Hostrocks to the quartz-carbonate vein showings discovered on the Irene claims are mainly amygdaloidal or vesicular basalt and agglomerate of the Irene Volcanic Formation in places slightly metamorphosed to regional greenschist grade (chlorite facies) and thus appearing as metabasalt or chlorite schist. Lenses of limestone and dolomite are intercalated in the volcanics, which are underlain near the eastern boundary of the claims by pebble conglomerate of the Toby Formation. Both these units belong to the Horsethief Creek Group of Upper Proterozoic age.

Mineralization consists of minor pyrite and chalcopyrite found in thin (usually less than 20 centimetres) irregular and discontinuous quartz-carbonate veins as both float and outcrop occurrences. The veins are commonly malachite stained and contain minor gold values (up to 0.24 gram per tonne) and silver values (up to 11.7 grams per tonne). Copper assays as high as 0.27 per cent were recorded; these veins are concentrated in places in limestone or dolomite beds. Rare sphalerite and galena were found in a quartz vein varying from 3 to 20 centimetres in width; trace chalcopyrite was also found as amygdale fillings with calcite.

CAPSULE GEOLOGY

Assessment Report 11439 reporting on exploration on the Castle, Queen and King claims near the headwaters of Maryland Creek, 30 kilometres west-southwest of Creston, describes mineralization on the adjoining Shunter claims, quoting from an unpublished report by L.S. Trenholme, P. Eng., in 1982. A seam of tetrahedrite, 2.5 centimetres thick, occurs in massive white dolomite and elsewhere in thin-bedded limestone, probably part of the Mount Nelson Formation (or less likely, part of the underlying Dutch Creek Formation). Both these formations are part of the Middle Proterozoic Purcell Supergroup. Samples in the report by Trenholme are said to have assayed up to 2775 grams per tonne silver along with significant copper, zinc and lead.

CAPSULE GEOLOGY

Mineralization in the Dodge-Sullivan Two system is spread over a large area; the location is centred on tourmalinite showings on the northern edge of the Dodge claims (Assessment Report 14951) near the headwaters of Dodge Creek, a south-flowing tributary to Boundary Creek. Further lead-zinc mineralization also occurs on the gently sloping east spur of Mount Rykert and in the headwaters of Urmston Creek (on the Sullivan Two claim; Assessment Report 17387).

The area is underlain by Middle Proterozoic Purcell Supergroup sedimentary rocks, metamorphosed to middle or upper greenschist facies (garnet-staurolite grade in places). In particular, the property is underlain by Middle Aldridge strata, thought from correlation of marker horizons to lie 900 metres above the Lower to

CAPSULE GEOLOGY

Middle Aldridge contact at which the Sullivan (082FNE052), a world-class sedimentary exhalative lead-zinc-silver deposit lies.

Hostrocks on the property include muscovite-biotite-garnet phyllite, micaceous quartzite, thin to massive bedded quartz wacke, argillite, and a calcsilicate siltstone layer intimately associated with mineralization. Gabbro sills belonging to the Moyie intrusions, also part of the Purcell Supergroup, are commonly intercalated with the metasedimentary rocks. These rocks strike generally north-northeast and dip gently at 20 to 30 degrees east.

Exploration on the Dodge-Sullivan Two property was prompted by the report of "large quantities of milling grade galena-quartz float" found in a burned area (Minister of Mines Annual Report 1929). All efforts so far have failed to relocate the site of, or source of, this float. However, mineralization consisting of a layer of quartz, carbonate and talc rock (the calcsilicate layer) containing disseminated galena, sphalerite and pyrite, with significant silver values, was discovered on the Dodge claim and traced geochemically onto the Sullivan Two claim. This mineralization is structurally overlain by a tourmalinite pipe with fragmental rocks typical of those at the Sullivan deposit. However, since the stratigraphy in this area is thought to be overturned, it is likely that the tourmalinite and associated albitized rocks are actually below the level of the stratabound mineralization. Sericitic and chloritic alteration are also noted on the property; such alteration is prominent at the Sullivan deposit. Drilling traced the calcsilicate layer below the surface and investigated a garnetiferous horizon which is exposed at surface as a manganiferous gossan; manganiferous garnets are prominent just below the ore horizon at the Sullivan deposit. Assays of representative material from surface trenches are up to 1.87 per cent lead, 1.46 per cent zinc and 24 grams per tonne silver; however, no mineralized interval was intersected in diamond drilling in 1990 to 1991 (Assessment Report 21589). Core losses in blocky ground led to the abandonment of four holes and the conclusion that the main stratigraphic target had not been tested.

A deep-penetrating electromagnetic survey by Cominco Ltd. on the Dodge claims revealed only weak cross-over conductors (Assessment Report 19225). In 1996, Quest International Resource Corporation drilled approximately 4000 metres in 8 holes on the Del claims at the head of Dodge Creek.

COMMENTS: Post-metamorphic intrusion hosts mineralization.

CAPSULE GEOLOGY

The Elmo claim is located 33 kilometres north of Creston in the headwaters of Sanca Creek. The mineralization is found near the centre of the claim about 1.25 kilometres west of Mount Dickson, at about 2000 metres elevation. The claim covers a double cirque basin that faces north. The claim is entirely underlain by rocks of the middle Cretaceous Bayonne batholith; within the claim area there are two discrete phases, a medium grained equigranular and a coarse grained equigranular to megacrystic (porphyritic) quartz monzonite. Both phases are cut to varying degrees by a stockwork of quartz-muscovite (greisen) veinlets. Molybdenite, scheelite, fluorite, magnetite, pyrite and chalcopyrite occur as infrequent accessory minerals within the quartz veinlets, most frequently where the veinlets are widest in certain areas of the porphyritic quartz monzonite.

The claims were explored by geochemical survey (soil sampling which revealed highly anomalous values for molybdenum and tungsten (Assessment Report 11448: Billiton Canada Ltd.). The area had been previously explored by Placer Development Ltd. as the Jaim claim (Assessment Report 7886).

CAPSULE GEOLOGY

The location of the Lavola Creek placer gold occurrence (number 212 in Bulletin 28, page 15) is poorly known, being described only as "a tributary of Goat River north of Kitchener". The topographic map shows a Lovola Creek in this position, and the occurrence is arbitrarily plotted on this stream. Nothing further is known except for the recorded production of 280 grams of gold in the period 1936-1940. The placer gold is assumed to be present in Quaternary glaciofluvial gravel and clay surficial deposits. Bedrock consists of argillite and siltstone of the Cambrian Eager Formation.

CAPSULE GEOLOGY

The Sha South geochemical anomaly is located on the Sha 29 and 30 claims, approximately 8 kilometres west of Yahk (Assessment Report 22057). Reconnaissance geophysical surveys by UTEM (University of Toronto electromagnetic) method disclosed several low-level conductors on the claims (Assessment Reports 17044, 18163, 18164). Earlier horizontal-loop electromagnetic and ground magnetic surveys had also shown several weak conductors and anomalies (Assessment Report 11210).

The area is underlain by the peri-cratonic Middle Proterozoic Purcell Supergroup, a thick succession of siliciclastic and lesser carbonate rocks. The Purcell Supergroup is well known for hosting a number of significant deposits that include the Sullivan (082FNE052) sedimentary-exhalative lead-zinc deposit and the Troy copper-silver deposit in Montana.

The claims are underlain by quartzitic turbidites and argillaceous siltstones of the Middle Aldridge Formation. No mineralization is reported, but spot highs of up to 200 parts per million lead and 250 parts per million zinc were found in soil samples (Assessment Reports 15025, 22057).

CAPSULE GEOLOGY

The Sha North property comprises the Sha 24-28 claims, which are located on the north side of the Highway 3 corridor, not contiguous with the Sha (082FSE104) and Sha South (082FSE998) groups, but explored by Cominco contemporaneously with the Sun (082FSE127) group. The Sha North claims are on the south and west slopes of Mount Kitchener, about 5 kilometres northeast of McConnell (Kitchener).

The property is underlain by sedimentary rocks of the Purcell Supergroup of Middle Proterozoic age, intruded by gabbro sills and dikes of the same age belonging to the Moyie intrusions. The sedimentary rocks include thin bedded quartzitic wackes and argillaceous siltstones; geochemical values up to 400 parts per million lead and 475 parts per million zinc appear to be correlated with the latter. There is no description of sulphides present, but it can be assumed that they are likely pyrrhotite, galena and sphalerite.

The sedimentary rocks dip moderately to the east and are bounded to the west by the Iron Mountain fault and to the east by the Kidd Creek fault. Numerous minor northeast and northwest-striking faults have been mapped on the property.

CAPSULE GEOLOGY

Drill indicated reserves in the Zinc Zone were reported as 36,280 tonnes at 3.16 per cent zinc (Spence, 1959, as reported in Auckland Expl L Prospectus, 11/06/85, Report by D.P. Taylor, p. 12). Salmo-Malartic Mines was dissolved in 1969.

The reverted Crown-grants were acquired in 1979 by John Mirko of Vancouver, and associates. The surrounding area was staked as The Crunch and The Rock claims (18 units each).

Total Resources Inc purchased the claims from Mirko by an agreement dated February 1980; the company name was changed in December 1980 to Extotal Resources Inc. Work by the company in 1980-81 included geological mapping, sampling, petrological studies and 2078 metres of underground diamond drilling in 74 holes. Based on this work the Silver Zone contains drill proven: 49,110 tonnes at 234.8 grams per tonne silver with minor lead-zinc; drill indicated: 12,179 tonnes at similar grade (A.M. de Quadros, 1981, as reported in Auckland Expl L Prospectus, 11/06/85, Report by D.P. Taylor, p. 15).

In 1983 former owners, Mirko & assoc, optioned a 60 per cent interest in the property from Extotal. In November/December 1983 Chopper Mines Ltd., under an agreement with Mirko, carried out rehabilitation of the B adit and bulk sampling.

In November 1984 Mirko & associates formed Auckland Exploration Ltd to continue work under the option agreement with Extotal.

The Aspen occurrence is probably a manto-type deposit hosted by limestone of the Lower Cambrian Laib Formation (Reeves Member) which is correlative with the Lower Cambrian Badshot Formation. The deposits have been strongly affected by folding, faulting, and by the emplacement of the Middle to Late Jurassic Nelson Intrusions. Three distinct stratabound, dolomitic (slump?), ore-bearing breccia horizons are recognized as follows:

1) Upper Zinc dolomitic breccia which hosts sphalerite-pyrite-pyrrhotite in a calcite-dolomite-olivine-serpentine-talc gangue. Sphalerite grains often display pyrrhotite exsolution lamellae.

2) Middle Silver dolomitic breccia which hosts pyrite-sphalerite-galena-tetrahedrite in a diopside-quartz-calcite-wollastonite-serpentine-humite gangue. Less than 1.5 per cent total sulphides are present. Sphalerite often displays chalcopyrite exsolution lamellae. The unit is 1 to 8 metres thick and is traced about 1100 metres on surface. Tetrahedrite occurs as small, irregular aggregates in an otherwise unmineralized, silicified dolomite and it may be easily mistaken for carbonaceous material.

3) Lower Lead-Zinc-Silver dolomitic breccia which hosts sphalerite-galena-tetrahedrite in a calcite-dolomite-olivine-wollastonite gangue. Assay values range from 2.3 to 6 per cent zinc, 2 to 24 per cent lead, and 291 to 2057 grams per tonne silver.

The zones have a general north-northwest trend and dip about 40 to 50 degrees northeast. The Middle Silver horizon contains blebs of tetrahedrite both in dolomite fragments and in the breccia matrix. Sulphide content is generally low but can be up to 60 per cent near fold noses in fracture zones. The Middle Silver zone may locally contain up to 15 per cent zinc, 14 grams per tonne gold and 1371 grams per tonne silver. The silver content shows a strong association with silica content (Assessment Report 9053). A weighted average drill hole sample graded 246.85 grams per tonne silver, 2.40 grams per tonne gold, 3.95 per cent zinc and 0.39 per cent lead (Assessment Report 9053).

Production, recorded for three years, totalled 28 tonnes from which 31 grams of gold, 36,359 grams of silver, 431 kilograms of lead and 365 kilograms of zinc were recovered. Reserves published in the Northern Miner (March 11, 1937), indicated 29,030 tonnes averaging about \$9 per tonne combined silver and gold. Also indicated was approximately 90,720 tonnes of ore in a low-grade zinc zone. Cominco's work in 1959 outlined 36,287 tonnes of 3.16 per cent zinc (Taylor, 1984).

Diamond drilling in 1951 also indicated a considerable tonnage of marginal material within replacement zones in the dolomitized Reeves limestone (Energy, Mines and Resources Canada, Mineral Bulletin, MR 198, page 209).

Auckland Explorations Ltd. optioned the property in 1984. Proven reserves in the silver zone are reported as 49,120 tonnes grading 235 grams per tonne silver, with minor lead and zinc. Also reported are 12,180 tonnes of indicated of similar grade material

CAPSULE GEOLOGY

Lower Cambrian Laib Formation quartzites and pelites close to granitic stocks of the Middle to Late Jurassic Nelson batholith host two types of mineralization: (a) quartz veins carrying pyrite and traces of molybdenite and (b) skarn zones hosting pyrrhotite and tungsten (scheelite). In 6 years, between 1933 and 1942, a total of 340 tonnes of ore were mined from which 3,298 grams of gold and 9,642

CAPSULE GEOLOGY

grams of silver were recovered.

The quartz veins vary in attitude, and are composed of glassy quartz with disseminated pyrite and traces of molybdenite and galena. The veins are 0.3 to 1.5 metres in width.

Closer to the granitic contact, skarn zones have developed in the impure limestones and argillites of the Laib Formation. The hornfels-skarn altered zones host sporadic scheelite disseminated with pyrite in garnet-bearing skarn and scheelite with anomalous gold values within local pods of relatively massive pyrrhotite. A chip sample taken from one such zone assayed 1.6 grams per tonne gold and 0.099 per cent tungsten (Assessment Report 12758). The best tungsten assays are 0.22 to 0.29 per cent WO₃, but most analysis are less than 0.1 per cent.

The veins and skarn zones are associated with late stage faulting, as well as crosscutting aplitic and lamprophyric dykes.

CAPSULE GEOLOGY

Middle Cambrian Nelway Formation dolomites contain clusters and vein-like lenses of galena and honey colored sphalerite. The main showings, which consist of limonitic gossan zones in dolomite, occur on both sides of Lead Creek. Mineralization consists of galena and sphalerite disseminated in cherty dolomite and brecciated dolomite exposed over an area of about 200 metres by 150 metres. The sulphides occur in relatively small, irregularly spaced, low grade areas.

