATEGORY: Assay/analysis	YEAR: 1927
SAMPLE TYPE: Grab	
COMMODITY	GRADE
Silver	202.0000 Grams per tonne
Gold	3.4000 Grams per tonne
Lead	4.5000 Per cent
Zinc	8.1000 Per cent
COMMENTS: Dump material from a vein 0.5 to 0.8 metre wide.	
REFERENCE: Minister of Mines Annual Report 1927, page 325.	

CAPSULE GEOLOGY

The location of the North Wind showings is uncertain; they are located at approximately 1920 metres elevation on the east side of Arkansas Lake, at the head of Next (Canyon) Creek, some 24 kilometres east-southeast of Salmo; Next Creek flows northerly and easterly to the south end of Kootenay Lake. A published description in Minister of Mines Annual Report for 1927 indicates it is "about 3.2 kilometres easterly from the Spokane (082FSE032) and on the opposite side of the creek"; if on the other side of Next Creek (then called Canyon Creek) it would fall about 5 kilometres east of the Spokane. The description (the vein strikes northerly, dipping vertically, and is exposed at several widely-spaced points over a distance of 1 kilometre, at elevations ranging from 1875 to 1925 metres) fits the location on the east side of Next Creek better than on the west side. In 1927 the property consisted of 4 claims, the North Wind, Caribou, Arkansaw, and Canyon, owned by W.B. McCreath and L.E. Borden. Work to date was done in open cuts and shallow shafts. In

CAPSULE GEOLOGY

1928 the property was bonded by W.H. Tyrrell, of San Francisco. St. Bernard Mines, Limited was incorporated in British Columbia in March 1929 to acquire the property. No work was reported and the company charter was surrendered in 1932. From incomplete information it appears that the North Wind showings were held in 1938 as the Virginia claim, owned by J. Mulholland and under lease to D. Masciangelo & associates. Development work to that date included 61 metres of drift; a small amount of ore was shipped to Trail.

At the southern end of the area, the vein is from 0.5 to 0.8 metre wide and dump material assayed 4.5 per cent lead, 8.1 per cent zinc, 202 grams per tonne silver and 3.4 grams per tonne gold; 1000 metres to the north, the vein is 0.8 metre wide and assayed 2.8 per cent lead, 0.6 per cent zinc, 48 grams per tonne silver and 9.6 grams per tonne gold (Minister of Mines Annual Report 1927). The showings are described as well defined quartz-filled fissure veins in biotite granodiorite or granite of the Nelson intrusions (Middle Jurassic in age) containing disseminated galena, pyrite and sphalerite. The veins are surrounded by leached and oxidized quartz and altered country rock (alteration is not described). Overburden is deep and extensive on the relatively gentle, wooded slopes and further discoveries could be expected.

CAPSULE GEOLOGY

The King is a small past producer, part of a group of small galena-quartz veins on and around Goat (Arrow) Mountain just north of Creston. The King vein is unusual in being located at the foot of the mountain, on the west side just south of Alice Siding and very close to (partly covered by) the main Creston-Salmo highway, at an elevation of 575 metres. The original discovery produced from a winze (now covered by the highway); there was another irregular vein discovered 1.6 kilometres to the north.

The veins are hosted by Middle Proterozoic Purcell Supergroup sedimentary rocks of the Middle Aldridge Formation, and the Moyie intrusions, comprising respectively, quartzofeldspathic wacke, quartz wacke and argillite, and diorite sills. The main showings consist of local concentrations of galena and pyrite with minor chalcopyrite in a quartz vein traced over 120 metres strike length and 0.6 metre wide; the northern showing consists of lower grade galena mineralization in an irregular quartz vein in a diorite sill.

CAPSULE GEOLOGY

The Bob property covers several showings located approximately 400 metres east of the Duck Creek road, 800 metres north of its junction with the Creston-Kootenay Bay highway at Wynndel. The main showing is exposed in an adit at 730 metres elevation, but it is reported that this property was formerly known as the Elsie Holmes and that the old workings included another longer crosscut, the portal of which was approximately 250 metres southwest of the main adit. Hostrocks in the area are argillaceous quartzites mapped as Creston Formation, part of the Middle Proterozoic Purcell Supergroup, which are metamorphosed to regional greenschist grade (biotite facies).

The occurrence is a quartz-calcite vein with chalcopyrite and lesser amounts of galena and copper carbonates. Where exposed underground the vein strikes northeast, dips 45 degrees southeast, and has a width ranging from 0.3 to 1.2 metres. The vein was drifted on for 15 metres and raised on for 10 metres, with approximately 9 tonnes of ore being stockpiled.

CAPSULE GEOLOGY

The Aurea showing consists of a 15-60 centimetre galena-bearing quartz vein on the west side of a small ridge, 1.6 kilometres north of the international border and 2.5 kilometres northeast of Rykerts, at 633 metres elevation on the margin of the Purcell Trench south of Creston. It is one of a series of galena-quartz veins in Aldridge Formation rocks found along the east side of the Trench. Although not described in the primary reference (Minister of Mines Annual Report 1956), the geology is inferred to consist of Lower Aldridge Formation equivalent, Ramparts facies (quartzitic wackes and lesser green-grey argillites) as recently compiled in the adjacent area by Brown and Stinson (Fieldwork 1994, page 113). The sedimentary rocks are intruded by gabbro sills of the Moyie intrusions; both these units are of Middle Proterozoic age and belong to the Purcell Supergroup.

REFERENCE: Minister of Mines Annual Report 1956, page 85.	

CAPSULE GEOLOGY

The Copper Queen property was staked by the owner of the Motherlode (082FSE080) which probably adjoins the Copper Queen to the north. The main showing is a spectacular iron-stained quartz outcrop exposed by stripping and opencut work on the east bank of an unnamed southerly flowing tributary to Monk Creek, at an elevation of 1675 metres (slightly below the reported elevation of the Motherlode showings). The quartz has been exposed over a width of 15 metres, roughly at right angles to the northerly strike of the host greenstone schist (Irene Volcanics Formation of the Upper Proterozoic Horsethief Creek Group) and dipping 80 degrees south. Visible minerals are quartz, chalcopyrite, hematite, limonite, sericite, malachite, azurite and minor bornite. The best part of the showing is a 6-metre section at the south end, over which samples ranged up to 0.17 per cent copper (0.34 gram per tonne gold, trace silver) (Minister of Mines Annual Report 1956). Another showing is exposed in an opencut 200 metres to the south, which contains iron-stained quartz stringers but with negligible mineralization.

CAPSULE GEOLOGY

The Canada Belle claims are located on a north-trending ridge about 2 kilometres northwest of the west end of Boundary Lake, near the headwaters of the Priest River and on the west flank of North Star Mountain. Note that there are a series of Crown grants with a similar strike (north-south) on North Star Mountain, but there is no record of mineralization on them. Also, the Reverted Crown grant Big Chief (Lot 12666) is on strike two kilometres to the north of the Canada Belle showings. R.V. Longe, in Assessment Report 10484, points out that the Canada Belle, Peanut (082FSE081) and Cultus Creek (082FSE082) occurrences and likely the Iva Fern deposits (082FSE056) are found along a similar stratigraphic level, associated with silicification of limestone or dolostone units in Proterozoic rocks.

On the Canada Belle claims, a series of northerly striking quartz veins in dolomite are conformable with the nearly vertical bedding of the dolomite. The quartz veins are exposed in opencuts over a range in elevation of 1433 to 1525 metres; veins vary from 0 to 0.6 metre wide and are sparsely mineralized with barite, galena, sphalerite and pyrite. The best showing is at 1525 metres elevation, where a vein has been stripped for 15 metres along the strike.

CAPSULE GEOLOGY

The Sarah (Lot 4903) or Imperial (Lot 4904) lies 200 metres higher and adjoining to the east of the Valparaiso (082FSE038). The geology is as described for the Valparaiso: within a lobe of the middle Cretaceous Bayonne batholith, near the contact with sedimentary rocks. The batholith consists of biotite granite and granodiorite, cut near the vein by a dull green biotite lamprophyre dike. The main quartz vein, which has been traced for 120 metres in pits and cuts, contains a little sparsely disseminated pyrite and galena and occasional copper carbonate stains. The quartz is rusty and honeycombed in places; at one point, a little wolframite is associated with pyrite and galena.

A trial shipment of 9 tonnes in 1906 contained 20.5 grams per tonne gold and 754 grams per tonne silver. In 1989, recent sampling by Little Bear Resources Ltd. over 15 centimetres of vein material yielded up to 0.12 per cent copper, over 1 per cent lead, 0.46 per cent zinc, 41 grams per tonne silver and 0.5 gram per tonne gold (Assessment Report 17527).

Copper 0.8400 Per cent
COMMENTS: Samples from quartz veins in siltstone.
REFERENCE: Minister of Mines Annual Report 1926, page 284.

CAPSULE GEOLOGY

The Cultus Creek showing lies at the north end of a band of showings extending from the Humdinger & Hunkadora (082FSE082) and Peanut (082FSE081) locations. The mineralization is variously described as a vein in a mineralized band of altered and silicified limestone contained in a formation of highly metamorphosed sedimentary rocks, or (more recently) as disseminated sulphides in a silicified dolostone unit or units contained in andesitic tuffs.

These rocks, formerly assigned to the Dutch Creek Formation of the Purcell Supergroup of Middle Proterozoic age, have recently been remapped to lie within the Irene Volcanic Formation of the Horsethief Creek Group (Upper Proterozoic Windermere Supergroup). In detail (Assessment Report 10484) they consist of schistose greenstone (possible andesitic tuffs) overlain or intercalated with orange-weathering dolostone, siltstone and phyllitic shales. The granitic Nelson batholith lies to the west of the claims; metamorphic

CAPSULE GEOLOGY

grade is staurolite amphibolite just to the south of the property, but may be greenschist in the area of mineralization.

Lamprophyre dikes are found near but not necessarily associated with the mineralization, which consists mainly of oxidized material containing disseminated pyrite, chalcopyrite and tetrahedrite. At the north end of the mineralized zone (which may be stratigraphically close to that of the Iva Fern showings (082FSE037), 2 kilometres to the northwest), quartz veins in siltstone between two carbonate units assayed up to 0.84 per cent copper, 16 grams per tonne silver and 0.1 gram per tonne gold (Minister of Mines Annual Report 1926).

CAPSULE GEOLOGY

The Country Girl showings are located at close to high water mark on the east shore of Kootenay Lake, 0.5 kilometre south of Columbia Point. The showings are within granite of the Bayonne batholith of middle Cretaceous age. Just above high water there is an old tunnel driven easterly along a silicified fracture zone; sparsely disseminated pyrite, galena and sphalerite are associated with the quartz and penetrating the country rock in places. Just below the waterline there is reported to be a showing 1.2 metres wide of quartz containing disseminated galena; a sample from the dump near this showing assayed 79 grams per tonne silver, 1 gram per tonne gold, 11.2 per cent lead and 0.8 per cent zinc (Minister of Mines Annual Report 1926, page 286). A short distance southerly along the lakeshore, opencuts expose a quartz vein striking northerly, 45 to 60 centimetres wide, with irregular disseminated galena.

CAPSULE GEOLOGY

The Iolanthe showing is located on the east side of Kootenay Lake, "near the lakeshore", about 0.5 kilometre north of Sanca Creek.

The showings are hosted in metasedimentary rocks tentatively assigned to the Purcell Supergroup of Middle Proterozoic age, but the formation is uncertain. These rocks, which comprise quartzose mica schist, talc schist and quartzite, form a roof pendant in the middle Cretaceous Bayonne granite batholith. Stringers and veinlets of quartz with pyrite, sphalerite and galena lie parallel to the foliation, which strikes southeast and dips east. A grab sample of the hangingwall mineralization (from the dump) assayed 16.5 per cent zinc, 3.4 per cent lead, 190 grams per tonne silver and 1.4 grams per tonne gold (Minister of Mines Annual Report 1926). Copper is mentioned in one Minister of Mines Annual Report (1927) but no copper minerals are described.

CAPSULE GEOLOGY

The Ebor showing lies about 2.5 kilometres north of Boswell on the east shore of Kootenay Lake, just south of the mouth of Holiday Creek. Opencuts near the lakeshore expose a small, well defined quartz fissure vein cutting quartzose schists of the Upper Proterozoic Horsethief Creek Group, which strike northerly and dip to the west. The strike of the vein is easterly and it dips steeply to the north. Mineralization consists of stringers and small masses of galena and pyrite, with small amounts of sphalerite. Samples representing small amounts of the mineralization are reported to yield good assays in silver and lead.