In 1953, 2 tonnes of ore were shipped, from which 156 grams of silver, 1069 kilograms of lead and 20 kilograms of zinc were recovered. In 1970, a further 255 tonnes were shipped, yielding 124 grams of gold, 1,306 grams of silver, 577 kilograms of lead and 764 kilograms of zinc.

CAPSULE GEOLOGY

level crosscut was driven during the winter but results were disappointing and the option was dropped in 1912. W.R. Salisbury & associates, of Salmo, in 1913 leased the area containing the workings and small amounts of carbonate ore were mined until the lease expired in August 1915. During this period the owners, Horton & Billings, drove the Zincton crosscut to explore the adjacent Zincton claim. On the expiry of the above lease the entire property was optioned to a Spokane syndicate operating under the name Hudson Bay Zinc Company. The low level No. 7 crosscut (3,100 level) was started in 1915 and reached a length of 579 metres on completion in 1916. Diamond drilling (473 metres) from the crosscut failed to find ore and the option was given up in 1917.

Crown-grants were issued to P.F. Horton and Agnes Billings on the Garnet (Lot 10809) and Zincton (Lot 10810) claims in 1919 and on the H.B. (Lot 12672) and 10 other claims and fractions (Lots 12668-12671 and 12673-12678) in 1921.

The Victoria Syndicate, Limited, optioned the property in 1925 and began driving the No. 4 level (3,500 level) crosscut. This was completed at a length of 335 metres and from it drifting north and south in the orebody continued into 1926. The option was subsequently given up and P.F. Horton one of the owners, carried out some work on the property in 1927. Exploration work to that date was all done in the heavily oxidized zone at the north and on No. 1 orebody where the flat-plunging ore was exposed on surface. Oxidation here extended to the full depth of the ore zone, about 91 metres below surface.

The Consolidated Mining and Smelting Company returned in 1927 to purchase the 18 Crown-granted claims and fractions, but the property remained idle until 1948. Starting about 1946, the company began geological investigations that led to an intensive diamond drilling program beginning in 1948. Large bodies of 9, low-grade disseminated sulphides plunging gently south from the oxidized orebody were indicated by this drilling. In June, 1949 an underground program began to investigate the drill results. The No. 4 level was rehabilitated and from the face the adit was extended south for nearly 457 metres. A parallel drive was subsequently made about 70 metres to the west and connected to the main drive by 3 crosscuts at 61-metre intervals. Diamond drilling from these two drives and from exploration raises in 1950 partly delimited two orebodies - the No. 1 and No. 2 - and work until 1953 was aimed at developing these orebodies for production. In 1951 construction of a 1,000 ton per day concentrator began and a new adit level (No. 8) was driven 823 metres north from the Sheep Creek valley millsite to the ore zone. The concentrator was completed early in 1953 but due to low lead and zinc prices, was not put into operation. All work ceased on March 31 and was not resumed until April 1955; milling began in May.

The Garnet (082FSW249) zone outcrops on the Garnet and Legal Tender claims between elevations of 1067 and 1158 metres on the Sheep Creek slope about 0.5 kilometre north of the concentrator. The Legal Tender claim (Lot 10823) was staked on this showing in about 1899. In 1912 the claim was Crown-granted to George Klavano. Development work at that time apparently consisted of a few short adits. In 1926 the claim was part of the Black Jack group of 4 claims. This group was optioned by P.F. Horton & associates in 1926 and late in the year exploration work was done in about a dozen trenches crosscutting the zone. The Legal Tender was part of the group sold to Cominco in 1927; the Black Jack claims, lying to the west of the Legal Tender, were apparently abandoned. Diamond drilling by the company in 1948-49 in more than 30 holes delimited a more or less continuous mineralized zone 15 metres wide lying 46 to 61 metres west of the Garnet fault. Mining of the Garnet zone began in 1965 as an open pit operation and was later incorporated with the underground operation. The mine and mill closed on November 1, 1966. The company name was changed in 1966 to Cominco Ltd. Plans to re-open the mine were announced late in 1972. The mill and underground workings were rehabilitated and production resumed in February 1973. Mining and milling operations continued until August 1978 when the mine closed. Measured and indicated reserves, as of December 31, 1978, were reported at 409000 tons, at 0.1 per cent lead and 4.1 per cent zinc (Canadian Pacific Limited, Form 10-K, December 31, 1978).

David Minerals Ltd. by an agreement dated May 8, 1981 purchased the mine, mill and adjacent properties from Cominco Ltd. for \$750,000; a 20 acre parcel was subsequently sold to Goldbelt Mines Inc. for a millsite. Renovation of the H.B. mill was carried out to prepare a flotation circuit to custom mill gold-bearing sulphide ores, and a second circuit to treat molybdenite-gold ore from the company's Rossland properties (82 F/4, Mo 2 and 3). The gold circuit was put into operation on ore from the Gold Belt property in December 1981.

CAPSULE GEOLOGY

The HB orebodies are currently thought to be Kootenay Arc-type carbonate hosted sedimentary exhalative (sedex) deposits. The orebodies are located within dolomitized limestone of the Lower Cambrian Laib Formation, Reeves Member (correlative with limestone of the Badshot Formation). The east boundary of the Laib Formation is in contact with argillites of the Lower to Middle Ordovician Active Formation, on a fault contact, with the Active rocks overthrust from the east over the Reeves rocks.

Two distinct calcareous layers of the Reeves Member can be recognized in the area, an upper one about 110 metres thick separated from a lower 12-metre member by 15 to 30 metres of micaceous brown limey argillite. The HB orebodies occur within a hundred metres or so to the west of the thrust fault. It is thought that the mineralization is related to the intrusion of granitic stocks of the Middle to Late Jurassic Nelson Intrusions with the nearest outcrop about 1 kilometre away from the mine. The only intrusives present in the mine are post-ore diabase dykes up to 3 metres thick.

In the vicinity of the HB mine, the beds are folded into a broad synclinerium, and the limestone layers in the mine are on the west limb of this structure. There is evidence of much isoclinal folding within the trough of the synclinerium, with axial planes steeply inclined to the east and folds plunging 20 degrees to the south. There may be similar folding along the west limb within the mine area, but the portions of the folded beds revealed by the mine workings indicate that here the limestone has only formed thickened wrinkles. Within these wrinkles the beds are highly distorted by complex folding. In the central portion of the structures there is cleavage banding which strikes north and dips steeply. The primary folding is disturbed by major crossfolding in at least two places, one at the north end of the mine, the other just south of the main orebodies. The crossfolds plunge steeply to the north and resemble "S" type dragfolds.

The principal ore zones consist of three steeply dipping, parallel zones lying approximately side by side and extending as pencil-like shoots for about 900 metres along the gentle south plunge of the controlling structures. The largest and most easterly ore zone has a maximum height of about 140 metres and a maximum width of 30 metres. Within these zones are steeply dipping discontinuous ore stringers with a lead to zinc ratio of 1:5.

In addition to the steep stringer lodes there is a second type consisting of flat lying, slightly brecciated zones with a lead to zinc ratio of about 1:2.5. These zones plunge at 20 degrees to the south, in general agreement with the plunge of the other orebodies. There are several separate ore zones of the flat lying variety. The layers of ore range from a few metres to 12 metres in thickness, but are generally from 3 to 5 metres thick. The sulphide mineralization within these layers is fairly regular and resembles bedding.

There is evidence to indicate ore deposition was controlled by shear zones within the folded limestone; the best ore concentrations occurring at the junctions between steeply dipping shears (the pencil-like ore bodies) and flat lying shears (the flat-lying brecciated orebodies).

The mineralogy of the ore is relatively simple with pyrite, sphalerite and galena in order of abundance and minor pyrrhotite found locally. The northern portion of these bodies is exposed at surface, near the original HB claim, and are oxidized to a depth of about 100 metres at that point. Where the ore is protected by enclosing dolomite relatively little oxidation has occurred. Other secondary minerals include calamine, smithsonite, anglesite, and the rare zinc phosphate, spencerite.

Wallrock alteration is typical of lead-zinc deposits in the area. The ore zones are enveloped by a broad zone of dolomitization which is bordered along its contact with the limestone by a narrow zone in which limestone is replaced by fine-grained silica. Talc and tremolite alteration, thought to be pre-ore, is concentrated near the silica-rich zone resulting from the silicification of dolomite. An appreciable amount of talc is found locally within the ore zone.

A smaller zone, located to the southwest of the main HB mine, is known as the Garnet orebody (082FSW249). The Garnet zone was mined from the surface from a small open pit, whereas the main mine is entirely underground.

The HB mine produced a total of 6,656,101 tonnes of ore in 29 years between 1912 and 1978. Recovered from this ore were 29,425,521 grams of silver, 49,511,536 kilograms of lead, 260,431,646 kilograms of zinc, 2,019,586 kilograms of cadmium, 105,412 kilograms of copper and 6,159 grams of gold. Measured and indicated reserves published December 31, 1978 by Canadian Pacific Limited were given as approximately 36,287 tonnes grading 0.1 per cent lead and 4.1 per cent zinc (Energy, Mines and Resources Canada Mineral Bulletin MR

CAPSULE GEOLOGY

The Lucky Boy showing is within limestone of the Lower Cambrian Laib Formation, Reeves Member which is correlative with limestone of the Badshot Formation. Several granitic stocks of the Middle to Late Jurassic Nelson Intrusions disrupt the strata. The area is underlain by a north plunging complex fold structure.

Pyrite, sphalerite and galena mineralization is controlled by steeply dipping shears, subparallel to the banding in dolomitized limestones. Veins, up to 1.3 metres wide, have been exposed but were found to be discontinuous in extent.

A drill program conducted in 1987 by Cominco Ltd. outlined two separate mineralized zones within the synclinal structure. Both zones occur at the same stratigraphic level, near the base of the Reeves Member. The host is a medium crystalline pinkish or white metadolomite.

The sulphide zone ranges in thickness between 0.3 and 5.0 metres. Within the zone, sulphides, mainly sphalerite, occur as

CAPSULE GEOLOGY

weak disseminations with occasional patches of heavier disseminations, streaks and thin bands, and in a few cases as small, nearly massive lenses. These lenses of massive sphalerite are rarely more than 0.5 metres thick. In nearly all cases the sulphide bands, streaks and lenses are parallel with the local foliation and/or bedding. The thickness and grade of the sulphides improve on the crest and in the trough of the attenuated isoclinal folds.

One of the highest assays taken from a 0.5 metre length of drill core graded 0.013 per cent lead, 4.7 per cent zinc, 1.27 grams per tonne silver and 0.0274 per cent cadmium (Assessment Report 17710).

CAPSULE GEOLOGY

The Black Rock North showing lies within dolomitized limestone of the westernmost unit of the Lower Cambrian Laib Formation, Reeves Member (correlative with the Badshot Formation). The Reeves limestone is interbedded with quartzites and phyllites with near vertical

CAPSULE GEOLOGY

dips. Minor amounts of skarn minerals have developed within the limestone and hornfelsed sediments.

In the showing area, north trending shears have been welded by irregular lenses of white quartz which are up to 1 metre in width but are barren of sulphides. Scattered lenses of disseminated sphalerite are hosted by dolomite and limestone and the largest of these lenses is about 5 metres in width and has a north-south strike length of about 9 metres. The Black Rock North is south and west of the HB mine (082FSW004) on Aspen Creek.

In 1986, mineralization consisting of alternating layers of galena, sphalerite and wollastonite, interpreted as skarn mineralization, was found in place on the HB Mine property immediately east of the Black Rock (Lot 14408) claim. Samples of the limestone from the claim assayed 2.35 per cent zinc, 0.62 per cent lead, 0.035 per cent copper, 187 grams per tonne germanium and 2.0 grams per tonne gallium (Assessment Report 15873).

CAPSULE GEOLOGY

The Black Rock South showing lies within dolomitized limestone of the westernmost unit of the Lower Cambrian Laib Formation, Reeves Member (correlative with the Badshot Formation). Grey and black limestones were mapped with quartzite beds.

The showing consists of small lenses of crackled dolomite and black limestone which contain minor discrete blebs, disseminations and irregular streaks of sphalerite, galena, and pyrite. The mineralization is reportedly fracture-controlled and rusty limonitic boxworks are characteristic of zones of higher sulphide concentration.

COMMODITY	GRADE
Silver	418.3000 Grams per tonne
Gold	0.3400 Grams per tonne
Lead	17.9000 Per cent
Zinc	13.9000 Per cent

COMMENTS: The sample width is 1.83 metres.
REFERENCE: Bulletin 41, pages 105,106.

CAPSULE GEOLOGY

The Iron Cap occurrence is hosted within limestone and dolomite of the Lower to Middle Ordovician, Active Formation. The occurrence is close to the eastern margin of the granitic, Sheep Creek stock of the Middle to Late Jurassic Nelson Intrusions. Workings on the property include two old shafts, a few bulldozer strippings and diamond drill holes made in 1951 and 1952.

Grey and white crystalline limestone and dolomite contain disseminations and blebs of sphalerite, galena, pyrite, and pyrrhotite in lensoidal zones which are less than about 35 metres long and 1 metre wide. The sulphides appear to parallel vague banding in the carbonates, but the length of the mineralized zone appears to be nearly at right angles to the banding. The mineralized outcrops weather to form a limonitic gossan on surface. A sample across 1.83 metres of the highest grade material assayed 0.34 grams per tonne

CAPSULE GEOLOGY

This property lies on the summit between Sheep & Lost Creeks, about 11 kilometres southeast of Salmo. Although the Emerald has in recent years been a tungsten producer (082FSW010), its early history as a lead-zinc producer is mentioned here because the Jersey workings were later extended into Emerald ground (082FSW310) and production figures for the two have not been recorded separately.

Production of lead-zinc ore from the Emerald was begun in 1906 by the owner, J. Waldbesen. In 1917 Iron Mountain Ltd. was formed to operate the mine and a 25 ton mill was put into operation. The Emerald was a small but steady producer of lead-zinc ore from 1906 to 1925.

A small amount of shallow development work was done on the Jersey claim from 1916 to 1919 and some ore was shipped, however the main ore deposit was not discovered at this time.

Canadian Exploration Ltd., while operating the Emerald tungsten mine, carried out an extensive diamond drilling program on the Jersey during 1948 and a large tonnage of lead-zinc ore was outlined. During 1948-49 the Emerald tungsten operation was closed down and the mill, beside the Nelson-Nelway Highway, was converted to a lead-zinc operation and production from the Jersey began in March 1949. The mine has operated continuously since that time, development work being done on all seven ore zones. Track mining has been used in A, C, and D zones and trackless

CAPSULE GEOLOGY

mining in A, D, E, F, and G zones. The A zone has been developed from the south end of the Jersey zone to a point north of the Emerald, a distance of 1524 metres.