CAPSULE GEOLOGY

The Alfred showings are located about 4 kilometres from Duck Creek Station (Wynndell) by an old logging road, east of the Canadian Pacific Railway, at about 1066 metres elevation. The showings are hosted within quartzose mica schist, limestone and quartzite regionally metamorphosed to biotite facies of greenschist grade but are believed to be derived from sediments of the Kitchener Formation (Middle Proterozoic Purcell Supergroup). The rocks strike northeasterly up the mountainside, with dips approximately vertical. The showings are located along the outcrop of a silicified band of limestone, 25 to 30 metres wide in places.

The old workings (trenches, opencuts, a glory hole, a shallow shaft and some short tunnels) are scattered along the outcrop over a vertical range of 915 to 1325 metres elevation. Mineralization consists of sparsely disseminated chalcopyrite, galena and pyrite associated with quartz; the sulphides occur in stringers, bunches and masses with specks of sphalerite and tetrahedrite. Selected ore from the dump at the glory hole assayed 1.5 per cent copper, 2 per cent

lead and 343 grams per tonne silver (Minister of Mines Annual Report 1924).

Recent exploration nearby on the Wilds Creek (082FSE005) property 2 kilometres to the northwest has suggested the possibility that mineralization in this area could be sedimentary exhalative in origin.

CAPSULE GEOLOGY

Five claims of the California group were staked in March 1949 to cover mineralization astride the Canadian Pacific Railway near Wynndel. A trial shipment of 8 tonnes was made to the Trail smelter in November of 1949 that assayed 122 grams per tonne silver, 5.5 per cent lead and 0.6 per cent zinc (Minister of Mines Annual Report 1949, page 194). No further description of the property is available, but by comparison to the Peggy vein one kilometre to the south along the railway, it is likely that the California showing consists of a quartz vein with galena and sphalerite in mica schist of the Middle Proterozoic Middle Aldridge Formation.

CAPSULE GEOLOGY

The Goat Mountain showing is described only as a quartz vein with values in copper, gold, silver and some lead; even the location is poorly known, as "near the Alice claim" (Lot 4104, on the adjacent 82F/2E sheet, 082FSE007). The geology is generalized from the description of Middle Aldridge Formation sedimentary rocks in Brown and Stinson (Fieldwork 1994, page 115) as quartzofeldspathic wacke to quartz wacke, with lesser argillite, mainly turbidites. The sedimentary rocks are intruded by gabbro sills of the Moyie intrusions; both sedimentary and intrusive rocks belong to the Purcell Supergroup of Middle Proterozoic age. Country rock at the mouth of one of the adits on the property is greenstone, likely a gabbro sill.

CAPSULE GEOLOGY

The Royal Crown showing is located at the junction of the Moyie River and Ridgeway Creek (Minister of Mines Annual Report 1929). Small galena lenses in a pegmatite stringer or vein occur in a Moyie diorite intrusion within Aldridge Formation quartzites and argillites (Middle Proterozoic Purcell Supergroup). At the quartzite-diorite contact a small patch of chalcopyrite-pyrite occurs.

CAPSULE GEOLOGY

The Yellow Metal is a series of old showings located on the divide between the heads of Perry Creek and Hellroaring Creek; it was extensively prospected in the 1915-1921 period. More recently, the showings were explored by Unique Resources as the Hawk property.

The area is underlain by thinly bedded quartzites of the Creston Formation belonging to the Purcell Supergroup of Middle Proterozoic age. These metasedimentary rocks (biotite facies of regional greenschist metamorphism) have a strike from 020 to 025 degrees and dip steeply west. On top of the ridge at an elevation of about 2100 metres, a zone of crushing is shot through with narrow stringers of quartz that yield colours of gold on crushing. This band of quartzites has a width of about 100 metres. A short distance down the Hellroaring Creek slope, a quartz vein 0.5 metre wide parallel to the strike of the quartzites is defined by 7.5 centimetres of gouge on the hangingwall. The vein assayed 6.5 grams per tonne gold and 7 grams per tonne silver, and the gouge assayed 11 grams per tonne gold and 10 grams per tonne silver (Minister of Mines Annual Report 1926,

CAPSULE GEOLOGY

page 127). On the Perry Creek slope, quartz veins up to 1.3 metres strike northwest across bedding, or parallel to bedding and contain minor limonite after pyrite with low gold values up to 1.7 grams per tonne (Minister of Mines Annual Report 1921, page 127).

There are also occurrences of minor disseminated pyrite and chalcopyrite in talcose seams and associated quartz stringers, in a zone crosscutting the regional strike. Assays of this material yield up to 1.7 grams per tonne gold over 1 metre; a one tonne sample of the best material assayed 14 grams per tonne gold and a trace of copper (Minister of Mines Annual Report 1915, page 109). A glassy quartz vein up to 12 metres wide, on the Perry Creek slope, yielded only trace gold values. Some 300 metres to the east, another quartz vein, striking 350 degrees and dipping 80 degrees west, occurs along the bedding of the quartzites which are sericitic on the bedding planes. Assays in this vein are up to 24 grams per tonne gold for picked samples, or 1.7 grams per tonne over 0.5 metre width (Minister of Mines Annual Report 1915, page 109).

CAPSULE GEOLOGY

The Princess property consists of the Victoria, Princess, Prince and Monarch Reverted Crown grants (Lots 14284 to 14287 respectively). Magnesite is exposed at the base and again on the north wall of an irregular cirque at the headwaters of Hellroaring Creek. Magnesite occurs in a bed 3 to 6 metres thick underlain by white quartzite of the Lower Cambrian upper Cranbrook Formation and is overlain by thin bedded, green siliceous argillites of the Lower Cambrian Eager Formation. The stratigraphy is folded into a tight north-trending (020 degrees) syncline with a northerly plunge. There is considerable shearing and fracturing along the trend parallel to the fold axis.

In the floor of the cirque, the bed of magnesite is exposed over a strike length of 131 metres and is exposed again in the north wall of the cirque for 213.4 metres horizontally and a vertical exposure of 122 metres to the top of the ridge. A small opencut exposed a badly sheared and fractured magnesite horizon containing abundant pods and veinlets of quartz. The magnesite varies from pearly grey to buff, is very coarse grained and has a brown weathered surface.

Sample A is a chip sample collected by McCammon (Minister of Mines Annual Report 1964, page 193) across a 10-metre face from the opencut. Sample B is a sample of unknown character reported by Cairnes (1932). All oxides in per cent.

CAPSULE GEOLOGY

The Peggy showing is located on the abandoned grade of the Great Northern Railway about 3.2 kilometres south of Wynndel in the Purcell Trench. Two opencuts in 1929 exposed a quartz vein striking 010 degrees and dipping 80 degrees west, hosted in mica schist that is mapped as part of the Middle Aldridge Formation (Purcell Supergroup of Middle Proterozoic age: Brown et al., Fieldwork 1994).

The vein varies in width from 0.3 to 1.2 metres and contains minor amounts of galena and sphalerite with associated silver and gold values. A sample of selected sulphides from the north opencut assayed 3.25 per cent lead, 0.4 per cent zinc, 10.3 grams per tonne silver and 0.7 gram per tonne gold (Minister of Mines Annual Report 1930).

METAMORPHIC TYPE: Regional RELATIONSHIP: GRADE: Greenschist

CAPSULE GEOLOGY

The Option claim group originally consisted of 25 claims located east of Kitchener just north of the highway to Cranbrook, on Hazel Creek. Pits expose four separate veins; on the north end of the claims there are two quartz veins, 1.2 to 2 metres wide, striking 330 degrees and dipping steeply to the northeast. These veins appear to be parallel. On the south end of the claims there are two shear zones, 1.2 to 2.2 metres wide, striking 350 degrees and dipping steeply to the east. The veins contain copper (assumed to be as chalcopyrite), gold (probably native) and tungsten (as scheelite). The country rock consists of granodiorite, quartzite (quartz and quartzofeldspathic wacke) and argillite belonging to the Aldridge Formation of the Middle Proterozoic Purcell Supergroup; it is not certain to what group the "granodiorite" belongs, but later reports describe diorite sills, likely of the Moyie intrusions of the Purcell Supergroup.

The same area was later staked as the Sky property (Assessment Reports 16501, 18153, 23093). Assessment Report 16501 states that sampling in the mid-1960s showed "fair to good values for tungsten along with lower values for gold, silver, copper and some rare earths such as yttrium". Assaying during the recent work yielded values of up to 8 grams per tonne gold and 4182 grams per tonne silver in a float specimen that "also contained the identical suite of minerals and trace elements as contained in the mineralized quartz veins". One particularly large diorite sill is reported to contain many of the quartz veins, which in part exhibit a finely banded cherty appearance. The sills are in some cases weakly mineralized with chalcopyrite and pyrrhotite. Furthermore, a prominent fracture which strongly suggests a fissure, occurs near the highway at Hazel Creek; a

CAPSULE GEOLOGY

sample of this material yielded values in zinc, lead and rare earths. This fissure appears to cut the sedimentary rocks at a shallow angle, trending 330 degrees and dipping nearly vertical; the age is speculated as probably Jurassic-Cretaceous. In 1995, Arbor Resources Inc. and Klondike Gold Mines drilled 1 hole (76.5 metres). In 1999, Black Bull Resources (BC) Ltd. surveyed the property.

COMMENTS: Grab sample; also assayed for copper (nil), gold (trace) and nickel (<0.1 per cent).

REFERENCE: Minister of Mines Annual Report 1957, page 62.

CAPSULE GEOLOGY

The Blue Rain property is east of and adjoins the Star or Leadville property (082FSE006). Traces of tetrahedrite in quartzite have been observed over a large area; a few short diamond-drill holes have been drilled at random locations in order to prospect the occurrence. It has been described as tetrahedrite "scattered" in quartzite by N. Carter (1993). A grab sample in 1957 assayed 10 grams per tonne silver, nil copper, less than 0.1 per cent nickel and only trace gold (Minister of Mines Annual Report 1957). Hostrocks are not described in detail, but consist of quartzite of the Aldridge Formation, part of the Middle Proterozoic Purcell Supergroup.

RELATIONSHIP: Syn-mineralization GRADE: Amphibolite

CAPSULE GEOLOGY

Coarse-grained kyanite has been reported from the Creston area (McCammon, 1965) in Helikian Purcell Supergroup micaceous quartzites and mica schists with minor pegmatite. At the Mike occurrence, kyanite forms clean, bladed crystals in clumps 15 to 20 centimetres in diameter associated with the pegmatites, which occur as irregular masses 30 centimetres by 1 metre to 2 by 10 metres in size. Kyanite is also disseminated throughout the schists and micaceous quartzites, where crystals vary from small needles to 1 by 5 centimetres in size (McCammon, 1964).

The Mike occurrence is close to the main Salmo-Creston highway, at low elevations, and near Creston. The best area of pegmatites and kyanite is found over an area 75 metres wide by 105 metres long. Further kyanite is reported on the south side of Summit Creek, across the valley from the Mike, by Brown et al. (Fieldwork 1994, page 138).

CAPSULE GEOLOGY

Pyrite, chalcopyrite and pyrrhotite are present as disseminations or fillings in fractures in a Purcell gabbro sill, part of the Moyie intrusions in Aldridge Formation sedimentary rocks which include quartzitic/quartzose wacke and argillaceous siltstone; both these units belong to the Middle Proterozoic Purcell Supergroup. As is typical of these occurrences in the sills, some small quartz-calcite veinlets are also present. A magnetometer survey of the claims in 1958 (Assessment Report 272) failed to find any anomalies.

CAPSULE GEOLOGY

The Ice showing is located in the headwaters of the Moyie River just east of the junction with South Moyie Creek. Disseminated ilmenite occurs in a metagabbro sill (N. Carter, personal communication, 1993), part of the Moyie intrusions into Aldridge Formation, both belonging to the Purcell Supergroup of Middle Proterozoic age.