Ore reserves as of April 1, 1965 are reported at 671,075 tonnes grading 1.2 per cent lead and 4.1 per cent zinc.

The Jersey mine is a Kootenay Arc-type sedimentary exhalative deposit that occurs in the Kootenay Arc within what is called the Mine Belt, an area of carbonate hosted lead-zinc deposits associated with Lower Cambrian limestones of the Reeves Member (Laib Formation) and its equivalent, the Badshot Formation.

The dominant structure of the Mine Belt is the north trending Jersey anticline, an isoclinal fold whose axial plane dips 45 degrees to the east. The Jersey orebodies are gently dipping tabular or lenticular bands of sulphide which lie on the normal limb of the anticline parallel to the banding in the sediments. The orebodies trend 015 degrees and plunge 10 degrees southerly over a distance up to 1800 metres. The maximum east-west width is 600 metres.

The Reeves limestone is 120 to 150 metres thick in the mine area. Lead-zinc mineralization, occurring mainly in dolomite near the base of the Reeves Member, varies from 8 to 30 metres in thickness. The limestone and dolomite varies from a blue-green banded type to a white massive type. The dolomites are typically finer grained than the limestones. The Truman Member of the Laib Formation conformably underlies the Reeves Member, and forms the mine footwall rocks. This member consists of hard, dense, reddish green skarn and a brown argillite. The skarn is characterized by tungsten and minor molybdenum mineralization. The mine is bound on the east side by the Argillite (Iron Mountain) fault which down faults younger beds on the east side. The Dodger and Emerald stocks of the Middle to Late Jurassic Nelson Intrusions underlie the mine area.

Secondary, symmetrical anticlinal and synclinal fold structures along the normal limb of the anticline have been used to delineate ten ore zones (A to J) within the deposit. Mineralization occurs more strongly in the fold troughs relative to the fold crests. The amplitude of these folds rarely exceeds 15 metres and their axis trends slightly east of north. Numerous post-ore faults and lamprophyre dykes crosscut the stratigraphy.

Five ore bands, ranging in thickness from 0.3 to 9 metres are recognized in the mine. These bands in order of stratigraphic sequence are: 1) Upper Lead Band; 2) Upper Zinc Band; 3) Middle Zinc Band; 4) Lower Zinc Band; and 5) Lower Lead Band. Ore mineralization consists of fine-grained sphalerite and galena with pyrite, pyrrhotite and minor arsenopyrite. Cadmium is associated with sphalerite, silver with galena. Iron content of the sphalerite is low (about 6 per cent). The overall grade of the deposit is about 3.7 per cent zinc and 1.2 per cent lead.

In the A zone the ore bands are very close together and frequently have been mined as a unit up to 24 metres thick. Throughout the remainder of the mine these bands have been mined separately or in combinations.

The Lower Jersey zone is a zinc and lead enriched dolomite horizon located about 60 metres below the previously mined Jersey orebody. The zone was recognized in 1996 when a new mine model was prepared on the basis of surface and underground geology as well as two underground drillholes drilled prior to the mine's closure. Within the area previously tested, the widest mineralized intercept is 9 metres and the best single intersection graded 8.1 per cent zinc and 3.8 per cent lead across 1 metre (George Cross News Letter No. 27, February 7, 1997).

The Bismuth Gold zone is a flat lying, gold-enriched horizon which overlies and trends parallel to the east limb of the former Jersey deposit. Two holes drilled into this zone in 1996 intersected a flat lying, 9-metre thick, pyrrhotitic horizon with gold grades ranging from 2.0 to 8.3 grams per tonne. A review of the mine records for drilling completed in the 1940s and 1950s indicates this gold-rich sulphide zone was intersected in surface and underground drillholes over a north-south distance of 1000 metres. These records suggest the body ranges from 1 to 18 metres in thickness (George Cross News Letter No.27, February 7, 1997).

The Jersey mine commenced milling of lead-zinc ores in 1949 and continued until 1970 when operations ceased due to depletion of ore reserves. The mine produced about 6.4 million tonnes of ore from which 115 thousand tonnes of lead, 263 thousand tonnes of zinc and 21.5 thousand kilograms of silver were recovered.

Sultan Minerals Inc. explored and drilled the area in 1996 (1700 metres in 16 holes) and 1997 (1204 metres in 16 holes underground). The best intersection was 2.65 per cent zinc and 4.62 per cent lead over a 5-metre core length (4 metres true thickness). Sultan had plans for more work in 1999.

CAPSULE GEOLOGY

The property lies on the summit between Sheep and Lost Creeks, about 13 kilometres southeast of Salmo. The early development work on the Emerald was done on a lead-zinc showing by J. Waldbesen and by Iron Mountain Ltd.; reference is made to this development in the Jersey (082FSW009).

After being inactive from about 1925 to 1940, the owners, Iron Mountain Ltd., increased their holdings from 17 to 41 claims and carried out exploration and a small amount of development for 3 years which led to the discovery of scheelite to the west of the principal lead-zinc showing early in 1942. Later in the year, scheelite ore was found on the Dodger (082FSW011) property to the east of the lead-zinc zone. At about the same time the Feeney (082FSW247) ore body, about 183 metres north of the Empire, was discovered.

In August 1942 the property was purchased by the Dominion Government who operated it through the Wartime Metals Corporation. A mill was built beside the Nelson-Nelway Highway and put into production in August 1943 but on September 10th an order was received to close down.

Early in 1947 the property was bought by Canadian Exploration Ltd. and production was resumed in June. Exploration for additional tungsten ore was extended to a study of the Jersey (082FSW009)

CAPSULE GEOLOGY

showing which was dominantly zinc bearing and by the end of 1948 a considerable tonnage of lead-zinc ore had been proven on the Jersey. The tungsten operation was closed down and the mill converted to a lead-zinc operation for production from the Jersey.

Early in 1951 the Canadian Government bought back from the company the known Emerald tungsten orebodies and the partly developed Dodger (082FSW011). An agreement was made for Canadian Exploration Ltd. to build a tungsten mill and to mine tungsten ore on a fee basis. A 227 tonnes mill was built near the portal of the Emerald 3,800 level and put into production in December 1951. Further diamond drilling on company ground demonstrated the existence of a large tonnage of tungsten ore so the company agreed to buy the tungsten operation from the Government. The mill operated until the end of 1958. On the Emerald claim all ore was mined from above the 3,800 level main haulageway by open pitting and underground mining. An inclined shaft was put down to the 2,730 level and 9 levels established off this, the bottom one 344 metres vertically below the 3,800 level. All ore was mined out above this lowest level. A small orebody on the Feeney claim was mined out by 1955. The mining of the Dodger zone was completed in 1957.

Diamond drilling on the Invincible claim revealed a tungsten orebody 245 to 275 metres below the surface that is estimated to contain 350,000 tonnes grading 0.83 per cent tungstic oxide. The sinking of a 275-metre vertical shaft was begun but the project was abandoned in 1958 on completion of a sales contract with the United States General Services Administration. Work was resumed on the property in 1967. A geophysical survey was made of the Invincible claim (Lot 12084) and 394 metres of diamond drilling was done in 2 holes in the Tungsten King workings (082FSW034, 321, 322).

Drilling during 1968 on the Invincible (082FSW218) showing totalled 2875 metres. Development work was begun in 1969 and production began in mid-October 1970. The Emerald tungsten mill was rehabilitated to handle about 454 tonnes per day. Ore reserves at the end of 1970 from three separate zones totalled 435,500 tonnes averaging 0.65 per cent W03. Initial production was from the rehabilitated Dodger workings since the Invincible ore zone had not been reached. The Invincible drift was advanced to 1310 metres during the year; the orebody was developed by a decline trackless haulageway. Mill capacity was increased to around 544 tonnes per day during 1971. The company name was changed in 1972 to Canex Placer Limited. Ore reserves were exhausted and the mine closed in August 1973, and in 1977, Canex's assets were acquired by Placer Development Limited. In 1979, Mentor Exploration and Development Co., Limited optioned the property from Placer. In 1980, they diamond drilled 4504 metres in 11 holes plus one wedged hole. The best intersection was 0.36 per cent W03 over 1.07 metres.

The Emerald Tungsten zone is located on the west side of the Emerald Stock granite of the Middle to Late Jurassic Nelson Intrusions. The zone occurs within the Lower Cambrian Laib Formation along the contact of the Reeves Member limestone with the Emerald Member argillite as well as on the limestone-granite contact.

The strata strike about 020 degrees and dip between 45 and 70 degrees east; many of the beds are actually overturned. The granite appears at the surface as a north trending elongate stock. West of the stock are argillite and skarn bands of the Truman Member (Laib Formation), which forms an isoclinal anticline overturned to the west. The Reeves limestone is on the west limb of this anticline, and dips 25 to 70 degrees east, terminating at depth against granite. It is succeeded on the west by the Emerald argillite that also dips east. Both the Emerald and nearby Feeney (082FSW247) ore zones are transected by the Granite fault; drilling, east and north of the fault, located the Invincible (082FSW218) tungsten zone at the same stratigraphic horizon.

Within the deposit four distinct types of mineralization can be recognized: sulphide, "greisen", skarn, and quartz ores. The sulphide-type consists of irregularly shaped "replacement" bodies in limestone and dolomite, consisting of pyrrhotite, calcite, biotite and scheelite. Locally quartz, pyrite, molybdenite and chalcocopyrite may be present. The "greisen"-type of ore is in altered granite and extends as much as 12 metres into the granite from the contact with the limestone. The ore consists of potash feldspar, in some places completely kaolinized, abundant quartz, sericite, pyrite, tourmaline and scheelite. Locally, calcite or ankerite, apatite, pyrrhotite or molybdenite may be present. The skarn-type of ore, occurring mainly at or near the contact of limestone and argillite, consists of garnet, diopside, calcite and quartz with small amounts of pyrrhotite, pyrite, scheelite and molybdenite. The quartz-type ore, which in many places grades into greisen, is silicified limestone intersected by numerous veins of quartz containing abundant ankerite,

CAPSULE GEOLOGY

large crystals of scheelite, a few flakes of molybdenite, and orange-fluorescing crystals of apatite. Near the veins are found disseminated scheelite and pyrite with some pyrrhotite and tremolite. Also reported are native bismuth, arsenopyrite, gold, tellurides, cassiterite, vesuvianite, fluorite, and wollastonite (G. Ray, 1995).

Scheelite is the main tungsten mineral but minor powellite and wolframite have also been reported. Most of the scheelite occurs as fine, disseminated grains in lenticular skarn zones which extend an average of about 5 to 6 metres from the granite contact along the limestone-argillite contact. Grades are 0.5 to 1.5 per cent W03.

The Emerald Tungsten mine was worked in 1943, 1947 to 1949 (inclusive) and again from 1951 to 1958 (inclusive). Production to the end of 1957 amounted to 597,100 tonnes of ore (Bulletin 41, page 119). Production for the Emerald deposit, combined with that of the Feeney (082FSW247) and Dodger (082FSW011) deposits, is recorded with the production statistics of the Jersey mine (082FSW009).

CAPSULE GEOLOGY

258,500 tonnes of tungstic oxide (WO₃) ore, (Bulletin 41, page 119). Between May 1970 and August 1973, 204,960 tonnes of ore with an average grade of 0.54 per cent WO₃ was produced from the mine (Geology, Exploration and Mining in British Columbia 1973, page 57). During this latter mine life, ore was combined and processed with ore from the nearby Invincible mine (082FSW218) and therefore specific amounts of commodities recovered from the Dodger are not available.

The Dodger was commonly referred to as the Dodger 4200 mine, the East Dodger was called the Dodger 4400 Mine, but both essentially mined the same orebody at different levels and were joined by workings on the 4300 level. All ore was trucked via the Dodger 4200 level workings to the mill near the 4200 level portal. The production statistics are included with those of the Jersey mine (082FSW009).

CAPSULE GEOLOGY

Jack Pot hill, the Santiago claim (Lot 5381) was Crown-granted to F.D. Le Mieux in 1902. The adjacent Big H, Highland Chief, Snowflake, Lerwick and Hercules claims (Lots 5619-5623 respectively) were Crown-granted to The British Lion Mining and Milling Company, Limited Liability in 1902-03. Exploration was done in open cuts, a 55-metre adit on the Big 4 claim, and a shaft on the Lerwick claim. The mineralization proved to be mainly zinc, which was of little interest at that time. The Crown-grants were subsequently cancelled.

The Jack Pot (Jackpot) group of 11 claims was staked in July 1948 by E.P. Haukedahl and E.H. and S.W. Barclay, of Ymir. The claims covered the ground between the two groups of Crown-grants, as well as some of the cancelled Crown-grants. The West zone showings were probably a re-staking of the Highland Chief claim. The Lerwick zone was restaked as the Ink Spot claim, and the East zone was staked as the Two Spot claim.

Late in 1948, New Jersey Zinc Explorations Limited optioned the claims. A road was built to the showings in 1949 and geological and geophysical surveys, trenching and bulldozer stripping were carried out. Diamond drilling on the Main zone, originally held as the Big 4 claim, was done in 21 holes totalling 2078 metres. Diamond drilling on the East zone, began in 1950 and continued into 1951. An adit at 1334 metres elevation (4400 adit) on the west side of Spot Creek, a tributary of Active Creek, was driven southwesterly for 305 metres to the East zone in 1951 and underground diamond drilling was in progress at year end. In 1952, assessment work was done in one diamond drill hole totalling 270 metres. During 1953-54 the 4400 adit was extended to a total length of 924 metres. A second adit (4100 adit), 90 metres in elevation below the 4400 adit, was driven as two headings, one north for 264 metres and the other south for 834 metres. Diamond drilling in 4 holes totalling 395 metres was done from the adits in 1954. The 4400 adit encountered zinc-lead mineralization at intervals but the 4100 adit did not encounter the mineralized zone.

New Jersey Zinc Explorations Limited surrendered its charter in 1954 and the property was transferred to New Jersey Zinc Exploration Company (Canada) Ltd. Further diamond drilling during 1966-68 was done in 4 holes totalling 536 metres on the Ink Spot and Spot No. 3 Fr. claims.

Cominco Ltd. optioned the property in 1973 and during 1973-74 carried out surface and underground geological mapping, and 640 metres of surface diamond drilling in 6 holes on the Two Spot claim. During 1975-77 Cominco carried out 4178 metres of surface and underground diamond drilling in 83 holes on the Two Spot and Canadian Girl claims. Reserves were reported at about 3,000,000 tonnes of 5 per cent combined zinc-lead mineralization (Northern Miner 05/03/81).

Tri Basin Resources Ltd in 1981 optioned a 50 per cent joint venture interest in 6 Crown-grants and 27 recorded claims (132 units) and began a program of geophysics and diamond drilling. Work in 1982 on the Jackpot, and on the Hunter V-Double Standard property (082FSW014, 015) adjoining to the west, included geochemical soil, biogeochemical, induced potential and magnetometer surveys and 1337 metres of diamond drilling in 12 holes. Work in 1983 included 1733 metres of diamond drilling in 23 holes in the vicinity of the Hunter V-Double Standard. By the end of 1983 Tri Basin had earned its 50 per cent joint venture interest with New Jersey Zinc (a wholly owned subsidiary of Gulf and Western Industries Inc). Based on work to date the mineralization is reported as: drill indicated 943,250 tonnes grading 4.68 per cent combined lead-zinc; and drill inferred and speculated - 2,928,400 tonnes, no grade stated (Tri Basin Resources Ltd. Filing Statement 148/84).

A further regional potential of approximately 2,225,000 tons is reported by New Jersey Zinc.

The Jackpot orebodies are currently thought to be Kootenay Arc-type carbonate hosted sedimentary exhalative (Sedex) deposits. The orebodies are located within dolomitized limestone of the Lower Cambrian Laib Formation, Reeves Member (correlative with limestone of the Badshot Formation).

In the occurrence area, the host Reeves member is complexly folded and faulted and close to the north margin of the Hidden Creek stock of the Middle to Late Jurassic Nelson Intrusions. The dolomite strikes about 290 degrees with a south dip and is bounded to the north by quartzites of the Lower Nevada Member of the Quartzite Range Formation. The contact is concordant but interpreted as a bedding plane fault. The mineralized dolomite zones vary in thickness from 1.5 to 15 metres wide, alternate with similar zones of limestone and locally contain small, irregular masses of yellowish green serpentine.

The mineralized zones on the Jackpot claims are called the East (082FSW013), Lerwick (082FSW256), Main and West (082FSW013) zones.

CAPSULE GEOLOGY

The East zone is exposed between elevations 1310 to 1554 metres on the steep slope west of Spot Creek. The Lerwick zone is exposed about 610 metres to the southwest between elevations 1707 and 1769 metres on the same slope. The Main zone is on the steep north facing slope of the hill about 460 metres northwest of Lerwick. The West zone is 305 metres southwest of the Main zone. These four zones of sulphide mineralization contain predominantly sphalerite with pyrite and very minor galena. Mineralization is restricted to zones of dolomite in Reeves limestone, although locally sulphide minerals occur in calcite within the dolomite zones.

Mineralization in the Main zone consists of sphalerite, pyrite, pyrrhotite and minor galena in serpentinized dolomite. The sulphides appear to follow the banding in the dolomite, which dips gently south but is locally steep and complexly folded. The mineralized zone plunges south at about 205 degrees at a low angle, parallel to the plunge of complex minor folds seen on surface. Individual mineralized zones are not extensive laterally but may contain in the order of 4 to 9 per cent zinc and minor lead. Recent reports indicate minor cadmium content in the ore. The mineralized dolomite also contains tremolite and diopside locally, and some scheelite may be present in skarn near the granite contacts. The occurrence has had extensive exploration work carried out but no significant production has been documented.

Tombstone Explorations Co. Ltd. acquired the Jackpot property from New Jersey Zinc Explorations Company (Canada) Ltd. in 1997.

CAPSULE GEOLOGY

The Jackpot East prospect is located on the ridge between Hidden and Porcupine creeks, 10 kilometres northeast of Salmo. See also Jackpot Main (082FSW012), Jackpot West (082FSW255) and Jackpot Lerwick (082FSW256).

The Jackpot orebodies are currently thought to be Kootenay Arc-type carbonate hosted sedimentary exhalative (sedex) deposits. The orebodies are located within dolomitized limestone of the Lower Cambrian Laib Formation, Reeves Member (correlative with limestone of the Badshot Formation). In the occurrence area, the host Reeves Member is complexly folded and faulted and is in close proximity to the north margin of the Hidden Creek stock of the Middle to Late Jurassic Nelson Intrusions.

The carbonates form the core of the Jackpot syncline which trends slightly northeast and dips about 60 degrees east above 1370 metres elevation. Below this elevation the dip changes through vertical to west dipping. The core carbonates are underlain by brown biotite hornfels and white to brown, micaceous limestone of the Truman Member of the Laib Formation and by fine grey micaceous quartzites of the Lower Cambrian Reno Formation. The hornfels is locally altered to a banded diopside rock and the limestones are locally altered to skarn and reportedly carry scheelite. The east limb of the syncline is in fault contact with the Ordovician Active Formation argillites.

CAPSULE GEOLOGY

The Jackpot East mineralization consisting of pyrite, pyrrhotite, sphalerite, and minor galena is confined to bands of dolomite up to about 3 metres thick which alternate with barren dolomites. Sulphides are disseminated and grade ranges from 3 to 15 per cent zinc and minor lead (Bulletin 41). The mineralized zone including barren horizons is in the order of 30 metres thick although individual mineralized horizons have not proven to be laterally extensive. The occurrence has had extensive exploration work but no significant production has been documented. For reserves and work history refer to Jackpot Main (082FSW012).

Tombstone Explorations Co. Ltd. acquired the Jackpot property from New Jersey Zinc Explorations Company (Canada) Ltd. in 1997.

GRADE: Hornfels

CAPSULE GEOLOGY

The property is located between elevations of 1524 and 1758 metres on the south side of Porcupine Creek, 8.8 kilometres northeast of Salmo. The Jack Pot property (082FSW012) adjoins to the east.

The Hunter V claim was located in May 1900 by A.A. Vernon. This and adjacent claims were acquired by W. Davis, of Nelson, and exploration work began in shallow shafts on the Hunter V and Double Standard claims. Late in 1902, the Double Standard Syndicate was organized to begin shipments of fluxing ore to the Nelson smelter. The B.C. Standard Mining Company, Limited was incorporated in June 1903 to acquire the property. An aerial tramway in 3 sections totalling 4663 metres was installed to connect with the Nelson and Fort Sheppard railway. Seven claims, the Hunter V, Double Standard (082FSW015), Mercia Fr., Tugulla, Vulgar Fr., Silver Bullion, and Aurora (Lots 2212, 2213, 2224, 3419-3421, and 6064 respectively) were Crown-granted to the company in 1903. Fluxing ore mined from open pits, one at an elevation of 1707 metres, and the other 76 metres lower and about 305 metres to the northwest, was shipped to smelters at Nelson, Trail, Northport, and Granby.

In mid 1905 the company was forced to liquidate and the property was leased to Hall Mining and Smelting Company, Limited, operator of the smelter at Nelson. A changeover was made to underground mining and a new adit was begun below the Double Standard open pit in 1906. The mine closed and the lease was given up in 1907, when the Hall smelter closed.

The Consolidated Mining and Smelting Company of Canada Limited purchased the property in 1919 and development work was begun in a new adit in 1925. A replacement of the aerial tramway was erected to

CAPSULE GEOLOGY

connect with what was now the Great Northern Railway, and shipments of low-grade ore to meet the fluxing requirements of the Trail smelter began in 1927. Development work in crosscuts, drifts and raises continued into 1929 because the silver values had decreased to such an extent that the operation became unprofitable.

New Jersey Zinc Exploration Company (Canada) Ltd., owner of the adjacent Jack Pot property, acquired the Hunter V Crown grants prior to 1959. Cominco Ltd. carried out exploration work under an option agreement on the New Jersey Zinc property during the period 1973-77 but no specific mention was made of work on the Hunter V.

The Hunter V deposit, part of the Jackpot orebodies, consisted of low-grade ores in the order of 4.35 grams per tonne silver and 0.016 grams per tonne gold. However, production between 1902 and 1929 benefitted from smelter credits for the lime content of the shipped ores and this allowed the operation to continue. The ores consisted of fine-grained sphalerite and pyrite with minor galena, tetrahedrite and native silver within a limestone matrix which contained about 22 per cent silica. Native silver occurred on fracture planes in the oxidized ore and was associated with limonite. The sulphide zone has apparently been completely mined out as later descriptions note that little or no sulphides are now visible in the old workings.

The Jackpot orebodies are currently thought to be Kootenay Arc-type carbonate hosted sedimentary exhalative (sedex) deposits. The orebodies are located within dolomitized limestone of the Lower Cambrian Laib Formation, Reeves Member (correlative with limestone of the Badshot Formation). The occurrences are within limestone which has been complexly folded and faulted close to the north margin of the Middle to Late Jurassic Hidden Creek stock (Nelson Intrusions). The limestones have an east trend with variable dips ranging from 10 to 40 degrees south.

Tombstone Explorations Co. Ltd. acquired the Jackpot property from New Jersey Zinc Explorations Company (Canada) Ltd. in 1997.

CAPSULE GEOLOGY

The Double Standard (Lot 2213) is located between elevations of 1524 and 1758 metres on the south side of Porcupine Creek, 8.8 kilometres northeast of Salmo. The Jack Pot property (82FSW012) adjoins to the east.

The Hunter V claim was located in May 1900 by A.A. Vernon. This and adjacent claims were acquired by W. Davis, of Nelson, and exploration work began in shallow shafts on the Hunter V and Double Standard claims. Late in 1902 the Double Standard Syndicate was organized to begin shipments of fluxing ore to the Nelson smelter. The B.C. Standard Mining Company, Limited was incorporated in June 1903 to acquire the property. An aerial tramway in 3 sections totalling 4663 metres was installed to connect with the Nelson and Fort Sheppard railway. Seven claims, the Hunter V, Double Standard, Mercia Fr., Tugulla, Vulgar Fr., Silver Bullion, and Aurora (Lots 2212, 2213, 2224, 3419-3421, and 6064 respectively) were Crown-granted to the company in 1903. Fluxing ore mined from open pits, one at an elevation of 1707 metres, and the other 76.2 metres lower and about 304.8 metres to the northwest, was shipped to smelters at Nelson, Trail, Northport, and Granby.

In mid 1905 the company was forced to liquidate and the property was leased to Hall Mining and Smelting Company, Limited, operator of the smelter at Nelson. A changeover was made to underground mining and a new adit was begun below the Double Standard open pit in 1906. The mine closed and the lease was given up in 1907, when the Hall smelter closed.

The Consolidate Mining and Smelting Company of Canada Limited purchased the property in 1919 and development work was begun in a new adit in 1925. A replacement of the aerial tramway was erected to

CAPSULE GEOLOGY

connect with what was now the Great Northern Railway, and shipments of low-grade ore to meet the fluxing requirements of the Trail smelter began in 1927. Development work in crosscuts, drifts and raises continued into 1929 because the silver values had decreased to such an extent that the operation became unprofitable.

New Jersey Zinc Exploration Company (Canada) Ltd., owner of the adjacent Jack Pot property, acquired the Hunter V Crown grants prior to 1959. Cominco Ltd. carried out exploration work under an option agreement on the New Jersey Zinc property during the period 1973-77 but no specific mention was made of work on the Hunter V.

The Double Standard occurrence is within limestone of the Reeves Formation of the Lower Cambrian Laib Formation which has been complexly folded and faulted in close proximity to the north margin of the Hidden Creek stock. This stock is part of the Middle to Late Jurassic Nelson Intrusions. The limestones have an east-west trend with variable dips from 10 to 40 degrees south. The Jackpot orebodies are currently thought to be Kootenay Arc-type carbonate hosted sedimentary exhalative (sedex) deposits.

The low-grade ores were in the order of 4.35 grams per tonne silver and 0.016 grams per tonne gold but production between 1902 and 1929 benefitted from smelter credits for the lime content and this allowed the operation to continue. The ores consisted of fine-grained sphalerite and pyrite with minor galena, tetrahedrite, and native silver within a limestone matrix which contained about 22 per cent silica. Native silver occurred on fracture planes with limonite in the oxidized ore. The sulphide zone has apparently been completely mined out as later descriptions note that little or no sulphides are now visible in the old workings.

Production was included with the Hunter V mining operation (082FSW014).

Tombstone Explorations Co. Ltd. acquired the Jackpot property from New Jersey Zinc Explorations Company (Canada) Ltd. in 1997.

CAPSULE GEOLOGY

Argillites, limy argillites, and grey limestone units 3 to 10 metres thick of the Lower to Middle Ordovician Active Formation are in close contact with the western margin of the Lost Creek granite stock of the Middle to Late Jurassic Nelson Intrusions. The limestones are locally altered to skarn and carry disseminated scheelite which has a yellowish fluorescence.

A channel sample across 1.5 metres assayed 0.5 per cent WO3 and 0.03 per cent MoS2 (Geological Survey of Canada Economic Geology Series No. 17, page 103). Locally, a quartz vein follows the granite-skarn contact and is observed to host pyrite with minor galena, sphalerite, and molybdenite.

CAPSULE GEOLOGY

The property is located on the east side of the Pend D'Oreille River at the British Columbia-Washington border, approximately 56 kilometres south of Nelson.

The International group was staked prior to 1908 by George Bell and associates and subsequently optioned to Shallenberger and Mcleod, of Spokane. Fifteen claims (Lots 6598-6612) were Crown-granted to H.H. Shallenberger in 1913. Several hundred metres of underground work in 2 adits and a raise was apparently carried out by the International Lead and Iron Company, of Spokane, prior to 1915. International Crown Mines Consolidated, a Washington company, is reported to have acquired an option on the Shallenberger property in 1929.

No further activity was reported until 1946 when Sheep Creek Gold Mines, Limited optioned the property. Diamond drilling totalling 249 metres was completed before the option was dropped. Messrs. Burgess and Lundgwen leased the property from G. Shallenberger, of Nelson, in 1948. Limonite ore from surface workings was shipped during 1947-1948 to Lehigh Cement Works at Metaline Falls for use in the manufacture of cement. During this same period Shallenberger prospected the property for lead-zinc showings and shipped sorted galena to the smelter at Trail. Limonite ore was mined under contract by D.G. White and G. Gimple during 1950.

The property was sold late in 1951 by Mrs. Shallenberger to E.G.

CAPSULE GEOLOGY

Brown & associates who incorporated International Lead & Zinc Mines Ltd. Geological mapping and bulldozer trenching was carried out in 1952. The company charter was surrendered in 1958.

In the vicinity of Lomond Creek highly oxidized, lead-zinc sulphides are exposed within the Middle Cambrian Nelway Formation. The zones of oxidized sulphides appear confined to the middle and upper stratigraphy of the Nelway Formation which consists of cream and grey banded dolomite containing discontinuous lenses of black dolomite. The black dolomite is commonly mottled with spots of white calcite. The trends are variable but the sediments have a general east strike and dip to the south at 25 degrees or greater.