GRADE: Greenschist

CAPSULE GEOLOGY

The Senasael showing is situated a little over a kilometre west of Kitchener, about 300 metres above the railway and on the north slope of the hill; the workings consisted (in 1940) of four opencuts distributed down the hill in a westerly direction. All the cuts are in a flat-lying gabbro sill of the Moyie intrusions, probably not over 30 metres thick although only the upper contact is well exposed. The sill is intruded into sedimentary rocks of the Lower Aldridge Formation (Ramparts facies of Brown and Stinson - Fieldwork 1994, page 113) that mainly comprise quartzitic wackes. Both the sedimentary rocks and the gabbro belong to the Purcell Supergroup of Middle Proterozoic age.

The showings consist of a quartz-calcite vein, dipping at a high angle and cutting across the sill. The vein is up to 2.4 metres wide at the upper contact of the gabbro, where it is well mineralized with chalcopyrite. The vein terminates abruptly against the overlying sediments and tapers with decreasing sulphide content in the other direction to become very narrow and almost barren in the centre of the sill. Near the bottom of the sill the vein widens but there is no increase in sulphide content.

CAPSULE GEOLOGY

The Blackmore occurrence is poorly documented and the best location is given as north of Kingsgate. An unknown reference plots the occurrence west of Kingsgate at the centre of the Ice #12 claim; the reference indicates drilling at this location.

Regionally, the area is underlain by the peri-cratonic Middle Proterozoic Purcell Supergroup, a thick succession of siliciclastic and lesser carbonate rocks. The Purcell Supergroup is well known for hosting a number of significant deposits that include the Sullivan (082FNE052) sedimentary-exhalative deposit and the Troy copper-silver deposit in Montana.

A shipment in 1948 of 5 tonnes produced 373 grams of silver and 9 kilograms of lead indicating grades of 82.2864 grams per tonne silver and 0.95 per cent lead (Minister of Mines Annual Report 1948).

CAPSULE GEOLOGY

The McPeak group originally comprised three claims situated on Corn Creek at a distance of 5 kilometres from Kootenay Flats, in an area largely covered by overburden. Although described as slates and schist in the Minister of Mines Annual Report for 1919, recent mapping shows the rocks of this area to be high-grade metamorphic (kyanite-sillimanite amphibolite facies) of regional extent, likely influenced by proximity to the Cretaceous Corn Creek Gneiss (Brown et al., Fieldwork 1994). These authors show the area concerned to lie within lit-par-lit gneiss developed from Aldridge Formation rocks (Middle Proterozoic Purcell Supergroup), at the edge of the granitic Corn Creek Gneiss.

The original showings consisted of a quartz vein striking southwest and dipping 25 degrees southeast; it was drifted on for 6 metres in greenish calcareous rock, probably dolomite, sparsely mineralized with chalcopyrite and pyrite. Another tunnel 12 metres west of the discovery outcrop struck a pocket of mineralization consisting of chalcopyrite, pyrite, sphalerite and galena, a sample of which assayed 3.5 per cent copper and 137 grams per tonne silver (Minister of Mines Annual Report 1919).

COMMENTS: Amphibolite grade (kyanite-staurolite-sillimanite) is in Wall stock.

CAPSULE GEOLOGY

The property is located at elevations of approximately 1768 to 1890 metres on the south side of Wall Mountain, near the head of the west fork of Wall Creek, some 35.4 kilometres west-northwest of Creston.

A claim adjacent to the Spokane group, and owned in 1915 by a Mr. Harris, was located on the westerly extension of the Spokane vein (082FSE032). This ground was apparently in part held as the Hilltop and Sitka (082FSW232) claims, owned in 1937 by John Bull. See Spokane for exploration details.

The Harris showing is originally reported on in the Minister of Mines Annual Report for 1915, where it is described as lying adjacent and to the west of the Spokane (082FSE032) vein, probably an extension of that vein. An opencut about 6 metres long exposes a 15-20 centimetre wide quartz vein containing galena and a little pyrite; no assays are reported. Exploration traced the vein toward the Spokane, where it remained narrow. The vein strikes 283 degrees.

The vein is hosted in biotite granodiorite of the Wall stock, presumed to belong to the Middle Jurassic Nelson intrusions; just to the south of and downslope from the vein, grit and quartzite of the Upper Proterozoic Three Sisters Formation (Horsethief Creek Group) occur. Metamorphic grade of this area is high (kyanite-staurolite-sillimanite amphibolite: Geological Survey of Canada Map 1714A).

In 1982 and 1984, the area to the west of the Spokane vein has been explored by Nugget Mines Ltd. (Assessment Reports 10841, 13393); a geophysical and geochemical survey suggested extensions of the vein both to the west and to the east of the Spokane.

COMMENTS: Samples of dump material.
 REFERENCE: Minister of Mines Annual Report 1937, page E40.

CAPSULE GEOLOGY

The Motherlode showings were staked in 1937 on a small south-flowing tributary, about 1.5 kilometres north of its junction with Monk Creek on the southwest slopes of Mount Irene at 1700 to 1850 metres elevation. The Copper Queen (082FSE053) of similar mineralization may adjoin on the south, at slightly lower elevation; see also the Irene (082FSE134) located in Char Creek to the north (Assessment Report 22054).

Mineralization occurs in sheared greenstone of the Irene Volcanic Formation, underlain to the east by pebble conglomerate of the Toby Formation. Both these units are part of the Horsethief Creek Group of Upper Proterozoic age, and are metamorphosed to chlorite facies of regional greenschist metamorphism. Mineralization is associated with a zone of fracturing and veining that trends northerly and dips steeply west, across a maximum width of 6 metres and strike length of 75 metres as exposed in numerous surface trenches and opencuts. In addition to rusty gossan, pyrite, chalcopyrite, pyrrhotite and a little galena are exposed in a gangue of quartz, ankeritic carbonate and sericitic material. Samples of dump material assay up to 2.4 per cent copper, 154 grams per tonne silver and trace gold; rusty gossan (in which gold is probably

CAPSULE GEOLOGY

The Peanut showing is located "south of Cultus Creek and about 3.5 kilometres west of Mount Burnett" (Minister of Mines Annual Report 1968). It is described as a shear zone cutting altered granite (alteration not described). The shear zone strikes 325 degrees and dips 75 degrees southerly; it contains a narrow lens of vein material (assumed to be quartz) which carries tetrahedrite. The vein, which is only 10 centimetres wide, has been traced for 12 metres on surface and to a depth of 8 metres in an inclined shaft. Although no granite is mapped in the area of the claims, there could be a small stock, possibly related to the Middle Jurassic Nelson intrusions, too small to show at the regional scale.

REFERENCE: Minister of Mines Annual Report 1927, page 326.

CAPSULE GEOLOGY

The Humdinger and Hunkadora showings are located in the low pass connecting Cultus and Next creeks, at an elevation of about 1450 metres. The recorded location is only one of several occurrences along a strike length of 1 kilometre in a mainly overburden-covered area. It is along the trend of mineralization referred to in the Cultus Creek (082FSE056) showing, and may be along strike of the Iva Fern (082FSE037) showings of similar character to the north. It is possible that the Peanut showing (082FSE081), which is reported to be hosted in granite, lies farther to the west than shown on the map. Mineralization is described as chalcopyrite disseminated through a siliceous and calcareous gangue, uniformly distributed over about 2 metres width; the lateral limits to the mineralization were not exposed. Other occurrences of similar mineralization are in float boulders along the strike between the Humdinger and Cultus Creek showings. A grab sample in 1927 from the dump assayed 4.58 per cent copper, 82 grams per tonne silver and 2 grams per tonne gold, the balance being 60.6 percent silica and minor lime and alumina (Minister of Mines Annual Report 1927, page 326). More

CAPSULE GEOLOGY

recent work by Minequest Exploration Associates Ltd. in 1981 confirmed minor copper and silver values up to 1.2 per cent and 29 grams per tonne respectively, with trace gold at 0.1 gram per tonne. This work extended the zone of interest with induced polarization and geochemical anomalies. Significantly, this work suggested that a stratabound horizon containing the mineralization might extend from the Iva Fern showing 5 kilometres to the north to as far south as the Canada Belle (082FSE054), a distance of roughly 30 kilometres.

Originally described as siliceous limestone, the hostrocks are characterized by Assessment Report 10484 as silicified dolostone, part of one or two carbonate units occurring with schistose andesitic tuffs, siltstone and overlying phyllitic slate in the Irene Volcanic unit of the Horsethief Creek Group, part of the Windermere Supergroup of Upper Proterozoic age. These units strike 340 degrees, parallel to the trend of the mineralization, with a steep westerly dip. The dolostone units are up to 600 metres thick, and locally contain as much as 10 per cent pyrite and chalcopyrite.

COMMENTS: Regional metamorphism is above almandine facies.

CAPSULE GEOLOGY

The Homestake (Skylark, Park, Victoria) showings are not accurately located, being described only as "on Boundary Creek". Thus, the plotted location could be in error by as much as 10 kilometres. There is no description in the single reference (Minister of Mines Annual Report 1900) of the geology to aid in positioning of the occurrence; hostrock is assumed to be phyllitic siltstones of the Aldridge Formation (Middle Proterozoic Purcell Supergroup), taken from Brown et al. (Fieldwork 1994). Showings at both the Homestake and Skylark consist of grey copper (tetrahedrite) and galena, assumed to be in a quartz vein gangue. On the Homestake, a tunnel was driven 25 metres on the vein, and on the Skylark a shaft traced it down for 15 metres.

CAPSULE GEOLOGY

The location of the Weaver Creek placer gold occurrence is poorly known; it is arbitrarily plotted on Weaver Creek just above the Highway 3/95 crossing. It had recorded production of 23,605 grams of gold over the period 1874 to 1930 (Bulletin 28, page 34). The gold is assumed to be contained within Tertiary glaciofluvial gravel and clay deposits. Bedrock geology consists of Middle Proterozoic Aldridge Formation argillite and quartzite intruded by diorite of the Moyie intrusions (also part of the Middle Proterozoic Purcell Supergroup).

LOCATION ACCURACY: Within 5 KM

COMMENTS: Location of this property appears to be highly uncertain; Minister of Mines Annual Report for 1915 describes it as "on the south branch of Hell Roaring creek (sic), about eight miles from where the main stream joins St. Mary river"; the Minister of Mines Annual Report for 1932 describes it as "situated on the East branch of Hellroaring creek, about 7 miles by trail from the road near St. Mary lake". The early MINFILE plots have it about 12 miles (19 kilometres) from the St. Mary River, in a location where the known strike of the vein and elevations described in the Minister of Mines Annual Report for 1932 are not possible.

COMMODITIES: Gold Silver Lead Zinc Copper

HOSTROCK COMMENTS: Granite is believed to be Cretaceous in age.

GEOLOGICAL SETTING

TECTONIC BELT: Omineca PHYSIOGRAPHIC AREA: Purcell Mountains
TERRANE: Ancestral North America
METAMORPHIC TYPE: Regional RELATIONSHIP: GRADE: Greenschist
COMMENTS: Mineralization is speculated to be related to Cretaceous granite.

CAPSULE GEOLOGY

The Wellington (Mascot, Eclipse) showings are not reliably located beyond the fact that they are near the headwaters of Hellroaring Creek, at an elevation of about 1800 metres. This may explain why they do not appear to have received recent attention during the exploration in the adjacent Perry Creek drainage; they could not be relocated.

A single vein of great strike extent is hosted by the Creston Formation of the Middle Proterozoic Purcell Supergroup, comprising argillaceous quartzites in this location, metamorphosed to greenschist facies. A porphyritic granite crops out about 60 metres below the vein, and is characterized as a stock. Recent mention of this stock (Assessment Report 16656) suggests it may be Cretaceous in age, and possibly related to the mineralization.

The vein is sharply defined, apparently following a strong fault-fissure zone conforming more or less with the schistosity of the enclosing quartzites rather than with their bedding; however, the two sources (Minister of Mines Annual Reports for 1915 and 1932) differ in the strike by 30 degrees, one suggesting the strike is due north and the other that it is 030 degrees, dipping 65 to 80 degrees east. The vein is mainly quartz with galena, pyrite, sphalerite and minor chalcopyrite; no alteration envelope is described. Values in gold

and silver are apparently confined to a pay streak which favours the hangingwall side of the vein. The vein may be traced over a length of 600 metres, with assays over widths up to 1.0 metre of up to 14.4 grams per tonne gold, 140 grams per tonne silver, 15 per cent lead, and 0.8 per cent copper (Minister of Mines Annual Report 1932, page 162).