The main showing area, once the site of mining iron oxide for a cement additive, lies along Lomond Creek at about 750 metres elevation. Associated showings are located adjacent to the Pend d'Oreille River and about 450 metres north of the main showings. These showings are described as podiform, oxidized sulphides, which are a few metres in size and which occur relatively closely spaced along an exposed strike length of about 300 metres. At least one of these pods is 6 by 15 metres in size and 5 metres thick. The oxidized sulphide zones occur within a stratigraphic interval of about 15 metres and are described as generally conformable to the dolomitic banding of the cream or mottled dolomites although at least some are hosted by black dolomite. Locally, crosscutting relationships are observed and the oxidized material is at least partly fracture controlled in some exposures. Walker (1934) described a 0.3 to 2-metre thick oxidized zone in an adit next to the Pend d'Oreille River. He does, however, indicate the zone dips west while the dolomites strike at 065 degrees and dip 80 degrees southeast. Fyles (1959) described, from the area of the main showings, two bands 1.5 and 3.6 metres thick separated by about 3 metres of crumbly dolomite. These oxidized bands are generally conformable to the dolomitic banding but locally crosscut the banding or follow fracture surfaces.

The oxidized zones consist of seams and pods of earthy brown limonite containing harder areas of goethite. Within the soft earthy limonite are nodules of galena with thin coatings of anglesite. Transparent to translucent crystals of cerussite occur mostly encrusted on the goethite. A sample of this material from the large pit at the main showings assayed 10.3 grams per tonne silver, 1.2 per cent lead and 2.7 per cent zinc (Bulletin 41, page 129). Just south of the Canada - USA border, within stratigraphy equivalent to the Nelway Formation, are pyrite rich, lead-zinc sulphide ores such as at the Yellowhead occurrence in Washington State. The Lomond showings are likely the weathered surface equivalents of such pyrite rich sulphide zones.

CAPSULE GEOLOGY

The Lone Silver occurrence is immediately east of Rosebud Lake and located on the Black Bluff fault. To the northwest of the fault are black, graphitic argillites and calcareous sediments of the Lower to Middle Ordovician Active Formation. On the southeast side of the fault are dolomites and limestones of the Middle Cambrian Nelway Formation. The dolomites form a large anticlinal structure with a shallow plunge to the southwest, truncated at a shallow angle by the Black Bluff fault.

Mineralization consisting of pyrite, chalcopyrite, galena, sphalerite, and tetrahedrite is of two main types. The dolomites within the Nelway Formation are commonly brecciated and the small angular fragments of dolomite contains disseminated sulphides in the matrix. Small quartz veinlets occur within the dolomite breccia zones. Within the Active argillites the Black Bluff fault has formed planar faults and shears characterized by graphitic schist and quartz veining along shears and fractures with the quartz veining carrying sulphides. The dolomitic breccia zones are characteristically high in silver-copper values while the vein/shears in the Active Formation have been more productive of gold, silver, lead, and zinc. Ore zones of both types have proven to be limited in extent and scattered along the trend of the Black Bluff fault.

Production to date has totalled approximately 174 tonnes from which about 2,674 grams of gold, 693 kilograms of silver, 10,746 kilograms of lead, and 3,693 kilograms of zinc have been recovered.

Gold	1.3700 Grams per tonne
Copper	0.2900 Per cent

REFERENCE: Minister of Mines Annual Report 1926, page 281.

CAPSULE GEOLOGY

The Meadow View deposit occurs in the Lower Cambrian Laib Formation within limestone of the Reeves Member near its contact with black argillites of the Emerald Member. The Laib Formation has a general northeast trend in the area, and the showings occur on the overturned limb of the Jersey anticline. Within one to two kilometres are granite stocks or plugs of the Middle to Late Jurassic Nelson Intrusions and augite-biotite monzonite of the Middle Eocene Coryell Intrusions. It is unknown if these intrusives have any association with the mineralization.

Mineralization is associated with siliceous alteration zones within the limestone and consists of disseminated tetrahedrite, some native silver, pyrite, and minor molybdenite. Copper staining and some molybdcic oxide is common. Analysis of sorted ore material indicates copper values range from 0.21 to 0.74 per cent. Gold averaged 0.4 to 1.37 grams per tonne and silver averaged from 0.9 kilograms to 2.4 kilograms per tonne (Minister of Mines Annual Report

CAPSULE GEOLOGY

name (Consolidated) was changed in 1966 to Cominco Ltd. During 1978 the company carried out a magnetometer survey over 4 kilometres, and 266 metres of diamond drilling in 3 holes.

The Molly mine is hosted by granites of the Lost Creek stock of the Middle to Late Jurassic Nelson Intrusions, which are intruded into a sequence of argillites and limy argillites of the Ordovician Active Formation. The granite is quartz rich and appears to have an upper fine-grained, aplitic chilled zone or border capping in the order of 2 metres thick.

The aplite is sparsely impregnated with molybdenum but the main molybdenum ore occurs below this capping within a zone about 3 metres thick containing numerous joints parallel to the intrusive contact. The best mineralization appears within this sheeted zone where the intrusive contact dips at low angles and/or where there are prominent fractures intersecting this sheeting. Molybdenite occurs as selvages on the joint planes or disseminated between the joints. The more massive granite below the sheeted zone is host to very little molybdenite. Tungsten, as scheelite, occurs locally disseminated in skarn zones of small size.

Records indicate that the Molly mine produced at least 171 tonnes of ore which carried 3.5 to 5.88 per cent MoS₂. From 1914 to 1917, a total of 11,366 kilograms of molybdenum were produced. Minor pyrite, pyrrhotite, and uraninite are also associated with the deposit. A sample assayed 0.13 equivalent uranium (Geological Survey of Canada, Economic Geology #16).

CAPSULE GEOLOGY

The Oxide occurrence is located on the divide between Oscar and Porcupine creeks. The main showings outcrop at the 1555-metre elevation just to the west of the north-south striking "Oxide Pass", about 1.2 kilometres east of the summit of Jubilee Mountain and 5.5 kilometres east southeast of Ymir.

The area is underlain by black argillite, slate and quartzite of the Lower(?) to Middle Ordovician Active Formation and Lower Cambrian quartzite, schist, argillite, slate and limestone. The Oxide fault separates Lower Cambrian metasediments on the west from Ordovician

CAPSULE GEOLOGY

sediments to the east.

Mineralization is hosted by the Oxide fault which strikes 010 degrees with a dip of 75 to 80 degrees east. East of the fault are black argillites and limestones and on the west side are white and micaceous quartzites. The fault, marked by a wide zone of crushed and sheared rock, contains a muddy clay-like gouge about 45 centimetres thick.

The mineralized zone at the Oxide adit is highly oxidized and is exposed along strike for 458 metres. The width is variable but may be up to 9 metres wide. Drilling and underground development indicate the oxidized zone extends more than 180 metres in depth. The limonitic gossan contains hemimorphite and parahopeite as the major zinc minerals and a few nodules of galena and pyromorphite as the major lead minerals. Manganese, up to 23 per cent, and minor pyritic quartz, with low gold assays, is present locally.

The highest assay from samples taken in the adit in 1948 was 0.34 grams per tonne gold, 3.4 grams per tonne silver, 1.4 per cent lead and 15.7 per cent zinc (Bulletin 41).

The International adit, to the south, intersects a similar zone, up to 7.3 metres wide, which hosts lead and zinc in oxidized material.

Development work was done from two adits on the north side of Porcupine Creek at elevations of 1204 and 1356 metres.

Early work on the showings was done in two short adits; one located about 152 metres below the crest of the pass was driven 18 metres; details of this early work are lacking. The showings were rediscovered in 1943 by Ed. Haukedahl, of Ymir, and held for a number of years in association with A. Bremner and A. Phare, also of Ymir.

Leta Explorations Limited held an option on the property in 1944 and carried out about 183 metres of diamond drilling in 2 holes. International Mining Corporation (Canada) Limited, a subsidiary of International Mining Corporation acquired an option on the property in 1945. Considerable trenching was done on the Porcupine creek side of the pass and diamond drilling on one hole cut the oxidized zone 152 metres below the crest of the pass. Late in 1946 work began in extending the old 18-metre adit at a 1356-metre elevation. Part of the drift had to be abandoned due to swelling ground and from a point 47 metres from the portal drifting was continued about 9 metres in the foot-wall. By September 1947, when the option was terminated, the adit had been driven north 10 degrees east for 196 metres from the portal. Three crosscuts were driven to investigate the zone, one at 41 metres from the portal, one at 122 metres from the portal, and one at the face, 196 metres from the portal. The crosscut at the face was extended west for 23 metres and a hole was drilled down at minus 54 degrees, a distance of 115 metres, to pass through the zone which appeared to be about 5 metres wide. The company reported a total of 294 metres of drifting and crosscutting. At that horizon, about 152 metres below the pass, the zone still comprised oxidized material of sub-ore grade. In the early part of 1948 the owners drive a 24-metre adit just below the crest of the ridge on the north side of "Oxide Pass" to cut the oxide zone at an angle of about 30 degrees.

New Jersey Zinc Explorations Limited optioned the property in mid 1948, and subsequently purchased. Considerable exploratory drilling was done in the latter part of the year in an attempt to locate an unoxidized part of the zone. In 1950 a new adit ("0 x 4") was begun at the 1204-metre elevation, 152 metres below and 344 metres south 15 degrees east of the "International adit". At 122 metres from the portal running silt was encountered and work ceased. In 1952 a branch adit was begun at 89 metres from the portal and driven north for 30 metres to about 9 metres east of the caved heading. When work ceased in January 1954 the adit had been extended to a length of 266 metres.

In 1954 New Jersey Zinc Explorations Limited surrendered its charter and the property was transferred to New Jersey Zinc Exploration Company (Canada) Ltd. In 1962 the company carried out 204 metres of diamond drilling in 2 holes; an additional 140 metres in 2 holes was drilled in 1965.

The Oxide claim (15 units) was owned in 1976 by Jack Butla of Trail. A geochemical soil survey (195 samples) was carried out during the year.

Cominco Ltd. conducted geological mapping and geochemical sampling on the Oxide property in 1998. Indo Metals Ltd. acquired the property from Cominco Ltd. in 1999.

CAPSULE GEOLOGY

Limited geological descriptions indicate the development of sulphide mineralization within altered quartzitic and limestone (Reeves Member) units of the Lower Cambrian Laib Formation. The first showing is about 122 metres south of Pete Creek at 862 metres elevation. There is a small lens of sphalerite and galena at the contact between a medium to coarse-grained, tremolitic limestone and what is defined as "granitized quartzite" which may be a tongue of granitic intrusive. A chip sample across 1.53 metres at this site contained 34.3 grams per tonne silver, 3.48 per cent lead, and 5.1 per cent zinc but the mineralization is extremely limited in extent (Bulletin 41, page 135).

About 458 metres southwest of this showing there is an occurrence of massive pyrrhotite at the contact between Reeves

CAPSULE GEOLOGY

limestone and "granitized siliceous rocks". The mineralization was traced 23 metres along a strike of 075 degrees. The limestones at this site are described as crystalline, grey limestone partly altered to a green silicate rock (skarn) in contact with the above mentioned "granitized siliceous rocks". Fyles (1959) shows Laib Formation limestones and quartzites in contact with granites of the Middle to Late Jurassic Nelson Intrusions in the vicinity of the showings.

FIELD CHECK: N

CAPSULE GEOLOGY

alteration which weathers buff. Poor exposures make it difficult to identify the full extent of the dolomitization but the main showing alteration is in the order of 30 to 50 metres thick and terminates against a northwest trending, northeast dipping transverse fault about 300 metres southwest of portal 1. The dolomite thins to the northeast to less than 30 metres. Zones of dolomitization have also been identified at various stratigraphic levels in the Reeves limestone along Red Bird and Harcourt creeks. South and west of Red Bird Creek, the Reeves limestone and associated stratigraphy is masked by an east to west overthrust wedge of Lower and (?) Middle Ordovician Active Formation argillites which is in the order of 600 metres thick.

The sulphide zones consist of oxidized sphalerite, galena and pyrite which plunge to the southwest within the trend of the host limestone. The zones are oxidized to a depth of 240 to 360 metres and at surface consist of a soft, earthy groundmass containing small nodules of brown limonitic material or a whitish material containing secondary lead and zinc minerals such as cerussite, anglesite, and smithsonite. Although on surface much of the gossanous material is locally transported resulting in the extent and setting of the source being obscured, underground mapping indicates a mineralized zone parallel to host rock attitudes, which is in the order of 183 metres along strike and 0.3 to 6 metres width.

Within the oxidized zone there is up to 30 per cent combined lead and zinc with zinc being dominant. A 0.24-metre drill core sample assayed 17.5 grams per tonne silver, 3.39 per cent lead, 8.95 per cent zinc, 0.02 per cent cadmium, 0.005 per cent germanium and 0.10 grams per tonne gold (Assessment Report 14960). Minor gallium is also associated with the sulphides.

Over 650 metres of underground development has been done on the deposit from 1925 to 1974, as well as hundreds of metres of diamond drilling.

Indicated reserves at Red Bird are 2,177,040 tonnes grading 18.5 per cent zinc, 68.5 grams per tonne silver, and 6.5 per cent lead (Assessment Report 15722).

The main showings are at elevations of 760 and 915 metres on the north side of Red Bird Creek about 1.6 kilometres south-southwest of the junction of the Pend D'Oreille and Salmo Rivers.

The Red Bird group comprising the Red Bird, Lead Pot, and Lead Cup claims, was owned in 1924 by S. Coulter and A.J. Campbell, of Ymir. Conrad Wolfe and associates optioned the claims in 1925 and incorporated the Red Bird Mining Company, of Spokane. Additional staking was done to a total of 17 claims. Over 305 metres of underground exploration work during the 1925-1927 period gave disappointing results. A controlling interest in Red Bird Mining was acquired by a Vancouver syndicate who during 1928 extended the lower adit several hundred metres and carried out a small amount of diamond drilling. The syndicate in February 1929 incorporated Boundary Basin Mines, Limited. No work was reported by the company. The workings at that time comprised a lower adit some 366 metres long, and at higher elevations 2 short adits, an 11-metre shaft, and open cuts. Sixteen claims and fractions, including the Lead Cup (Lot 13466), Lead Pot (Lot 13465), and Red Top (Lot 14148) were Crown-granted to Boundary Basin Mines in 1932 and 1934.