CAPSULE GEOLOGY

The Hawk occurrence is poorly documented and the best location is given as 10 kilometres south-southeast of Creston, on Huscroft Creek at the International Boundary (Exploration in British Columbia 1978, page E47). At this location, the occurrence should lie near the eastern base of the Creston Ramparts which are west-facing cliffs that rise to peaks in excess of 2100 metres from the Creston valley floor.

Regionally, the area is underlain by the peri-cratonic Middle Proterozoic Purcell Supergroup, a thick succession of siliciclastic and lesser carbonate rocks. The Purcell Supergroup is well known for hosting a number of significant deposits that include the Sullivan sedimentary-exhalative lead-zinc deposit (082FNE052) and the Troy copper-silver deposit in Montana.

More locally, this occurrence lies west of the Iron Range fault within gabbroic rocks of the Moyie sills which are interlayered with the siliciclastic rocks of the Middle Proterozoic Aldridge Formation (Purcell Supergroup).

Chalcopyrite, malachite, silver and gold mineralization is reported to occur within gabbro of the Middle Proterozoic Moyie intrusions.

Previous work consists of re-timbering tunnels and constructing opencuts.

CAPSULE GEOLOGY

containing hornblende phenocrysts. The microdiorite bodies are generally pervasively chloritized and locally contain quartz stockwork; argillites on both footwall and hangingwall are siliceous, possibly due to the intrusive event. Disseminated pyrite occurs in both the quartz stockwork in the microdiorite and the adjacent phyllites.

Gold mineralization is associated with quartz veins, stockworks and siliceous zones in the vicinity of the microdiorite bodies that are emplaced along regional shear zones in the sedimentary rocks. These shear zones run parallel to Perry Creek (i.e. northeast) on the west side of the creek. The shear zones are filled by vein, irregular lenses and stringers of quartz containing boxworks of limonite (after pyrite) and occasionally gold, galena, sphalerite and chalcopryrite; silver is known from assays, which range up to 53 grams per tonne silver and 3.4 grams per tonne gold over 3 metres in trenches (Assessment Report 13007). Hydrothermal alteration of wallrocks occurs as chlorite, sericite and talc schists. The shear zones are topographically recessive, occurring between resistant ledges of siliceous sediments, possibly due to the ease with which breccia, gouge and hydrothermally altered materials in and marginal to the shears are eroded. Thus, much of the mineralization associated with these shears may be yet to be discovered.

Additional work (very low frequency electromagnetic survey) has been carried out on the Walsh claims which adjoin to the south, but no mineralization was discovered (Assessment Report 12983). Kokanee Exploration worked on the Price property adjacent or nearby to the north (possibly actually on the next sheet, 082FNE; description only locates it as 20 kilometres west of Cranbrook in the Perry Creek area, underlain by gently rolling terrain ranging in elevation between 1370 and 1525 metres and accessible by good year-round logging roads; only reference is George Cross News Letter No.183, 1990). The Kokanee property covers a large quartz vein which contains visible free gold with minor values in lead and silver, hosted by strongly sheared Middle Proterozoic sediments, and is adjacent to the large regional Perry Creek fault. Previous work partly exposed the vein for a distance of 35 metres, dipping steeply west and striking northeast with a true width at surface of 6 metres and containing up to 206 grams per tonne gold.

CAPSULE GEOLOGY

The location and character of the Creston fireclay deposit is poorly known; it is described as along railway, best by Goat Canyon. It is most likely a bed of clay in Quaternary or Recent glaciofluvial deposits.

The deposit is described as silty, grey-yellow, slightly calcareous clay; workability is described as 28 per cent water, gives fair plasticity. It is of average shrinkage, 3.1 per cent; tensile strength, 1.72 bars, fit for common brick by the soft mud process. Other characteristics, including cone, absorption and shrinkage, are described in Bulletin 30.

CAPSULE GEOLOGY

The Star (West) occurrence is located about 6 kilometres north of Kitchener on the east side of the Goat River.

Regionally, the area is underlain by the peri-cratonic Middle Proterozoic Purcell Supergroup, a thick succession of siliciclastic and lesser carbonate rocks. The Purcell Supergroup is well known for hosting a number of significant deposits that include the Sullivan (082FNE052) sedimentary-exhalative lead-zinc deposit and the Troy copper-silver deposit in Montana.

This deposit occurs within Middle Aldridge quartzites in a structural panel bounded by the Iron Range fault to the west and the Kid fault to the east. In the vicinity of the Star occurrences, the strata dips moderately (25-35 degrees) to the east with north-northwest strikes. This strata forms part of the eastward dipping limb of the Goat River anticline. Near this occurrence, there are two sills of the Middle Proterozoic Moyie intrusions that are remarkably continuous from the international boundary to just

CAPSULE GEOLOGY

north of Leadville Creek.

Mineralization occurs within a narrow quartz vein striking 071 degrees and dipping 72 degrees to the south. The vein is irregularly mineralized with galena and minor amounts of sphalerite and chalcopyrite. Mineralization is described as pods of galena ranging from 5 to 30 centimetres in width. This vein is hosted in limy quartzites and a 2.1 metre deep pit exposes a dioritic sill.

A sample taken over 9 centimetres from the opencut assayed 720 grams per tonne silver, 61.1 per cent lead and 0.04 per cent copper; a grab sample from the ore dump assayed 363.43 grams per tonne silver, 34.8 per cent lead, 7.2 per cent zinc and 0.05 per cent copper (Minister of Mines Annual Report 1957).

In 1956, a 0.9-tonne shipment of crude ore produced 717.9 kilograms of lead, 5.9 kilograms of zinc and 870 grams of silver (Minister of Mines Annual Report 1956). A small shipment also occurred in 1965. Production is included with Leadville, 082FSE006).

Recent drilling by Kokanee Resources and Barkhor Resources in 1990 intersected bedded pyrrhotite laminae overlying disseminated sphalerite and galena in quartzites that assayed 75 grams per tonne silver, 8.29 per cent lead and 0.71 per cent zinc over an interval of 6 metres. The main vein zone overlying the stratiform zone assayed up to 92 grams per tonne silver, 8.17 per cent lead and 0.1 per cent zinc over 3 metres (Northern Miner - August 20, 1990).

CAPSULE GEOLOGY

The Black Douglas lead-zinc showing is located on the south slope of Hughes Creek, in granite of the middle Cretaceous Bayonne batholith about 50 metres downslope from the same contact with schists as passes through the Wisconsin property (082FSE036) to the west. The country rocks adjacent to the granite are highly metamorphosed through both regional and contact metamorphism to amphibolite facies (staurolite-kyanite according to Map 1714A of the Geological Survey of Canada), but are mapped as belonging to the Monk Formation of the Upper Proterozoic Windermere Supergroup.

Mineralization consists of quartz veins with bunches of galena and sphalerite, narrow in the schist and more persistent within the granite. The main fracture trends 070 degrees in the granite and is covered with a gossan rich in manganiferous oxides (grade up to 11 per cent manganese) and enriched in gold (a channel sample assayed 22 grams per tonne gold, 237 grams per tonne silver and 1.88 per cent manganese across 1.6 metres) (Minister of Mines Annual Report 1946, page 149). In places, the quartz is mineralized with arsenopyrite, but it does not contain gold.

CAPSULE GEOLOGY

This particular beryl locality is just south of Midge Creek about 1.6 kilometres from Kootenay Lake (Rice, personal communication, in Geological Survey of Canada Economic Geology Series 23). Beryl was found in large blue-green crystals, with garnet, magnetite and black tourmaline in pegmatite dikes, which are reported by Rice (Geological Survey of Canada Memoir 228) to be abundant in that part of the middle Cretaceous Bayonne batholith comprising granite and granodiorite.

CAPSULE GEOLOGY

The Great War group of claims originally stretched for 5 kilometres on either side of the Canadian Pacific Railway line, near Kitchener. The principal showing, however, was apparently located near the head of Thompson Creek on the south side of Goat River, at an elevation of about 1370 metres (although one description gives the elevation as 1830 metres). It is clear that the occurrence is part of the Iron Range showings, possibly forming the southernmost extension of the showings. The regional geology, deposit description and local geology is similar to that of the American Flag occurrence (082FSE016) which occurs at the north end of the belt of showings, 15 kilometres to the north.

Massive to disseminated hematite, with local magnetite and pyrite, occurs within Middle Proterozoic Aldridge Formation Purcell Supergroup argillaceous quartzites along the north trending, subvertical Iron Range fault zone, adjacent to the contact of the sedimentary rocks with a Middle Proterozoic Moyie intrusions gabbro sill. In the best showing two samples were taken: one along 4 metres of soft hematite assayed 52 per cent iron (sulphur and phosphorus trace), and the adjoining 12 metres of harder hematite and magnetite disseminated in greenstone (?altered gabbro) assayed 42 per cent iron, 2.63 per cent sulphur, 0.04 per cent phosphorus and was judged to be of high silica content. The width of the mineralization is given at about 1.2 metres in this location (Minister of Mines Annual Report 1919, page 137).

CAPSULE GEOLOGY

It is not possible to be sure of the location of the Sarah showing; it is described as being "situated on the west side of Prospect Creek, which flows into the Goat River about 5 kilometres north of Duck Creek Station; the property is reached by a trail about 1.6 kilometres in length from the Canadian Pacific Railway tracks at an elevation of 1000 metres, or 400 metres above the tracks" (Minister of Mines Annual Report 1924). Neither Prospect Creek nor Duck Creek Station occur on the existing topographic maps near the location shown on the NTS map sheet 82F/SE. The plotted location of this showing (if correct, which does not seem likely) is in the same area as a lead-zinc geochemical anomaly on the Elk claims (Assessment Report 20060 on work done in 1989, which found the anomalous values to be associated with an area of altered sediments).

The Sarah showing is hosted in sedimentary rocks of the Aldridge Formation, part of the Purcell Supergroup of Middle Proterozoic age. In the property area, the hostrocks consist of quartzites, limestones, and siliceous and calcareous schists which have a

northeasterly trend up the steep mountainside, with dips varying from 80 degrees to the east to nearly vertical. A wide band (about 20 metres wide) of shattered limestone contains replacement lenses, stringers and disseminations of sphalerite, pyrite and galena. This band has been traced for about 100 metres southwesterly from the Sarah tunnel. Assays range up to 32 per cent zinc and 100 grams per tonne silver (Minister of Mines Annual Report 1924).

CAPSULE GEOLOGY

The Kitchener-Sullivan showing is located 4 kilometres from Kitchener on the south side of the Goat River, about 0.8 kilometre upslope and 180 metres in elevation above the railway, on a steep north-facing slope. The strike of the quartz-filled vein, which varies between 1 and 1.2 metres thick, is east-west parallel to the contour of the slope; dip is vertical.

The vein is hosted by hornblende diorite of the Moyie intrusions of Middle Proterozoic age (Purcell Supergroup). Here, it intrudes sedimentary rocks of the Aldridge Formation (also Purcell Supergroup) which in this area comprise quartzitic wackes and argillaceous siltstones (Brown and Stinson, Fieldwork 1994, page 114).

Mineralization consists of bunches of chalcopyrite and pyrite in the quartz, with assays up to 6 per cent copper and 35 grams per tonne silver over 0.95 metre (Minister of Mines Annual Report 1919, page 138). The vein was traced over a strike length of 33 metres as exposed in a short shaft and several opencuts.

CAPSULE GEOLOGY

The Running Wolf prospect is an old showing known only as a "gold-quartz vein" that underwent reconditioning and sampling of the old tunnels in 1928 (Minister of Mines Annual Report 1930, page 243). The prospect is located in the Middle Proterozoic Creston Formation, known regionally to consist of siltstone and thin bedded and laminated argillites. Creston Formation is part of the Purcell Supergroup that has been regionally metamorphosed to greenschist facies.

The vein likely contains pyrite and gold but no details of mineralogy, alteration, width, grade or orientation are known. It is assumed to be a mesothermal gold-quartz vein by comparison with other mineralization known nearby (e.g. David, 082FSE108) that is believed to be related to Cretaceous felsic intrusions. A description in Assessment Report 13609 states that the Running Wolf deposit consists of a number of quartz veins occupying fissures in greatly altered Creston argillaceous quartzite. The workings consist of five adits; the main adit exposes three veins, each about 10 metres wide. A hundred metres down the hill another adit has been driven along a vein that parallels the main veins above; the veins are composed of massive quartz with occasional specks of pyrite and are reported to carry gold. The veins have been fractured by post-mineral movement along the original faults that controlled them.