Hecla Mining Company, of Wallace, Idaho, purchased the property in 1944. Work by the company included geological mapping and limited surface work in 1947, and bulldozer stripping and 130 metres of diamond drilling in 2 holes in 1958. Cominco Ltd. optioned the property in 1961. Work during 1961-1962 included 211 metres of drifting and crosscutting, and 1247 metres of diamond drilling in 2 holes.

Reeves MacDonald Mines, Limited obtained a lease-option agreement from Hecla in 1973 and a program of exploration was begun to test for the projected westerly extension of the Annex zone in Red Bird ground. The program included a westerly lateral and diamond drilling from the 183-metre level of the Reeves mine. This work was successful in locating the faulted extension of the Annex zone. In 1974 some 65 metres of crosscutting and drifting and 1038 metres of diamond drilling were done as part of the development program. Some 1,700 tons of development ore was milled. Further development was deferred due to the marginal character of the ore (Hecla Operating Company, 1974 Annual Report).

Hecla Mining Company continued to hold 16 Crown-granted claims. Golden Eye Minerals Ltd. in 1985 acquired an option on an 80 per cent interest in the property from Diem Mines, Limited, a Canadian subsidiary of Hecla Mining Company. Late in 1985 Golden Eye gave Teck Corporation an option.

From 1995 to 1998 Redhawk Resources Inc. consolidated the Redbird and other properties under the Remac project name and

CAPSULE GEOLOGY

acquired additional claims as well. In 1998, two holes were drilled on the Caviar No. 5 claim south of the Redbird showing, and the Beer Bottle showing just west of the Redbird showing was re-trenched. This showing was sampled giving a footwall section grading 21.93 per cent zinc, 3.11 per cent lead, and 25.37 grams per tonne silver over 6.5 metres. The overlying hangingwall section yielded 5.27 per cent zinc, 1.82 per cent lead and 3.4 grams per tonne silver over 6.3 metres (Redhawk Resources Inc. 1999 Second Quarter Report).

Redhawk optioned the adjacent Reeves MacDonald Mine property (082FSW026) in April 2000 and plans to explore it and the Redbird property with joint ventures partner ZincOx Resources under the Remac project name. Historic properties included under this project include: Reeves MacDonald (082FSW026), Point (082FSW027), O'Donnell (082FSW029), and Annex (082FSW219).

The extensive, overlying zinc-oxide capping was not mined due to the lack of extraction technology at that time. The zinc oxide deposits occur over a distance of 3 kilometres, extend from the surface to a depth of up to 450 metres and contain zinc grades comparable to those of the primary sulphides. In 2000, Redhawk conducted a trenching and 2600-metre reverse-circulation drilling program to confirm the structural continuity and overall zinc grades of the oxidized zones. Highlights of the program included: Hole R-2000-02 (zone B) which assayed 15.43 per cent zinc and 1.55 per cent lead over 5.3 metres, and Hole R-2000-09 (zone C) which assayed 8.68 per cent zinc and 4.27 per cent lead over 12.2 metres. Follow-up drilling is planned for 2001. Metallurgical testing to demonstrate that zinc metal can be economically extracted from the oxides using new recovery technology is planned for 2001.

CAPSULE GEOLOGY

or upslope from the No. 3 to the No. 1 adit, contains a section of Lower Cambrian Laib Formation black phyllites and siliceous grey argillites in fault contact with micaceous quartzites of the Lower and Upper Nevada members of the Lower Cambrian Quartzite Range Formation, which in turn are in conformable contact with a thick section of Lower Cambrian, Reno Formation micaceous quartzites. Reno Formation quartzites act as structural hanging wall and footwall to Reeves Member limestone (Laib Formation) which is host to the sulphide occurrence. To the north a second, thinner unit of Reeves limestone, in conformable contact with black phyllites of the upper Laib Formation, acts as the structural footwall to the more north unit of Reno Formation quartzites.

The main sulphide showing is on the sheared footwall contact of the Reeves limestone with Reno Formation micaceous quartzites. Smaller sulphide showings occur to the north within quartzite, limestone, and argillites. The main showing consists of two bands or lenses of coarsely crystalline galena, high iron sphalerite and pyrite with manganiferous siderite and locally arsenopyrite. The sulphides are shear controlled and partly replace the hangingwall limestone. Including sheared country rock the zone has a maximum thickness of 3 metres and thins along strike in both directions. The sulphides are relatively thick within a central, 15-metre long zone and then thin and disappear over a further 6 metres. The sulphides apparently disappear within 60 metres down dip.

The mineralization differs from the Reeves-MacDonald (082FSW026) type ore and is apparently more similar to that found at the Emerald mine (082FSW310). The deposit is primarily lead-zinc with variable amounts of pyrite but the sulphide proportions vary greatly at different locations. In contrast to other Reeves limestone deposits, the Red Rock occurrence has no dolomite associated with the sulphides. There is little oxidation of the sulphide ores. From sporadic production in 7 years between 1935 and 1979, a total 525 tonnes of ore were mined yielding 154,738 grams of silver, 155 grams of gold, 16 kilograms of copper, 85,059 kilograms of lead and 94,987 kilograms of zinc. The high proportion of silver indicates a high temperature epigenetic manto-type replacement deposit.

CAPSULE GEOLOGY

drilling during this period totalled about 3048 metres. Five promising ore zones were indicated.

Reeves MacDonald Mines, Limited, was incorporated in 1928 with Pend D'Oreille Mines & Metals Company, of Spokane, holding a controlling interest; the Victoria Syndicate retained a small interest in the new company. During 1929 the 1900 level was driven to intersect the Reeves orebody. Operations were suspended in 1930. The Drumlumin (Lot 12076), International Lead No. I (Lot 12692) and a number of other claims were Crown-granted to the company in 1931. Further crosscutting, and diamond drilling, was done in the 1,900 level during 1937-38. Work resumed in 1947 with a view to bringing the mine into production. A 450 tonne-per-day concentrator was installed and put into operation in August 1949; concentrator capacity was increased to 900 tons-per-day in 1950. With the exception of a two year closure (1953-1955) due to a decline in metal prices, operations were continuous until July 1971 when the ore reserves were depleted and the mine closed. The mine was developed from the 2438-metre long 1,900 level main haulage, and on the upper 2,650 level. The two levels are connected by an internal 55 degree shaft. Two internal inclined shafts extend from the 1,900 to the 1,100 level. Development work was carried to the 17-metre level, 562 metres below the 1,900 level. The B.L. and O'Donnell orebodies were developed from separate openings established at the 2,350 level.

Subsequent mining operations were carried out on the Annex part of the property (see 82 F/3, Zn 4).

Some salvage mining was done during the years 1972-1974, inclusive. Lateral development work and raising in 1974 totalled 252 metres. The mine and mill closed in April 1975.

The Reeves MacDonald zinc-lead-silver-cadmium mine is a Kootenay Arc-type sedimentary exhalative deposit hosted by a dolomitized envelope of Reeves Member limestone of the Lower Cambrian Laib Formation. Production from the various Reeves MacDonald orebodies for the period 1949 to 1971 inclusive, totalled 5,848,021 tonnes. From this ore 19,842 kilograms of silver, 203,616,006 kilograms of zinc, 57,692,784 kilograms of lead, 1,215,665 kilograms of cadmium and 27,584 kilograms of copper were recovered.

The Reeves, B.L., O'Donnell (082FSW028) and No. 4 and/or Prospect (082FSW029) orebodies are all faulted segments of a single ore zone located on the axis of the Reeves syncline which is developed as a secondary fold on the south limb of the Salmo River anticline. The Point (082FSW027), Prospect (082FSW029), and MacDonald are separate deposits although the Red Bird (082FSW024), Annex (082FSW219), and MacDonald are probably related by the same style of faulting as the above orebodies. The orebodies are fairly continuous downplunge but are segmented by a series of north striking normal faults which dip shallowly 25 to 40 degrees east and which downfault portions of the sulphide zone to the east.

The Reeves syncline plunges about 55 degrees southwest on a bearing of 215 degrees. It contains a core of Reeves limestone with massive sulphides within an envelope of dolomite along the synclinal axis. Truman Member (Laib Formation) green and brown phyllites, with minor limestone form the hangingwall and footwall limbs of the syncline and to the south the Truman Member is in fault contact with black and green phyllites of the Emerald Member (Laib Formation). On the north limb, the footwall side, phyllites of the Truman Member are in conformable contact with white quartzites of the Lower Cambrian Reno Formation.

The Reeves Member near the Reeves MacDonald mine is repeated three times by folding. It is found on both limbs of the Salmo River anticline and south of the anticline in what is known locally as the "Prospect Member". The Reeves Member is mainly limestone and locally contains dolomite. Small lenses of dolomite occur close to the Point, Reeves, B.L. and O'Donnell orebodies, and extensive masses are found in the Prospect Member.

The Reeves limestone is a grey weathering, grey or black and white banded rock. It is finely crystalline and locally massive. Dark grey bands are carbonaceous and may contain very fine muscovite. Although coarsely crystalline calcite and dolomite are usually present as crosscutting veinlets, the dolomitized zones are finer grained than the limestones and are of two general types:

- 1) Dolomite close to sulphides is usually mottled or has a streaky banding identified as a "tweedy" texture. This dolomite commonly has a lineation which plunges steeply southwest.
- 2) Dolomite in the Prospect Member is generally massive and light grey. Locally, it may be darker grey and poorly banded. Near the Pend d'Oreille River and locally near the Prospect adits, it is black and highly siliceous.

CAPSULE GEOLOGY

The Reeves ore zone is in the form of an attenuated syncline with limbs striking west and a plunge parallel to the axis of the Reeves syncline. Along the axial plane the orebody is about 105 metres long by 25 metres wide. The north limb extends about 150 metres to the west and is 0.3 to 0.6 metre thick although it thins to the west. The south, hangingwall limb contains only low grade discontinuous sulphides.

Sulphides occur as well-laminated bands and lenses of massive and disseminated pyrite, honey-colored sphalerite and galena in a medium to dark grey banded dolomite. Laminations are generally discontinuous and locally highly contorted. Commonly, the ore is brecciated, particularly on the synclinal limbs and the breccias contain rounded to angular, rotated fragments of dolomite and limestone in a sulphide matrix. Breccias are usually rich in pyrite. The ore is cut by narrow veinlets of coarsely crystalline white calcite, dolomite, and quartz with minor sphalerite and galena.

The Reeves-type sulphide ores contain an average of 1 per cent lead and 3 to 6 per cent zinc with a relatively consistent lead:zinc ratio of 1:5. Concentrations of other metals vary locally but silver is usually present in amounts of less than 34 grams per tonne. Copper may occur at up to 0.5 per cent locally and cadmium is present in the order of less than 1 gram per tonne based on production records from 1949 to 1971. Minor gallium and germanium has been reported from grab samples but average values and distribution is unknown.

The small amount of production from salvage mining (1972-1974) is recorded with the statistics of the Annex deposit (082FSW219). The Reeves MacDonald mine and mill were closed in April 1975.

The MacDonald ore zone is completely weathered limonitic clay containing secondary lead and zinc minerals. The portal of the MacDonald adit, located about 330 metres upstream from the Point zone, was caved about 1954. The 1900 level portal of the Reeves mine occurs about 120 metres east of the MacDonald adit and is considered to have been driven through part of the MacDonald zone.

In April 2000, Redhawk Resources Ltd. announced an option agreement with Reeves MacDonald Mines Limited on the Reeves MacDonald property. Redhawk along with joint venture partner ZincOx Resources will explore the Reeves MacDonald, Redbird (082FSW024) and Annex (082FSW219) properties under the Remac project name. See Redbird for further details.

CAPSULE GEOLOGY

The Point deposit, on the south limb of the Salmo River anticline, is located on the north side of the Pend d'Oreille River, about 450 metres west of the 1900 level portal of the Reeves MacDonald mine (082FSW026). The Reeves MacDonald mine and associated occurrences are Kootenay Arc-type sedimentary exhalative deposits.

The zinc-lead mineralization occurs within irregular, tabular or pod shaped envelopes of dolomitized limestone of the Lower Cambrian Reeves Member, Laib Formation. These limestones occur in a package of sediments with a general east-west trend but within a complex synclinal structure containing southwest plunging "Z" shaped drag folds and lineations.

The Reeves limestone is a grey weathering, grey or black and white banded rock. It is finely crystalline and locally massive. Dark grey bands are carbonaceous and may contain very fine muscovite. Dolomitized zones are finer-grained than the limestones although coarsely crystalline calcite and dolomite is usually present as crosscutting veinlets. There are two basic textural types:

- 1) Dolomite close to sulphides is usually mottled or has a streaky banding identified as a "tweedy" texture. This dolomite commonly has a lineation which plunges steeply southwest.
- 2) Dolomite in the "Prospect Member" is generally massive and light grey. Locally, it may be darker grey and poorly banded. Near the Pend d'Oreille River and locally near the Prospect adits, it is black and highly siliceous. See Reeves MacDonald (082FSW026) for an explanation of the "Prospect Member" and other related geological information.

Mineralization consists of bands and lenses of massive and disseminated pyrite, honey-colored sphalerite, and galena. The Point

CAPSULE GEOLOGY

ore zone consists of two sulphide horizons, each about 6 metres thick and separated by about 18 metres of barren dolomite. Disseminated, fine-grained yellow sphalerite and occasional grains of galena occur in a matrix of brecciated dolomite. Irregular, tabular masses of limonitic gossan probably represent original bodies of pyrite.

By 1960, no development had taken place on the Point zone and there is no mention of this zone after this period.

Refer to the Reeves MacDonald mine (082FSW026) for further details.

CAPSULE GEOLOGY

The O'Donnell orebody is a Kootenay Arc type sedimentary exhalative deposit situated within a dolomitized envelope of the Reeves Member limestone of the Lower Cambrian Laib Formation. The O'Donnell orebody, along with the Reeves, B.L. and No. 4 ore bodies which together make up the Reeves MacDonald mine (082FSW026), are all fault displaced segments of a single ore zone located on the axis of the Reeves syncline. The Reeves syncline is developed as a secondary fold on the south limb of the Salmo River anticline. Refer to the Reeves MacDonald for a summary of area geology and for production statistics which include O'Donnell ore.

The O'Donnell orebody, exposed in the O'Donnell adit, is enveloped by dolomite and seems to have a shape and plunge comparable to the Reeves orebody although the barren limestone between the dolomite halo and the Truman Member (Laib Formation) phyllites is thinner than it is to the west. The Reeves orebody is in the form of an attenuated syncline with limbs striking west and plunging parallel to the axis of the Reeves syncline.

Sulphides in the Reeves MacDonald orebodies occur as well laminated bands, lenses, and as disseminated pyrite, honey-colored sphalerite, and galena in a medium to dark grey banded dolomite. Laminations are generally discontinuous and locally highly contorted. Commonly the ore is brecciated, particularly on the synclinal limbs

CAPSULE GEOLOGY

and the breccias contain rounded to angular, rotated fragments of dolomite and limestone in a sulphide matrix. Breccias are usually rich in pyrite. Copper locally, may be about 0.5 per cent and cadmium is in the order of less than 1 gram per tonne, based on production records from 1949 to 1971. Minor gallium and germanium have been reported from grab samples. The ore is cut by narrow veinlets of coarsely crystalline, white calcite, dolomite and quartz with minor sphalerite and galena.

In April 2000, Redhawk Resources Ltd. announced an option agreement with Reeves MacDonald Mines Limited on the Reeves MacDonald property which includes the O'Donnell. Redhawk along with joint venture partner, ZincOx Resources will explore the Reeve MacDonald, Red Bird (082FSW024) and Annex (082FSW219) properties under the Remac project name. See Redbird (082FSW024) for further details.

CAPSULE GEOLOGY

mineralization with limited extent. By 1960, the zone has been tested by two short adits which expose very irregular and sparse mineralization containing spot highs of 10 per cent lead and 9 per cent zinc over widths of about 60 centimetres (Geological Survey of Canada Memoir 172, page 61). Surface trenching has exposed oxidized zones greater than 4 metres wide (Bulletin 41, page 146). It is not clear whether or not the Prospect deposit was developed further and contributed to the production of the Reeves MacDonald mine.

In April 2000, Redhawk Resources Ltd. announced an option agreement with Reeves MacDonald Mines Limited on the Reeves MacDonald property which includes the Prospect. Redhawk, along with a joint venture partner, ZincOx Resources will explore the Reeves MacDonald, Redbird (082FSW024) and Annex (082FSW219) properties under the Remac project name. See the Redbird occurrence for further details.

possibly sheared and silicified, and contain sparsely disseminated sulphides. The best assays from grab samples contain up to 1.4 grams per tonne gold, up to 70 grams per tonne silver, 1 to 4 per cent zinc and 3 to 7 per cent lead (Assessment Report 14903). Chip samples across vein widths on a regular spacing may be significantly lower in metal content.

From the Florence property, in 1937, 6 tonnes of ore were shipped yielding 2,343 grams of silver, 46 kilograms of lead and 83 kilograms of zinc; it is unclear if the property is related to the Salmo-Consolidated.

CAPSULE GEOLOGY

Lower Cambrian Laib Formation limestones (Reeves Member) and micaceous quartzites are exposed with what are likely Active Formation black, graphitic argillites on the north and south side of the Salmo River at Shenango Canyon. The geology described is similar to that in the vicinity of the Lone Silver (082FSW019) occurrence to the east; the Shenango occurrence is along the west strike extension of the Black Bluff fault. Highly sheared, graphitic argillite is exposed in an adit south of the Salmo River.

Mineralization is of two types:

- (1) A sulphide bearing quartz vein, averages 15 centimetres in width, strikes northeast and dips shallowly to the southeast. The vein contains a white quartz gangue with small lenses of galena, sphalerite, and pyrite. A sample across 76 centimetres contained 44.56 grams per tonne silver, 1.06 per cent lead, and 2.5 per cent zinc (Bulletin 41, page 149).
- (2) A zone 3 to 5 metres wide of Reeves Member limestone contains disseminated pyrite with minor galena and sphalerite. The zone is restricted to the south side of the northerly band of limestone and the sulphides are traceable along 125 metres of

CAPSULE GEOLOGY

strike length. Analysis indicates less than 1 per cent combined lead and zinc and less than 30 grams per tonne silver within the disseminated zone (Bulletin 41, page 149).

CAPSULE GEOLOGY

The Silver Bell occurrence lies at about 1952 metres elevation along a northwest trending ridge formed along the contact of Lower to Middle Ordovician Active Formation limestones and the Hidden Creek granodiorite stock of the Middle to Late Jurassic Nelson Intrusions. Along the contact, grey crystalline limestone is locally altered to coarse calcite and actinolite and in places to garnet, actinolite and other lime silicates typical of skarn zones. The limestones have a general northeast trend with steep dips while the intrusive contact appears to dip east.

Mineralization consists of minor pyrite and barite within altered limestones about 1 metre from the granodiorite contact. In addition three zones of brecciated limestone, 1.2, 0.76, and 2.7 metres wide respectively, contain small pockets of dark brown sphalerite.

COMMENTS: The sample width is 0.20 metres.
REFERENCE: Bulletin 41, page 152.

CAPSULE GEOLOGY

A large anticlinal structure is exposed within Lower Cambrian Laib Formation and Lower Cambrian Reno Formation stratigraphy along the west flank of Truman Hill. The Reeves Member limestones (Laib Formation) are exposed on the east limb, near the Mona adit and also on the west limb near the base of the hill near the Trillium adit. To the east, the anticlinal stratigraphy is in fault contact with argillites of the Ordovician Active Formation. Reeves limestones are underlain by phyllites, argillites and quartzites of the Truman Member (Laib Formation) and the core of the anticline contains micaceous quartzites of the Reno Formation overlying white and brown, more massive quartzites of the Nevada Member of the Lower Cambrian Quartzite Range Formation.

Mineralization appears confined to dolomitized limestone at the base of the Reeves Formation. It consists of pyrite, pyrrhotite,

CAPSULE GEOLOGY

sphalerite, and galena both disseminated and in masses within 60 to 100 centimetre thick dolomite bands interlayered with barren limestone. In the Trillium adit the sulphides are coarser-grained, and more massive than at the Mona and occur associated with the sheared contact between whitish dolomite of the Reeves Formation and siliceous argillite of the Truman Member. The sulphides appear to be more closely related to the argillites at this location.

A 20 centimetre chip sample across the best mineralization assayed 137.2 grams per tonne silver, 7.41 per cent lead and 17.1 per cent zinc (Bulletin 41, page 152). The deposit description, along with the high amount of silver, indicates a manto-type deposit.

Sultan Minerals Inc. is exploring the area.

Zinc	8.4000	Per cent

COMMENTS: The sample width is 0.68 metres.
REFERENCE: Bulletin 41, page 153.

CAPSULE GEOLOGY

Disseminated pyrite and dark brown sphalerite occur within dolomite zones parallel to the banding of the Lower Cambrian Reeves Member (Laib Formation) limestones. The 30 to 90 centimetre wide mineralized horizons are separated by barren dolomites. Total width of the mineralized zone including barren dolomites is about 2 to 3 metres and the zone is underlain by unaltered limestones and argillites. The best assay was across 68 centimetres which contained 6.86 grams per tonne silver, 0.27 per cent lead and 8.4 per cent zinc (Bulletin 41, page 153). Other analysis indicated lower metal contents over similar widths.

Regionally, the attitudes of banding and the distribution of dolomite indicates that it and the showing occur in an open, south plunging syncline, with complex internal folding and faulting of the Lower Cambrian Laib Formation. To the east the Laib Formation is in fault contact with quartzites of the Reno Formation.

CAPSULE GEOLOGY

The Reno-Donnybrook property is on the west limb of the western anticline in quartzites of the Lower Cambrian Reno Formation (correlative with rocks of the Hamill Group). The quartzites are in contact immediately to the west with argillites and calcareous argillites of the Lower Cambrian Laib Formation.

A series of quartz veins, containing visible gold, occur in Reno Formation quartzites, strike 012 degrees and dip vertically to steeply south. Gangue is quartz with occasional quartzite. Metallic sulphides are almost completely absent although visible gold occurs most frequently in areas of quartz stained with limonite.

On the Reno-Donnybrook property, seven parallel quartz veins called the Lake, Clarence, Donnybrook, No. 3 (Middle), No. 1 (or Reno Vein), No. 2, and Crescent have been identified north to south. South of the Crescent, quartz float indicates the possible presence of other veins. Most work has been concentrated on the No. 1, or Reno Vein, but the Donnybrook Vein, 518 metres north, is a well-defined 1 metre wide vein striking 080 degrees and dipping 80 degrees south. It is less oxidized than the Reno and gold values are lower. The Clarence and Lake veins to the north are similar to the Donnybrook Vein.

Refer to the Reno property (082FSW036) for a summary of the Sheep Creek mining camp.

CAPSULE GEOLOGY

silver, 2,858 kilograms of copper, 89,056 kilograms of lead and 60,907 tonnes of zinc. Some of this production has come from other nearby workings such as the Donnybrook (082FSW035) and the Bluestone (082FSW037).

The Sheep Creek mining camp consists of auriferous sulphide mineralization within a regional system of quartz veins controlled by faults. The camp hosts four distinct fault/fracture systems. All productive veins are associated with faults trending northeast and dipping southeast. The veins are particularly productive where they cross the axis of the two regional, northerly trending anticlines which dominate the geology of the camp. In addition there are a few northwest trending strike slip faults, north trending normal faults and flat faults, on which the hanging wall has been thrust westwards.

Ore occurs in shoots and is almost without exception confined to parts of fault zones in which one or both walls are quartzite. Other parts of the veins are either too narrow or low grade to be economic. The ore shoots are found at the intersection of northeast faults with quartzite stratigraphy, particularly the Upper Nugget and Upper Nevada Members of the Lower Cambrian Quartzite Range Formation (correlative with rocks of the Hamill Group). The underlying Motherlode quartzite is, without obvious reason, almost completely barren of economic gold mineralization. The veins contain a quartz gangue containing pyrite with lesser amounts of pyrrhotite, chalcopyrite, galena, and sphalerite. Visible gold is rare. Precious metal grades are exceedingly variable and zones of high grade appear to be distributed randomly. Such zones or ore shoots are rarely greater than a few tens of metres in size.

Throughout the camp, economic mineralization is found within a vertical range of less than 500 metres in any given vein and from north to south in the camp this vertical range occurs at progressively lower elevations. At the north end of the camp, near Reno Mountain, the economic zone lies at about 1675 to 2150 metres elevation and at the south end near Mount Waldie the zone is entirely below 915 metres above sea level. The veins may occur above the economic zone but are generally too narrow and below the zone the veins usually persist but are commonly wider and of lower grade. Higher grades of greater than 150 grams per tonne are generally restricted to the top of the zone.

CAPSULE GEOLOGY

The Bluestone vein is a northeast trending quartz vein along a fault plane and is similar to the parallel veins at the Reno mine (082FSW036). Quartz is the gangue with ore consisting of some visible gold with disseminated pyrite. A geological cross-section by Starr (1940) shows two adits driven at 060 degrees into the western limb of the western anticline. The upper and lower adits start in argillite of the Lower Cambrian Reno Formation (correlative with Hamill Group rocks) and after about 65 and 130 metres, respectively, they enter quartzite of the Nevada Member of the Lower Cambrian Quartzite Range Formation (correlative with rocks of the Hamill Group). The upper and lower adits remain in the Nevada Member for about 45 and 140 metres, respectively, whereupon they re-enter Reno Formation argillites on the anticline's eastern limb. It is within the quartzites of the Nevada Member that the ore veins occur.

The property has belonged to Reno Gold Mines and the Gold Belt Mining Co. at various times but little specific information is recorded regarding grades and production, which is included with those mines. The Bluestone vein was not as productive as other related veins in the area. The tonnage mined to December 31, 1951 was 3174 tonnes, from which 40435 grams of gold was recovered (Bulletin 31, page 52).

Refer to the Reno mine for a summary of the Sheep Creek mining camp.

CAPSULE GEOLOGY

The Cayote mine consists of over 570 metres of underground workings which tested northeast trending quartz veins within Lower Cambrian Reno Formation quartzites and Lower Cambrian Laib Formation argillites and calcareous sediments. The Laib Formation is correlative with the Lardeau Group and the Reno Formation with the Hamill Group.

The adit exposes one of the five major north trending normal faults known in the Sheep Creek camp. Some gold and silver values are reported from the Cayote but production is included with the Reno mine (082FSW036). It is difficult to identify grades and tonnages originating from the Cayote adit although it is apparent that results of the development were economically unsatisfactory.

In 1987, Lightning Minerals Inc. drilled four holes on the occurrence. The highest assay result achieved was 2.78 grams per tonne gold over a 0.30 metre interval (Assessment Report 16833).

Refer to the Reno mine for a summary of the Sheep Creek mining camp.

CAPSULE GEOLOGY

The Nugget veins occur within white quartzites, argillic quartzites and argillites of the Hadrynian-Lower Cambrian Reno and Quartzite Range formations (Hamill Group). Gold-bearing ore shoots are within quartzites of the Upper and Middle Nugget Member and Nevada Member of the Quartzite Range Formation. The ore shoots may be up to about one metre wide and are in the order of 10 to 60 metres along strike. The main workings have intersected the same shoot along a vertical extension in the order of 100 metres. Although there are a number of documented parallel veins (7), most production came from two main veins, the Calhoun and the Nugget, which are about 30 metres apart (Bulletin 31).

The sediments strike from 010 to 015 degrees and dip 60 degrees east and the showing lies on the west limb of the eastern anticline. The more northerly of the two main veins strikes 60 degrees and the southerly vein strikes 065 to 070 degrees. In the upper levels the veins dip about 75 degrees south but steepen at depth, while for most veins in the Sheep Creek camp the dips are near vertical and shallow with depth. The quartz veins may be very narrow or up to about one metre wide and contain crushed country rock and commonly bifurcate. There is little evidence of fresh sulphides even in the lower workings as they have been oxidized to limonite in association with disseminated free gold. Gold grades in the Nugget veins were apparently some of the higher values found in the camp and production records indicate much of the material contained about 35 grams per tonne gold. Mineralization in the veins includes pyrite, pyrrhotite, chalcocopyrite, galena, sphalerite and native gold.

Production figures have been intertwined historically between the Nugget and Motherlode (082FSW041) and later the Reno (082FSW036) occurrence. Production values have been separated out among the three as best as possible but some error may still exist. About 37,000 tonnes of ore was produced from the Nugget and 768 kilograms of gold, 283 kilograms of silver, 3294 kilograms of lead and 1273 kilograms of zinc recovered. Most production took place between 1907 and 1954.

Indicated reserves on the Nugget property are 30,089 tonnes grading 16.1 grams per tonne gold; indicated reserves on the Calhoun zone are 15,184 tonnes grading 15.4 grams per tonne gold; indicated reserves on the Fawn zone are 3,882 tonnes grading 28.4 grams per tonne gold (George Cross News Letter No. 217 (November 12), 1987).

Refer to the Motherlode (082FSW041) for a summary of the Sheep Creek mining camp.