CAPSULE GEOLOGY

The location of the Gold Queen (Gold King) is so poorly known that it is difficult to plot it. It is described only as "At this prospect, between Gray Creek and Boswell, a crosscut tunnel is being driven below the highway to test the superficial showings of gold-copper ore described under Gold Queen in Bulletin No. 1, 1932" (Minister of Mines Annual Report 1933). A shipment of 2 tonnes of gold-silver ore is mentioned in the Minister of Mines Annual Report for 1931, but no grade or recovered metals are given. The showing is assumed to be a quartz vein with chalcopyrite. The coordinates given in the MINFILE data file would position the showing right on top of Copper Canyon (082FSE045), which has the same metals (copper, silver and gold).

CAPSULE GEOLOGY

The Moran property consists of three Reverted Crown grants (May Flower, Blue Bird and Last Chance, Lots 9356-9358 respectively) at elevations of 1920 to 2133 metres on the northeast ridge of John Bull Mountain near the head of Bluebird Creek, 30 kilometres west-northwest of Creston. The claims lie between the Bayonne (082FSE030) to the west and the Summit Bell (082FSE034) to the east.

The Bluebird claim was owned in 1910 by T. Moran and W. Gasnell. Development work had been done in a 7-metre crosscut adit which was expected to reach the vein in another 12 metres. The claims were Crown-granted to Moran and Gasnell in 1915.

The claims are underlain by granodiorite of the Mine stock, part of the Nelson intrusions of Middle Jurassic age. Gold-silver values apparently occur in a vein-type deposit (National Mineral Inventory 082F2 Au6). The surrounding area was explored more recently by Goldrich Resources (Assessment Report 16846).

CAPSULE GEOLOGY

The location and character of the Creston fireclay deposits are poorly known. It is most likely a bed of clay in Quaternary or Recent glaciofluvial deposits. The only comment in Bulletin 30, page 52 is "clays suitable for common brick by soft mud process" and "along railway, best by Goat Canyon". Some physical measurements of the clay quality are given in this reference.

CAPSULE GEOLOGY

The rocks concerned, formerly identified as Lardeau series metamorphic rocks, occur over a large area on the west side of Kootenay Lake, mainly concentrated around the margins of the middle Cretaceous Bayonne batholith. As such, it is not realistic to assign a "showing" location; it is more an area, best defined by reference to Map 603A (to accompany Geological Survey of Canada Memoir 228) or Geological Survey of Canada Map 1714A. Sillimanite occurs with andalusite and kyanite in what are now mapped as Middle to Upper Proterozoic rocks of the Dutch Creek Formation (Purcell Supergroup) to Horsethief Creek Group (the "showing" location is in the former).

CAPSULE GEOLOGY

The Osprey claim is located at 1950 metres elevation on a steep east-west ridge between the headwaters of Jack Creek and a tributary to Boulder Creek, 4.5 kilometres southeast of Kuskanook on Kootenay Lake.

Regionally, the area is underlain by sedimentary rocks of the Horsethief Creek Group, part of the Windermere Supergroup of Upper Proterozoic age. In this area, these rocks comprise phyllite, quartzite and grit, metamorphosed to biotite facies of greenschist grade regionally and partly contact metamorphosed due to proximity to the Bayonne batholith, a mid-Cretaceous granodiorite to granite. Mineralization is described as traces of galena, sphalerite and free gold in a quartz vein.

COMMENTS: Reserves are in cubic metres and the gold grade is 0.47 gram per cubic metre.

REFERENCE: Assessment Report 16706.

CAPSULE GEOLOGY

Placer gold occurs in Tertiary channels in Moyie River gravels. The Moyie River occurrence bedrock geology consists of Helikian Aldridge Formation (lower Purcell Group) oxidized and fractured argillite and massive quartzite in contact with upper Purcell Moyie diorite. Auriferous gravels occur in a Tertiary channel that mostly parallels the north and west bank of the Moyie River valley. The channel (outlined by seismic and drill data) is buried beneath 10.6 to 14.0 metres of till, gravel and varved clay and is 82.2 metres wide and 1.8 metres thick. Bedrock gradient varies from 1.51 to 3.88 per cent. Higher gold grades are observed at bedrock/Tertiary channel interfaces where favourable bedrock conditions exist, these

CAPSULE GEOLOGY

being friable, fractured and oxidized (limonitic, hematitic) argillite. Massive, competent diorite, quartzite or silicified argillite bedrock surfaces have a tendency to cause the Tertiary channel to narrow. A steep gradient to the channel and narrowness are negative factors for particulate gold entrapment.

During the summer (1988), 42,433 cubic metres were mined at an overall grade of 1.37 grams gold per cubic metre from which 106,542 grams gold were recovered (George Cross News Letter No. 97, 1989). The 1988-1989 winter stockpile is 34,405 cubic metres. Processing of 11,468 cubic metres from this stockpile contained 30,509 grams gold (George Cross News Letter No. 109, 1989).

There are inferred reserves of 1,556,642 cubic metres at 0.47 grams gold per cubic metre (Assessment Report 16706).

CAPSULE GEOLOGY

On the west flank of the Bayonne batholith, west of Kootenay Lake, a band of quartz-muscovite-kyanite schist forms the youngest unit of the Helikian Dutch Creek Formation belonging to the Purcell Supergroup of Middle Proterozoic age (Leclair, 1983). Kyanite porphyroblasts, up to 5 centimetres long, are common in this area (Leclair, 1982). In the various pelitic units, flanking the Bayonne batholith of post-metamorphic middle Cretaceous age, garnets up to 2 centimetres in diameter are also common (Leclair, 1982). The area is also shown as lying in kyanite amphibolite grade by Geological Survey of Canada Map 1714A.

CAPSULE GEOLOGY

The Sha occurrence is centred on diamond-drill hole S87-1, located approximately 15 kilometres southeast of Creston (Assessment Report 16769).

Regionally, the area is underlain by the peri-cratonic Middle Proterozoic Purcell Supergroup, a thick succession of siliciclastic and lesser carbonate rocks. The Purcell Supergroup is well known for hosting a number of significant deposits that include the Sullivan (082FNE052) sedimentary-exhalative lead-zinc deposit and the Troy copper-silver deposit in Montana.

More locally, the area of interest is underlain by the Aldridge Formation. The Aldridge Formation is the lowermost division of the Purcell Supergroup and is composed of turbiditic siliciclastic rocks and numerous gabbro sills. The focus of exploration in the Aldridge Formation is the contact between the Lower Aldridge and the Middle Aldridge which corresponds to the depositional time of the Sullivan deposit. In this particular area of the Purcell basin, the contact between the lower and middle Aldridge is somewhat enigmatic in that there is no recognizable facies change.

Structurally, the Sha occurrence lies to the east of the Iron Range fault and is encompassed within the east limb of the Goat River anticline. The regional strike of the Aldridge Formation near this occurrence is north, with gentle dips.

Mineralization consists of disseminated sphalerite and rare chalcopyrite occurring within quartz wacke turbidite sequences with argillaceous tops. Associated sulphides are pyrrhotite and pyrite. Mineralization occurs in two thin zones (less than three centimetres) in the diamond-drill hole (Assessment Report 16769). A weak anomaly from a UTEM (University of Toronto electromagnetic) survey was the initial focus of interest on the property (Assessment Report 15428).

CAPSULE GEOLOGY

The Yah occurrence is located near the community of Yahk, just to the east of the Moyie River (Assessment Report 19952). Regionally, the area is underlain by the peri-cratonic Middle Proterozoic Purcell Supergroup, a thick succession of siliciclastic and lesser carbonate rocks. The Purcell Supergroup is well known for hosting a number of significant deposits that include the Sullivan (082FNE052) sedimentary-exhalative lead-zinc deposit and the Troy copper-silver deposit in Montana. More locally, the area of interest is underlain by the Aldridge Formation. The Aldridge Formation is the lowermost division of the Purcell Supergroup and is composed of turbiditic siliciclastic rocks and numerous gabbro sills. The focus of exploration in the Aldridge Formation is the contact between the Lower Aldridge and the Middle Aldridge which corresponds to the time of deposition of the Sullivan deposit. In this particular area of the Purcell basin, the contact between the Lower and Middle Aldridge is somewhat enigmatic in that there is no recognizable facies change. Structurally, the Yah occurrence lies to the east of the Moyie fault and is encompassed within the broad north trending and plunging Moyie anticline. A fault that follows the Moyie River valley occurs

CAPSULE GEOLOGY

within 500 metres to the west of this occurrence.
A mineralized vein contains visible amounts of galena in an oxidized sulphide zone. The best reported grab sample of mineralized material contained 1.83 per cent copper and 72.9 grams per tonne silver (Assessment Report 19952). A diamond-drill hole approximately 500 metres to the west of this occurrence intersected very minor sphalerite and galena with associated pyrite and pyrrhotite (Assessment Report 20829).

CAPSULE GEOLOGY

The Eng 2 occurrence, diamond-drill hole E90-4 (Assessment Report 20828), is located about 2 kilometres south of the community of Yahk.

Regionally, the area is underlain by the peri-cratonic Middle Proterozoic Purcell Supergroup, a thick succession of siliciclastic and lesser carbonate rocks. The Purcell Supergroup is well known for hosting a number of significant deposits that include the Sullivan (083FNE052) sedimentary-exhalative lead-zinc deposit and the Troy copper-silver deposit in Montana.

More locally, the area of interest is underlain by the Aldridge Formation. The focus of exploration in the Aldridge Formation is the contact between the Lower Aldridge and the Middle Aldridge which corresponds to the deposition time of the Sullivan deposit. In this particular area of the Purcell basin, the contact between the Lower and Middle Aldridge is somewhat enigmatic in that there is no recognizable facies change.

Structurally, the Eng 2 occurrence lies to the east of the Moyie

CAPSULE GEOLOGY

fault and is encompassed within the broad north trending and plunging Moyie anticline. Numerous northeast and northwest faults cut this area.

Mineralization, consisting of native silver, native copper and gold, occurs within a 15 centimetre zone of fragmented quartzitic argillite and siliceous mud beds (Assessment Report 20828). The mineralization is described to be contained within bedded seams less than 0.5 millimetre thick within a purple-brown siliceous fragment. The 15 centimetre zone is described as subrounded fragments and mud; the fragments are heavily clouded with fine pyrite and pyrrhotite. A sample of a mineralized fragment yielded 34,183 grams per tonne silver, 10.3 per cent copper and 0.27 gram per tonne gold (Assessment Report 20828).

CAPSULE GEOLOGY

The David deposit is located about 30 kilometres southwest of Cranbrook. The showing was discovered in 1990 and work that year comprised prospecting, geologic mapping, soil geochemistry, trenching, geophysics and diamond drilling by Dragoon Resources Ltd. The area is underlain by sedimentary rocks of the Aldridge Formation of the Middle Proterozoic Purcell Supergroup (Belt). These strata are folded in the core of the Purcell anticlinorium. The Aldridge Formation consists of a thick section of basinal turbidites overlain by quartzites and siltstones of the Creston Formation and siltstones and carbonates of the Kitchener Formation.

CAPSULE GEOLOGY

The Aldridge Formation is intruded by gabbro to diorite sills also of Middle Proterozoic age. Cretaceous granodiorite and quartz monzonite intrusions cut these rocks. Faults occur in two main orientations: northeast striking, predominantly west dipping normal and reverse faults, and easterly striking transcurrent faults.

Locally, the area is underlain by fine grained clastic rocks of the Middle Aldridge and Lower Creston formations. Middle Aldridge lithologies are typically medium-bedded siltstones and quartzites to laminated silty argillites. Lower Creston lithologies exposed on the northwest side of the property are thin bedded and laminated argillites. Gabbro and diorite sills and dikes are present mainly in the Aldridge Formation. At least seven sills have been identified on the property; some of these appear to be related to mineralization. Structure is dominated by north-northeast oriented steeply west dipping normal and reverse faults and shear zones. The most prominent is the Baldy normal fault.

The discovery showing was an exposure of gold-mineralized quartz. Chip sampling across 40 centimetres assayed up to 144 grams per tonne gold (Property Development Report by Bapty Research Ltd., 1991).

Significant gold mineralization is restricted to shear zones, semiparallel to bedding in the hostrocks, or closely related quartz veins. Mineralization consists of pyrite, galena, chalcopyrite and sphalerite with some visible gold. Alteration consists mainly of silicification, with lesser chlorite and clay.

The David shear occurs within quartzites and siltstones of the Middle Aldridge Formation and has been traced along strike for 1600 metres and 150 metres downdip. The shear contains anomalous gold values over this entire length. The 0.20 to 1.5 metre wide shear strikes 010 degrees and dips 60 degrees west, cutting the bedding of the hostrocks at an oblique angle. The average gold content is 0.5 to 2.0 grams per tonne. Mineralized ancillary shears intersect the main shear.

Quartz veining is locally common throughout the quartzites and siltstones ranging from small irregular quartz veins, through thin quartz-feldspar stringers to wider (greater than 20 centimetres) quartz veins. Wide quartz veins that occur in the shear zone often carry significant gold values and about half the noted visible gold occurrences have been in such veins.

The mesothermal gold mineralization is structurally and lithologically controlled and is believed to have been deposited from oxidizing fluids associated with Cretaceous felsic intrusions.

Drilling outlined one continuous zone of gold mineralization over a strike length of 150 metres and to a depth of more than 100 metres; thickness averages 2.35 metres. Inferred resources for this zone are 96,000 tonnes grading 13.08 grams per tonne gold (uncut) or 7.11 grams per tonne gold (cut) (Property Development Report by Bapty Research Ltd., 1991).

CAPSULE GEOLOGY

The McNeil property is centred on the approximate middle of the claim group on which diamond drilling was carried out and reported on in Assessment Report 19989 (1990). The prospect lies about 20-25 kilometres southwest of Cranbrook, at about 1370-1675 metres elevation in McNeil Creek. This occurrence consists of minor stratabound and vein-controlled Zn-Pb-Cu mineralization (sphalerite, pyrrhotite, chalcopyrite and pyrite noted) in drillholes intended to determine the source of anomalous lead, zinc, and silver geochemistry and weak geophysical (UTEM and Maxmin) conductors.

The area is underlain by (meta-)sedimentary rocks of the Middle Proterozoic Purcell Supergroup, a thick succession of siliciclastic and lesser carbonate rocks that is known to host the Sullivan Sedex lead-zinc deposit (082FNE052). On the property, rocks of the Lower and Middle Aldridge formations are broadly folded into a north-northeast plunging syncline. Lower Aldridge rocks crop out east of McNeil Creek fault and north of the major northeast-trending Moyie fault; this is a similar location to the Fors (082GSW035) and Vine (082GSW050) prospects located 10 kilometres to the northeast. The Lower-Middle Aldridge contact, or LMC, which corresponds to Sullivan time, is found at depths from 0 to 2000 metres across the property. Several thick regional gabbroic intrusions (Moyie sills) occur on the property, of which the uppermost, the Hiawatha sill, was intersected in drillholes.

Vein and stratiform massive lead-zinc-silver mineralization have been the main targets of exploration on the McNeil property, but

CAPSULE GEOLOGY

surface trenching and drilling has disclosed vein-controlled copper mineralization partly associated with the gabbros, as is common elsewhere in the region. Anomalous gold also occurs on the property in quartz veins, gabbro and fault zones, and may be related to the McNeil Creek fault (which extends into the Palmer Bar fault, known to carry gold mineralization).

Geochemical anomalies at surface are weak (less than 800 parts per million lead, 450 parts per million zinc and 5.3 parts per million silver). Twenty-one drillholes for a total of 5621 metres were drilled and intersected anomalous (250 parts per million) zinc and lead (100 parts per million) over true widths of 7-16 metres at the LMC. Anomalous gold up to 30 parts per billion occurs in Aldridge rocks, and anomalous gold to 19 parts per billion plus platinum-group metals platinum, palladium and rhodium, occurs in drill intersections of gabbro.

Alteration is very weak and consists of minor chlorite on fractures associated with mineralized intervals, chalcedonic silica and sericite associated with stratabound mineralization, and biotite-chlorite associated with anomalous gold. Lamprophyre dikes, believed to be Cretaceous or Tertiary, may be associated with the anomalous gold. Tourmalinite (identified in thin section as recrystallized coarse-grained material compared to Sullivan tourmalinite) is known in float.

Sedex Mining Corp. drilled the property in 1998. See McNeil (082GSW024).

COMMENTS: Over 2.55 metres.
REFERENCE: Exploration 1997, page 44.

CAPSULE GEOLOGY

The LEW group has been explored by Cominco over the period 1980-1985 for sedimentary stratabound exhalative mineralization of the Sullivan type, mainly by UTEM (University of Toronto electromagnetic) survey searching for buried conductors supplemented by surface geochemistry. Although not reported in the assessment reports, detailed stratigraphy and geology are likely to have been completed. UTEM conductors were investigated by diamond drilling, which intersected minor stratabound, disseminated and veinlet lead-zinc mineralization, and established that the hostrocks are Middle

CAPSULE GEOLOGY

Aldridge Formation (Purcell Supergroup) wackes and quartzitic wackes intruded by Middle Proterozoic Moyie gabbro sills.

In 1997, Kennecott Canada Exploration Inc. (in joint venture with Hastings Management Group of companies, mainly Sedex Mining Corp. and Abitibi Mining Corp.) drilled four core holes totalling over 2500 metres and intersected 2.55 metres of massive to semimassive, coarse-grained sulphides grading 9.65 per cent zinc, 5.82 per cent lead and 49.4 grams per tonne silver at a depth of 505 metres in the third hole (Exploration 1997, page 44). The hole is located in Panda Basin at the head of Lewis Creek, a north-flowing tributary of the upper Moyie River. The basin is located on the edge of what appears to be a hydrothermal vent indicated by the presence of extensive stratabound and discordant fragmental units and widespread albite-tourmaline-chlorite-sericite alteration of the Middle Aldridge siliciclastic rocks. The sulphide interval consists of sulphide bands which are both parallel to and discordant to bedding.

Mineralization occurs in the Active and Lewis ridge areas 3 to 6 kilometres to the north northwest.

CAPSULE GEOLOGY

The Brook property is located on the ridge between Ridgeway and McNeil creeks, south of upper Moyie River; it adjoins the McNeil property (82FSE109) to the east and the LEW property (82FSE110) to the south. The focal point of interest is a shear zone which yielded values up to 5 grams per tonne gold over 3 metres in surface trenching. Gold mineralization is known in the nearby Perry Creek area (David, 82FSE108 and Mark, 82FSE087). Geochemical silt and soil sampling failed to extend the mineralization. Hostrocks are described very generally as quartzites, siltstones and argillites of the Middle Proterozoic Middle Aldridge Formation; there is no description of mineralization or alteration.

CAPSULE GEOLOGY

The Bear claims are located near the headwaters of Leadville Creek; access is by Forest Service road branching off at kilometre 8.5 of the Leadville/Goat River road. Mineralization discovered as a result of prospecting and soil sampling on the Bear property consists of minor malachite and bornite associated with semimassive magnetite within a gabbro of the Proterozoic Moyie intrusions near its inferred contact with Middle Aldridge Formation (Purcell Supergroup) sedimentary rocks, which include quartzite, siltstone and argillaceous wacke. The mineralization occurs within diopside, fine-grained gabbro, suggesting a skarn-type occurrence.

PHYSIOGRAPHIC AREA: Purcell Mountains

TERRANE: Ancestral North America

METAMORPHIC TYPE: Regional

RELATIONSHIP: Pre-mineralization

GRADE: Greenschist

COMMENTS: Assume metamorphism is pre-gold vein mineralization.

CAPSULE GEOLOGY

The Lamb and Fall claim blocks (staked by two separate parties) were intended to cover the possibility of lode gold source for placer gold known to occur in the headwaters of Lamb Creek. Heavy mineral concentrates from stream sediments downstream of the Moyie fault assayed up to 286 parts per billion gold and were anomalous in copper and arsenic as well.

Minor copper mineralization was located on fractures in the Kitchener Formation in the immediate footwall of the Moyie fault. The Kitchener Formation, part of the Middle Proterozoic Purcell Supergroup, here consists of siltstone, dolomitic siltstone, argillite and turbidite quartzite. Extensive silicification is observed near the fault where exposure permits. Several large barren quartz veins are present.

Ground magnetic surveys were used to locate structures. One short diamond-drill hole (24.7 metres) was drilled to test below the sheared silicified copper mineralized zone but failed to intersect any mineralization.

GEOLOGICAL SETTING

TECTONIC BELT: Omineca

PHYSIOGRAPHIC AREA: Purcell Mountains

TERRANE: Ancestral North America

METAMORPHIC TYPE: Regional

RELATIONSHIP: Pre-mineralization

GRADE: Greenschist

COMMENTS: Metamorphism assumed to be late and therefore pre-mineralization.

CAPSULE GEOLOGY

The Cooper property is located between the headwaters of Kamma Creek, which drains into the Goat River, and the South Moyie Creek, which drains into the Moyie River. The claim area is south of and along strike from a regional fault underlying Perry Creek, where lode gold mineralization has been found; exploratory and active placer gold operations are present along the Goat and Moyie rivers respectively. Gold has been found in individual quartz veins (2-20 metres wide), mineralized shear zones associated with Middle Proterozoic Moyie intrusions, and altered zones surrounding syenite intrusive bodies located along major faults.

The property is underlain by rocks of the Creston and Aldridge formations, comprising respectively shallow water sedimentary and deeper water turbidite facies; siltstone, argillite and fine-grained quartzite are represented. These strata have an average strike of 215 degrees and dip 40-85 degrees west; there are a number of medium to small sized shear or fault zones throughout the property that strike northeast and dip vertically.

Pyrite is associated with small quartz veins up to 0.5 metre thick within the Aldridge Formation, occurring as single cubes and

CAPSULE GEOLOGY

fine disseminations throughout the veins; specular hematite is also associated with small quartz veins.

Pyrrhotite occurs as fine blebs in Aldridge argillaceous quartzite float, and there is also abundant float of milky white quartz ranging up to large 5 metre angular boulders of quartz vein float that suggest a local source.

Anomalous gold up to 670 parts per billion was found in bulk stream sediment samples draining east off the property but follow-up soils were not able to pinpoint the source of the gold; anomalous gold was found to 180 parts per billion in a five metre quartz vein which contains hematite and chlorite. This sample also contains anomalous copper (100 parts per million) and arsenic (177 parts per million) (Assessment Report 19436).

COMMENTS: Metamorphism assumed to be post-metamorphism if it is exhalative.

CAPSULE GEOLOGY

The Laurie appears to be a new showing found by prospecting in an area where some old showings are known (the Royal Crown lead showing (082FSE064) is 2 kilometres to the east and the Cariboo lead-zinc-tungsten-uranium-silver showing (082FSE003) is 6 kilometres to the west). The most important mineralization discovered is 300 to 700 metres up North Moyie Creek from the crossing of the road following the upper Moyie River; it consists of what is described as stratiform to stratabound beds to irregular lenses or fracture coatings of sphalerite, galena, chalcopyrite and minor pyrrhotite. Other showings found elsewhere on the claims are mostly described as vein occurrences of quartz containing pyrite, chalcopyrite, rare bornite, and stained with limonite, malachite, and manganese oxides (pyrolusite?) at the surface. Old trenches, believed to occur on a Reverted Crown grant (name not given) a short distance northeast of the confluence of the Moyie River and the North Moyie Creek, expose a vein along a northeast-oriented Middle Proterozoic Moyie intrusion

CAPSULE GEOLOGY

containing scheelite, galena, sphalerite and chalcopyrite. Silver is only known geochemically.

Host rocks are gently to moderately north dipping Middle Proterozoic Middle Aldridge Formation (Purcell Supergroup) sediments including siltstone, impure quartzite and argillite; known marker beds are presumed to place the showings stratigraphically. VLF-EM surveying located conductors attributed to structures.

The LEW group has been explored by Cominco over the period 1980-1985 for sedimentary stratabound exhalative mineralization of the Sullivan type, mainly by UTEM (University of Toronto electromagnetic) survey searching for buried conductors supplemented by surface geochemistry. Although not reported in the assessment reports, detailed stratigraphy and geology are likely to have been completed. UTEM conductors were investigated by diamond drilling, which intersected minor stratabound, disseminated and veinlet lead-zinc mineralization, and established that the hostrocks are Middle Aldridge Formation (Purcell Supergroup) wackes and quartzitic wackes intruded by Middle Proterozoic Moyie gabbro sills.

In 1997, Sedex Mining Corp. (previously Otis J. Exploration Corp.) drilled approximately 1300 metres in 3 holes on the property. It is centred on the Lew "Vent", a tourmalinized fragmental zone. Sedex had earlier found stratiform mineralization grading over 10 per cent combined lead and zinc.

INVENTORY

ORE ZONE: SAMPLE REPORT ON: N
CATEGORY: Assay/analysis YEAR: 1991
SAMPLE TYPE: Grab
COMMODITY: Gold GRADE
Gold 31.8000 Grams per tonne
COMMENTS: The Hill vein is between 0.5 and 1 metre thick; grab samples of vein material only.
REFERENCE: Assessment Report 20013.

CAPSULE GEOLOGY

The Weaver property covers several significant showings of gold-quartz veins and shears located in the Weaver Creek drainage in the upper reaches of the Moyie River, a known placer gold area (82FSE102) where placer mining was carried on recently by Queenstake Resources. Other known gold mineralization in the area includes David (82FSE108, 6 kilometres southwest) and Perry Creek

CAPSULE GEOLOGY

drainage, 10 kilometres to the northwest.

The claims are underlain by sedimentary rocks of the Aldridge and Creston formations of the Middle Proterozoic Purcell Supergroup. Lithologies include turbidite siltstone, quartzite, argillite and Moyie gabbro intrusions; there are rare felsic dikes of possible Cretaceous-early Tertiary age, likely associated with mineralization.

Gold-quartz veins of possible mesothermal to epithermal character occur in at least three locations on the property, and are called the Hill vein, the MC2 shear, and the Galena vein. The Hill vein is a north striking, shallow west-dipping quartz vein exposed by trenching along a strike length of more than 500 metres. Grab samples of the vein material, which contains visible gold, pyrite and limonite, yielded assays up to 31.8 grams per tonne gold (Assessment Report 20013). The vein is between 0.5 and 1 metre thick. Felsic dikes associated with the vein contain disseminated pyrite, specular hematite and chloritic fractures, as well as thin lens quartz veinlets; Middle Aldridge sediments adjacent to the dikes are altered and stained by manganese and limonite. A possible extension to the vein is 0.5 metre thick and bedding-parallel; altered quartzites on both sides of the vein are brecciated with quartz veining, limonite and minor pyrite, and assay up to 340 parts per billion gold.

The MC2 shear is a northeast-trending structure in the upper Weaver Creek area that contains gold values up to 2800 parts per billion; galena is rarely observed in quartz veinlets in this structure.

At the Galena vein, gold values up to 4800 parts per billion over 40 centimetres were found in the sheared margins of a diorite dike that probably is part of the Moyie intrusions of Middle Proterozoic age. Gold and minor galena occurs in quartz veins up to 1.2 metres thick and silicified Middle Aldridge siltstones and argillites at the margins of the diorite dike.

GRADE: Greenschist

CAPSULE GEOLOGY

The Buck property is centred on some old trenching on a landing on the slope between Noke and Negro creeks. There is also an old adit in Noke Creek. Placer gold is known in this part of the upper Moyie river drainage (e.g. Moyie River, 082FSE102), and there are several other lode gold showings in the vicinity (e.g. Prospector's Dream, 082FSE029; Weaver, 082FSE116; and showings in Perry Creek, 10 kilometres to the northwest).

The property is underlain by rocks of the Purcell Supergroup of Middle Proterozoic age, mainly Aldridge Formation; some veins are found at the boundary with Creston Formation (Purcell Supergroup). These formations consist of siltstone, argillite and quartzite, regionally metamorphosed to greenschist facies. Mineralization is found in milky quartz veins along northeast-trending faults and shears parallel to the old Baldy fault. Float boulders of Middle Proterozoic Moyie intrusions gabbro are found in proximity to the Palmer Bar fault on the southeast and northeast portions of the property.

Mineralization consists of pyrite-bearing and limonite-stained quartz, or quartz containing hematite; minor visible gold is present in the ELCR vein on the property, but more is expected due to the placer gold taken from Noke Creek. A magnetite-hematite breccia with

CAPSULE GEOLOGY

a width of 4 to 5 metres and strike length of 20 metres, associated with shearing and numerous narrow quartz veins, was discovered on the eastern part of the property in Palmer Bar Creek; wallrock here is silicified and partly chloritized.

An airborne, helicopter-mounted magnetic, electromagnetic and VLF (very low frequency) electromagnetic survey was flown over this and the adjoining Racki and LDM properties (082FSE118), to define the regional and local structures along which gold mineralization is found in this camp. The survey (Assessment Report 21098) indicates several such structures.

Rock geochemical sampling (Assessment Report 21863) did not reveal any significant anomalous values for gold or base metals.

INVENTORY

ORE ZONE: SAMPLE REPORT ON: N
CATEGORY: Assay/analysis YEAR: 1992
SAMPLE TYPE: Grab
COMMODITY: Gold GRADE: 16.4000 Grams per tonne
REFERENCE: Assessment Report 21863.

CAPSULE GEOLOGY

The Racki property is centred on Wuhun Creek that drains into Perry Creek, a known lode gold area on strike from the David (082FSE108) occurrence; it is an outgrowth of exploration by Dragoon Resources on that property. The main showings occur in trenches on

CAPSULE GEOLOGY

the north slope of the east fork of Wuhun Creek at about 1950 metres elevation.

The claims are underlain by sedimentary rocks of the Aldridge Formation belonging to the Middle Proterozoic Purcell Supergroup; siltstone is most common, but argillite and quartzite are also present. The Aldridge Formation is intruded by gabbro to diorite sills and dikes, also of Middle Proterozoic age. Cretaceous quartz monzonite and granodiorite are reported just off the property both to east and west. A complex system of northeast to north-northeast trending normal and reverse faults occur parallel to the strike of the sedimentary rocks. A series of easterly striking transverse faults cut across the regional trend at an oblique angle. The most significant mineralization discovered is contained within a silicified shear zone within the old Baldy fault structure, traceable for 2 kilometres along strike.

The showings consist of narrow quartz veins, stained with limonite, hematite, pyromorphite? and minor malachite at surface; pyrite with rare gold and galena are reported in the quartz. Rare chalcopyrite is found in gabbro. Geochemical sampling yield gold values up to 175 parts per billion over widths less than 10 centimetres, although grab samples assay up to 16.4 grams per tonne gold (Assessment Report 21863). Molybdenum is only known from anomalous geochemistry (up to 175 parts per million); zinc and silver likewise are only known from geochemical sampling (900 and 53 parts per million respectively).

Alteration is confined to silicification and minor chloritic zones associated with hematite. Ground geophysics (detailed total field magnetics and VLF-EM surveys) delineated a strong magnetic anomaly on the west edge of the property coincident with a gabbro exposure; weak VLF-EM responses suggest the presence of easterly oriented structural breaks. This work was in follow-up to a regional airborne magnetic and VLF-EM survey (Assessment Report 21098).

CAPSULE GEOLOGY

The Shakespeare is an old showing located on the edge of and just off (west) Reverted Crown grant Lot 10228, immediately south of Liverpool Creek in the Perry Creek drainage. It is one of a series of subparallel veins, "ledges", or shears that have received recent exploration by Gallant Gold Mines Ltd. as part of the Perry Creek lode gold property that includes the old showings Homestake (082FSE012), Columbia (082FSE009), McIntosh (082FSE120) and British American Corp., or Petra (082FSE121).

The showings are hosted in quartzite of the Creston Formation; old reports mention the presence of a "miner's porphyry", likely a reference to microdiorite dikes found in float in this area and ascribed to a local source by recent work. Both these rock types belong to the Middle Proterozoic Purcell Supergroup, assuming that the microdiorites are part of the Moyie intrusions. Showings consist of several major "ledges" or zones of silicified rock composed of angular fragments of grey quartzite cemented by milky and lesser clear quartz, with minor disseminated pyrite and stains of limonite and hematite. Alteration is principally silicification; minor sericite is mentioned adjacent to the silicified and in places stockworked zones. Gold values up to 34 grams per tonne were reported in 1898, but subsequent sampling has been less (all 1986 samples were 0.07 gram per tonne gold or less) (Assessment Report

CAPSULE GEOLOGY

The McIntosh is an old showing located at the boundary between Reverted Crown grants Eclipse (Lot 10223) and Anna (Lot 10224), immediately north of Shorty Creek, a tributary in the Perry Creek drainage. It is one of a series of subparallel veins, "ledges", or shears that have received recent exploration by Gallant Gold Mines Ltd. as part of the Perry Creek lode gold property that includes the old showings Homestake (082FSE012), Columbia (082FSE009), Shakespeare (082FSE119) and British American Corp. or Petra (082FSE121). The showings are also known as the Annie, on which an opencut exposed a quartz vein 8 metres wide stained by limonite assaying only trace gold.

The showings are hosted in quartzite of the Creston Formation; there are also microdiorite dikes found in float in this area and ascribed to a local source by recent work. Both these rock types belong to the Middle Proterozoic Purcell Supergroup, assuming that the microdiorites are part of the Moyie intrusions. Showings consist of several major "ledges" or zones of silicified rock composed of stockworks of quartz veinlets with minor disseminated pyrite cubes and hematite. Alteration is principally silicification adjacent to stockworked zones. All 1986 samples assayed 0.07 gram per tonne gold or less.

A VLF-EM (very low frequency-electromagnetic) survey carried out over the adjoining ground to the west by Trans-Arctic Exploration revealed northeast and northwest-striking conductors that likely

COMMENTS: Age of Perry Creek mineralization widely believed post-metamorphism.

CAPSULE GEOLOGY

The Gold Run property as defined here covers the large CD claim group staked recently by Partners Oil and Minerals Ltd. near Richmond Lake at the head of Perry Creek. The main area of interest in the recent work covers the southern strike extension of gold-quartz vein mineralization discovered at the turn of the century on the Yellow Metal property (082FSE065), and recently explored by Unique Resources Ltd. as the Hawk claim.

The Gold Run property is underlain by grey, green, white-purple quartzites and siltstones with minor interbedded argillite which are part of the Creston Formation of the Middle Proterozoic Purcell Supergroup. These well-bedded rocks strike 030 degrees and dip steeply northwest.

The major showing on the property consists of a large geochemical anomaly (500 by 400 metres of greater than 100 parts per billion gold) that is on strike with a zone of shearing and anomalous gold found to the north on the contiguous Hawk claim (082FSE065). Peak values within the anomaly are in excess of 500 parts per billion gold; no other elements were analysed for. A second anomaly consists of one soil line 400 metres long with gold values over 100, locally over 1000 parts per billion. This anomaly also lies on the southern extension of a gold-mineralized shear known on the Hawk property to the north. The shear zones on the Hawk (Yellow Metal) property have great strike extent of up to 2500 metres, widths of up to 50-100 metres and gold assays ranging from trace to 30.5 grams per tonne (Assessment Report 16656); the zones strike 020 degrees and dip steeply east, cutting across the stratigraphy. Mineralized zones are

COMMENTS: Age of Perry Creek mineralization widely believed post-metamorphism.

CAPSULE GEOLOGY

The recently staked Swenson property covers the old Real Thing showings on Reverted Crown grants (Lots 6023-6025, 6863-6866, 7216-7217) centred on a prominent 2260 metre high peak west of Richmond Lake at the head of Perry Creek.

The Swenson property is underlain by grey to purple coloured quartzites and siltstones with minor interbedded argillite which are part of the Creston Formation of the Middle Proterozoic Purcell Supergroup. These well-bedded rocks strike 030 degrees and dip from vertical to 75 degrees east. Quartz is abundant, occurring as small stringers or veins conforming to the general strike of the country rock and as larger veins or lenses that crosscut the bedding; best mineralization is in the latter. Faulting and shearing is evident, with the largest displacement noted being 6 metres.

Two major showings on the property are found. The first old adit is located on Lot 6864 (Real Thing) and exposes a quartz vein that varies from 5 to 20 centimetres thick conforming with the strike of the country rock over a strike length of 22 metres, but does not appear to show any mineralization. A second adit is driven on a quartz vein that strikes westerly and dips to the south, crosscutting the bedding; it is approximately 30 centimetres wide at the mouth of the adit and pinches to a few centimetres 15 metres from the portal. At its widest point it is well mineralized with pyrite,

REPORT: RGEN0100

CAPSULE GEOLOGY

chalcopyrite, native copper and traces of malachite. Gold is visible as small flakes the size of a pin head associated with native copper. Another mineralized quartz vein, on Lot 6866 (Viking) strikes 025 degrees, dips at 80 degrees to the east, is approximately 45 centimetres wide and is heavily mineralized with pyrite. It is traceable for 60 metres to the south.

CAPSULE GEOLOGY

A molybdenum anomaly was found by soil sampling on the southeast portion of the ME4 claim, just above a small lake at the head of an east-flowing tributary at the headwaters of the west branch of Hellroaring Creek.

The area is underlain by quartzites and grits of the Cranbrook Formation (Lower Cambrian Gog Group), intruded by a small stock of Mesozoic granodiorite, likely of Early Cretaceous age. Contact metamorphic effects peripheral to this medium-grained intrusion appear to be minimal, but the rocks are metamorphosed to biotite facies regionally. Molybdenite mineralization was not located in place but is assumed to be present. Pyrite and pyrrhotite occur as disseminations up to 10 per cent by volume in the Cranbrook Formation, which is marked by a prominent gossan.

CAPSULE GEOLOGY

The Hall property was staked by Cominco to explore for stratiform lead-zinc mineralization in the Middle Aldridge Formation. It lies 22 kilometres north of Creston in the upper headwaters of the Arrow Creek watershed. Cominco conducted an induced polarization survey over an area of anomalous soil geochemistry first discovered by silt sampling; it was also explored by Amoco as the Paul property.

The original stream silt anomaly had lead and zinc values up to 480 and 2750 parts per million respectively; the source was defined by soil sampling and profiling, giving values as high as 12,000 parts per million lead and 4230 parts per million zinc (Assessment Report 19533). One diamond-drill hole was put down by Cominco about 1 kilometre southwest of Mount Bohan.

The property in the area of the drillhole is underlain by carbonate rocks of the Dutch Creek Formation of the Middle Proterozoic Purcell Supergroup. Lithologies include limestone, dolomitic limestone and variable argillites; locally the limestone is argillaceous. From 63 to 86 metres in the 147 metre drillhole, there is a breccia of white calcite and grey to white quartz replacing the limestone; some alteration is associated, including tremolite-actinolite and talc. Mineralization is very limited in the core; very weak pyrite, galena and sphalerite can be seen in the breccia zone, with greater amounts of disseminated pyrite in the underlying thin-bedded argillites.

Another area of anomalous lead in contour soil lines was found on the eastern side of the Hall property (162 parts per million lead) but no source was discovered.

CAPSULE GEOLOGY

The Sun claims are located about 3 kilometres southeast of Kitchener, on a steep north-facing slope between Russell Creek and Birch Creek; access is by bulldozed trail leading south from Kitchener.

The area is underlain by sedimentary rocks of the Middle Aldridge Formation and dioritic intrusions of the Moyie intrusions, both belonging to the Purcell Supergroup of Middle Proterozoic age. Hostrocks are described as quartzites, in part calcareous, and thinly bedded shales with a varve-like appearance. The strike is due north with a gentle east dip at about 30 degrees. Folding on an east-west axis is evident, and may have controlled east-west fracturing that hosts the mineralization.

The area of the claims covers some showings known since before the turn of the century, which consist of a number of east-west trending fractures which exhibit scattered areas of galena and sphalerite. The individual veins range in thickness from 5 to 15 centimetres and are contained in an area of about 100 by 200 metres. Numerous quartz veins and veinlets are also located in this area. Two adits were driven below and across the veins in the late 1930s. Recent work by Cominco discovered north-striking wacke beds that contain pyrrhotite and elevated lead and zinc; however, no economic occurrences of mineralization were found.

Geochemical surveys in more recent times (Assessment Reports 12239, 14623 and 18154) have disclosed strong geochemical anomalies for lead (over 1000 parts per million) but only weak anomalies for zinc. Rock specimens assayed indicated anomalous silver is associated with the galena. Geophysical surveys by Cominco using the UTEM (University of Toronto electromagnetic) system failed to show any conductors.

CAPSULE GEOLOGY

The ENG 1 property is located 4.5 kilometres north-northeast of Yahk, centred on diamond-drill holes E90-1 and E90-2 (Assessment Report 20827) on a flat bench at an elevation of 1160 metres.

The claims are underlain by Aldridge Formation quartzites intruded by gabbro sills of the Moyie intrusions, both of the Purcell Supergroup of Middle Proterozoic age. Limited exploration by Cominco Ltd. and Kennco Inc. have indicated the presence of quartz veins with sulphides and some disseminated pyrrhotite and sphalerite. Drilling by Kokanee Explorations Ltd. intersected minor laminated pyrrhotite and some pyrite.

Abitibi Mining Corp. drilled 3 holes totalling 304 metres in 1998 on the Yahk property. The holes intersected zones of galena, sphalerite and pyrrhotite fracture filling in altered sediments of the Aldridge formation.

Rio Algom Ltd. is seeking interest in the property in 1999.

CAPSULE GEOLOGY

quartz vein that has been traced by an adit, trenching and blasting over a strike length of 138 metres. The vein averages 0.9 to 1.0 metres wide and strikes approximately east-west with a very flat dip of 5 to 15 degrees to the south. The hangingwall and footwall of the vein are in slightly sericite and chlorite altered granite and contain small slivers of quartz veinlets for up to 0.5 metre from the vein. Fracturing of the vein is pronounced in places but fault offsets were not observed.

Mineralization consists mainly of galena, pyrite, sphalerite, chalcopyrite and malachite with rare pyrrhotite and melanterite; the dominant sulphide, galena, is found as small isolated pods or stringers in the vein, mainly less than 5 per cent of the vein. Assays over widths of up to 1.2 metres are up to 2.1 per cent lead, 0.11 per cent zinc and 338 grams per tonne silver; all gold assays were nil. Silver assays average about 35 grams per tonne to 1 per cent combined lead plus zinc (Assessment Report 7845).

Magnetometer and VLF (very low frequency electromagnetic) surveys carried out on the property failed to show any anomalies (conductors) worthy of follow-up (Assessment Report 9316).

The adits on the property might be the documented 1951 and 1952 producers for the Cricket No. 2, which is the property near Kuskanook operated by E. Bainbridge. A 40-tonne shipment from the Mohawk No. 1 was also made in 1976.

CAPSULE GEOLOGY

The Vancouver (Lot 3797) and Kootenay (Lot 3798) Reverted Crown grants are located on the west flank of Mount Sherman at about 2000 metres elevation. The showings are situated on the relatively gentle south-facing slope at the headwaters of Martell Creek, near the crest of the ridge between Akokli and Sanca creeks, about 4 kilometres east of the shore of Kootenay Lake and 1.5 kilometres southwest of the Gold (German) Basin showing (082FSE039).

The showings are described in Assessment Report 17527 as massive to vuggy limonite-stained quartz veins containing minor pyrite, exposed in old trenches on the Kootenay (northern) Reverted Crown grant. The veins are entirely hosted in granite and granodiorite of the middle Cretaceous Bayonne batholith; aplite float is common on the Vancouver (southern) Reverted Crown grant, where an extensive shear zone was also noted. The veins strike 122 degrees and dip 22 degrees south where observed. Assays of the veins in old trenches reveal weak values in silver (up to 139 grams per tonne), lead (up to 0.56 per cent), zinc (up to 0.27 per cent) and traces of gold (up to 0.55 gram per tonne) (Assessment Report 17527).

CAPSULE GEOLOGY

The Lockhart is a new showing discovered in the late 1970s during construction of a logging road (actually, the Upper showing, which is on map sheet 82F10 to the north). Subsequent road building and exploration in the early 1980s discovered the Lower and LK-3 showings at an elevation of 1000 metres, about 4 kilometres north of Boswell on the east side of Kootenay Lake.

The country rock consists of quartzite, argillite, limestone and quartzite boulder conglomerate of the Horsethief Creek Group of Upper Proterozoic age (Windermere Supergroup). The local formations are unnamed; the rocks strike northerly. Mineralization consists of quartz veins up to 15 centimetres thick containing pod-like and erratic concentrations of galena and sphalerite; grab samples assay up to 14 per cent lead and 750 grams per tonne silver, with zinc not specified (Assessment Report 8889). Minor pyrite is associated with the veining at the Upper showing, but at the lower showings pyrite is

Lead		0.6700	Per cent
Zinc		0.1300	Per cent

COMMENTS: Vein float.
 REFERENCE: Assessment Report 11026.

CAPSULE GEOLOGY

The Amic (Yukon) claims are located on a new showing discovered in 1982 when following up a stream sediment anomaly using a heavy metal kit. A vein with 300 metres strike length and a fissure zone were found striking 045 degrees and dipping almost vertically. The vein and fissure are hosted in the Mine stock, part of the Nelson intrusions of Middle Jurassic age, described in Geological Survey of Canada Memoir 228 as calcic biotite amphibole granite and thus distinct from the Bayonne batholith to the south, which does not contain significant amphibole. However, the mineralization may be related to the middle Cretaceous Bayonne batholith, which is post-amphibolite grade metamorphism.

The quartz vein and the fissure contain galena, pyrite and sphalerite as small pockets; assays of up to 0.67 per cent lead, 0.13 per cent zinc, 23 grams per tonne silver and 19.5 grams per tonne gold occur in vein float and outcrop over up to 25 centimetres width (Assessment Report 11026).

CAPSULE GEOLOGY

Geochemical surveying and trenching by Cima Resources Ltd. in 1982 revealed the presence of several subsidiary veins with similar strike on the property.

Bluebird Minerals Ltd. drilled 6 holes totalling 1132 metres in 1997.

MINFILE NUMBER: **082FSE134**

NATIONAL MINERAL INVENTORY:

NAME(S): **IRENE**

MINING DIVISION: Nelson

STATUS: Showing
REGIONS: British Columbia
NTS MAP: 082F02W
BC MAP:

UTM ZONE: 11 (NAD 83)

LATITUDE: 49 04 45 N
LONGITUDE: 116 58 19 W
ELEVATION: 1765 Metres

NORTHING: 5436257
EASTING: 502049

LOCATION ACCURACY: Within 500M

COMMENTS: Located on common location post for Irene 1, 2 and 3 claims.

COMMODITIES: Copper Silver Gold Zinc Lead

MINERALS

SIGNIFICANT: Chalcopyrite Pyrite Sphalerite Galena Malachite
COMMENTS: Sphalerite and galena are rare.
ASSOCIATED: Quartz Carbonate
MINERALIZATION AGE: Unknown

DEPOSIT

CHARACTER: Vein
CLASSIFICATION: Hydrothermal Epigenetic
TYPE: 106 Cu±Ag quartz veins

HOST ROCK

DOMINANT HOSTROCK: Volcanic

STRATIGRAPHIC AGE	GROUP	FORMATION	IGNEOUS/METAMORPHIC/OTHER
Upper Proterozoic	Horsethief Creek	Irene Volcanic	
Upper Proterozoic	Horsethief Creek	Toby	

LITHOLOGY: Amygdaloidal Vesicular Basalt
Agglomerate
Chlorite Schist
Pebble Conglomerate
Limestone
Dolomite

HOSTROCK COMMENTS: Toby conglomerate occurs along the eastern boundary of the claims; limestone/dolomite as intercalations in the volcanics.

GEOLOGICAL SETTING

TECTONIC BELT: Omineca
TERRANE: Ancestral North America
METAMORPHIC TYPE: Regional
COMMENTS: Chlorite facies of regional metamorphism.

PHYSIOGRAPHIC AREA: Selkirk Mountains
RELATIONSHIP:
GRADE: Greenschist

CAPSULE GEOLOGY

The Irene property consists of three claims staked in 1990 to cover strong gold, base metal and indicator element stream sediment anomalies in Char Creek. The claims are centred on the common location post at 1765 metres elevation on the west side of Char Creek; they extend to Mount Irene, almost to the similar copper-silver showings known as the Motherlode (082FSE080) and Copper Queen (082FSE053) on the south side of Mount Irene.