FIELD CHECK: N

CAPSULE GEOLOGY

economic gold mineralization. The veins contain a quartz gangue containing pyrite with lesser amounts of pyrrhotite, chalcopyrite, galena, and sphalerite. Visible gold is rare. Precious metal grades are exceedingly variable and zones of high grade appear to be distributed randomly. Such zones or ore shoots are rarely greater than a few tens of metres in size.

Throughout the camp economic mineralization is found within a vertical range of less than 500 metres in any given vein and from north to south in the camp this vertical range occurs at progressively lower elevations. At the north end of the camp near Reno Mountain the economic zone lies at about 1675 to 2150 metres elevation and at the south end near Mount Waldie the zone is entirely below 915 metres above sea level. Above the economic zone the veins may occur but are generally too narrow and below the zone the veins usually persist but are commonly wider and of lower grade. Higher grades of greater than 150 grams per tonne are generally restricted to the top of the zone.

The Motherlode occurrence is south of the Nugget (082FSW040) and occurs within coarse, white to grey quartzite with interbeds of argillite and schist of the Lower Cambrian Quartzite Range Formation. The most westerly workings are close to the contact with the lower part of the Lower Cambrian Reno Formation (correlative with rocks of the Hamill Group). Two gold bearing ore shoots, the Motherlode and Independence, were discovered on surface within the Motherlode vein which strikes 70 to 75 degrees and dips near vertically. The ore shoots rarely exceed 1 metre.

They are about 100 metres along strike and the Independence ore shoot has been tested to a depth of about 190 metres. The Motherlode ore shoot was tested to a depth of about 147 metres. The two shoots are 168 metres apart and there is one very small ore shoot between them.

Mineralization consists of a gangue of vein quartz with some crushed country rock which has been oxidized leaving brown iron oxides and free gold. Oxidation is documented at the lowest mining levels.

Production figures have been intertwined historically between the Motherlode and Nugget (082FSW040) and later the Reno (082FSW036) occurrence. These production values have been separated out among the three as best as possible but some error may still exist.

Production from these shoots between 1906 and 1985 amounted to about 67,444 tonnes which contained 1,257 kilograms of gold and 588 kilograms of silver, 3010 kilograms of copper, 11,000 kilograms of lead and 4260 kilograms of zinc. Of the total mined, about 64,760 tonnes was mined between 1906 and 1922. Indicated reserves are reported to total 3,152 tonnes grading 12.0 grams per tonne gold (George Cross News Letter No.217 (November 12), 1987).

CAPSULE GEOLOGY

Fr., Sunbeam Fr., and Double Joint claims.

A theory put forth in 1934 that the favorable host rock lay on the crest of an anticline and should occur at depth led to North American Mines, Inc. acquiring an option on a share interest in Gold Belt Mining. At the instigation of North American, several holes were drilled down from the 600 level (altitude 1538 metres) in the late spring of 1935 to confirm the presence of the quartzites, and in the latter part of that year a long low-level crosscut (1,850 level) was driven at the 1158 metres elevation to explore these favourable beds. By July of the following year this crosscut had been driven 960 metres from the portal and several veins had been intersected. Drifts totalling 288 metres on the 2360 vein, 130 metres on the 2590 vein, and 122 metres on the 3040 vein revealed no orebodies; with few exceptions the assays indicated subcommercial grade. After almost 1524 metres of workings on the 1850 level had yielded no ore, the management was reluctant to expend more money on exploration, but one other vein zone exposed in the crosscut was tested. This vein zone had been intersected 457 metres from the adit portal in argillaceous schists, and it would be necessary to drift westward for several hundred metres before favourable wallrocks would be encountered. The sole encouragement for this work was the fact that a small amount of ore had been recovered from surface workings (the Columbia adits) in what appeared to be this vein zone. The distance from the crosscut to the quartzites proved even greater than had been anticipated amounting to slightly more than 259 metres, but a few metres beyond the eastern edge of the quartzites, on what is now known as the 8000 vein, the drift entered a low-grade oreshoot, and a few hundred metres farther west higher-grade ore averaging almost 1 metre in width was encountered. The results of development on this vein and on a parallel vein 61 metres to the north were so encouraging that another crosscut, the 2100, was driven from the 1098 metre elevation and 610 metres southwest of the 1850 level to explore these veins 76 metres lower. This crosscut intersected another vein, the 6600, which had been prospected in the early part of the century, and which had yielded a few tons of ore from the Nevada adit. The 8000 vein at the 2100 level contained three orebodies, but the work on the 8200 vein disclosed only subcommercial grades. A 150 ton per day cyanide mill was put into operation in October 1938. The development work from 1935 and mill construction were financed by North American under the option agreement, giving them a controlling interest in Gold Belt Mining. In 1941 work began to drive a raise from the 1400 level to connect with the old 600 level but was not completed before the suspension of development work in July 1942. The mine closed in July 1943 due to wartime conditions. Development work during the period 1939-42 totalled about 6096 metres of drifts, crosscuts and raises.

In the fall of 1945 about 305 metres of drifting and crosscutting was carried out on the 600 level. A raise from 1400 level was advanced 152 metres to the 600 level. Development work in 1946 included 500 metres of drifting, 459 metres of crosscutting, and 143 metres of raise. This work exposed an ore shoot 52 metres on 1100 level on 3500 vein between 1400 and 1100 levels. In 1947 about 3352 metres of drifting and crosscutting was done in exploring the 3040 and 3500 veins westward on the 1100, 1400, and 1600 levels. The mine closed at the end of March 1947. The mill equipment was sold in 1948 and the mill building demolished by a snowslide in 1949. Gold Belt Mining Company, Limited was dissolved in 1950 and all its assets transferred to the parent company North American Mines, Inc. Lessees shipped small amounts of ore in 1950. A. Burgess & Associates of Salmo mined a small amount of ore from 3500 vein east on No. 14 level in 1951. Lessee A. Endersby mined small remnants of ore during the period 1958-1967.

Goldbelt Mines Inc. was incorporated in July 1976 to acquire the property. By 1979 the company had paid the entire purchase price under the option agreement with North American Mines, Inc. Work to 1980 included rehabilitation of the workings, the installation of equipment, and raising on one of the veins. Probable and possible reserves in the 1067 metres vein were estimated in 1978 at 15,658 tonnes at 15.05 grams per tonne gold (Northern Miner, April 10, 1980). About 900 tonnes of ore were shipped to Trail in 1979 and by April 1990 about 3600 tonnes were stockpiled. In 1981, 3 new levels were being driven on the 3500 vein and a start was made in shipping 6350 tonnes grading 8.57 grams per tonne gold to the nearby HB mill of David Minerals Ltd. Exploration outlined 36,290 tonnes of proven ore grading better than 17.1 grams per tonne gold (Northern Miner, December 17, 1981). In April 1982, operations were suspended after 9070 tonnes were stockpiled.

The Sheep Creek mining camp consists of auriferous sulphide mineralization within a regional system of quartz veins controlled by

CAPSULE GEOLOGY

faults. The camp hosts four distinct fault/fracture systems. All productive veins are associated with faults trending northeast and dipping southeast. The veins are particularly productive where they cross the axis of the two regional, northerly trending anticlines which dominate the geology of the camp. In addition there are a few northwest trending strike-slip faults, north trending normal faults and flat faults, on which the hanging wall has been thrust westwards.

Ore occurs in shoots and is almost without exception confined to parts of fault zones in which one or both walls are quartzite. Other parts of the veins are either too narrow or low grade to be economic. The ore shoots are found at the intersection of northeast faults with quartzite stratigraphy, particularly the Upper Nugget and Upper Nevada Members of the Quartzite Range Formation and to a lesser extent the Reno Formation. Both of these formations are of Hadrynian-Lower Cambrian age and are part of the Hamill Group. The underlying Motherlode quartzite is, without obvious reason, almost completely barren of economic gold mineralization. The veins contain a quartz gangue containing pyrite with lesser amounts of pyrrhotite, chalcopyrite, galena, sphalerite and rare visible gold. Precious metal grades are exceedingly variable and zones of high grade appear to be distributed randomly. Such zones or ore shoots are rarely greater than a few tens of metres in size.

Throughout the camp, economic mineralization is found within a vertical range of less than 500 metres in any given vein and from north to south this vertical range occurs at progressively lower elevations. At the north end of the camp near Reno Mountain, the economic zone lies at about 1675 to 2150 metres elevation and at the south end near Mount Waldie, the zone is entirely below 915 metres above sea level. The veins may occur above the economic zone but are generally too narrow, and below the zone the veins usually persist but are commonly wider and of lower grade. Higher grades of greater than 150 grams per tonne are generally restricted to the top of the zone.

The Gold Belt occurrence consists of two main veins and several lesser parallel fractures. The major production was from the 8200 vein (Columbia) and the 8000 vein (Gold Belt) which lie within the western overturned anticline. The veins crosscut Lower and Upper Nevada Member quartzites of the Quartzite Range Formation and extend east and west into the Reno Formation and Lower Cambrian Laib Formation. Ore zones were almost entirely within Lower Nevada Member quartzites and to a lesser extent in the Upper Nevada Member. As the veins pass into the Reno Formation they become narrow and uneconomic. Mineralization consists of quartz and crushed country rock with disseminated pyrite, galena and sphalerite. Visible free gold was present in much of the ore. Oxidation was shallow or absent in these veins.

A total of 236,502 tonnes of ore were mined between 1934 and 1979, from which was recovered 2,512,906 grams of gold, 1,061,298 grams of silver, 681 kilograms of copper, 10,457 kilograms of lead and 6,605 kilograms of zinc. Some of the ore mined may have come from other nearby sources such as the Bluestone occurrence (082FSW037).

CAPSULE GEOLOGY

The Gold Belt property covers ground located west of the Motherlode (082FSW041) and Golden Belle (082FSW043) mines, between Sheep Creek on the south and the south slope of Reno Mountain on the north, some 11.2 kilometres southeast of Salmo. The principal claims include the Joint (Lot 8344) (082FSW259), Double Joint (Lot 8345), Navada (Lot 8869), and Columbia (Lot 8870) (082FSW044).

The Navada was staked in 1905 at about 1371 metres and Crown-granted in 1911 to H. Amas and A. Pool. A 51-metre adit was driven on the Navada claim.

The Navada vein is part of the old Gold Belt property (082FSW044). The vein is a northeast trending fissure typical of the Sheep Creek camp (refer to the Gold Belt property for details of the camp geology and exploration and development). It is near vertical and hosted by Lower Cambrian Reno Formation quartzites (correlative with the Hamill Group) along the western anticline.

The vein is very narrow and carries a quartz gangue with disseminated pyrite, arsenopyrite and some galena and sphalerite. One sample across 25 centimetres assayed 7.2 grams per tonne gold and 13.71 grams per tonne silver (Geological Survey of Canada Memoir 172, page 34). Access at lower levels was via the Dixie adit. The vein has

CAPSULE GEOLOGY

been designated the Nevada, Dixie or 6600 vein in various references.
Tonnage mined to the end of 1950 was 33,500 tonnes from which
11,725 ounces of gold was recovered (Bulletin 31, p. 52).

CAPSULE GEOLOGY

mineralization within a regional system of quartz veins controlled by faults. The camp hosts four distinct fault/fracture systems. All productive veins are associated with faults trending northeast and dipping southeast. The veins are particularly productive where they cross the axis of the two regional, northerly trending anticlines which dominate the geology of the camp. In addition there are a few northwest trending strike slip faults, north trending normal faults and flat faults, on which the hanging wall has been thrust westwards.

Ore occurs in shoots and is almost without exception confined to parts of fault zones in which one or both walls are quartzite. Other parts of the veins are either too narrow or low grade to be economic. The ore shoots are found at the intersection of northeast faults with quartzite stratigraphy, particularly the Upper Nugget and Upper Nevada Members of the Lower Cambrian Quartzite Range Formation (correlative with rocks of the Hamill Group). The underlying Motherlode quartzite is, without obvious reason, almost completely barren of economic gold mineralization. The veins contain a quartz gangue containing pyrite with lesser amounts of pyrrhotite, chalcopyrite, galena, sphalerite and rare visible gold. Precious metal grades are exceedingly variable and zones of high grade appear to be distributed randomly. Such zones or ore shoots are rarely greater than a few tens of metres in size.

Throughout the camp, economic mineralization is found within a vertical range of less than 500 metres in any given vein and from north to south in the camp this vertical range occurs at progressively lower elevations. At the north end of the camp near Reno Mountain the economic zone lies at about 1675 to 2150 metres elevation and at the south end near Mount Waldie the zone is entirely below 915 metres above sea level. Above the economic zone the veins may occur but are generally too narrow and below the zone the veins usually persist but are commonly wider and of lower grade. Higher grades of greater than 150 grams per tonne are restricted generally to the top of the zone.

The Kootenay Belle deposit lies south of Sheep Creek within quartzites, argillites and argillaceous quartzites of the Nevada and Nugget Members of the Quartzite Range Formation. The sediments strike 0 to 15 degrees with a dip of 50 to 75 degrees east and they lie on the west limb of the eastern anticline. Production from the deposit was from the #1 and #2 fissure which contained two ore shoots each. The fissures each dipped 64 to 76 degrees south and intersected along strike. The ore shoots were in the order of 20 to 40 metres long and about 30 centimetres wide. The veins contained quartz and crushed country rock mineralized with pyrite and some galena and sphalerite. A quartz-porphphy sill intrudes along the contact of the Lower Cambrian Reno and Laib formations and is exposed at surface between the 2 and 3 level adits. Wolframite and scheelite are reported locally in the vein quartz. The quartz-porphphy intrusive extends the length of the Sheep Creek gold camp from Reno Mountain to Mount Waldie. Its influence on the gold mineralization is undetermined.

Between 1904 and 1967, the Kootenay Belle mine produced a total of 305,610 tonnes of ore. From this ore 3,507,079 grams of gold, 1,306,232 grams of silver, 52,517 kilograms of lead and 59,335 kilograms of zinc were recovered.

Locke Goldsmith drilled 8 holes (1115 metres) in 1988 and conducted a geochemical survey in 1992.

CAPSULE GEOLOGY

This property is located on Waldie creek near its junction with Sheep Creek. The Kootenay Belle (082FSW046) property adjoins on the northeast. Other associated properties are Yellowstone, Vancouver, Midnight and Alexander (082FSW052, 049, 050 and 051).

Leasers began development work on the Queen property in about 1900; the Holmes Syndicate carried on development work during part of 1902; the Queen claim (Lot 1076) was Crown-granted to Messrs. Turner and Scully that same year.

In 1903 W. Waldie, one of the owners, began development of the property and also obtained a lease on the Yellowstone mill. Waldie completed purchase of the property in 1905, acquired the Yellowstone group in 1907, and sold the combined property to Queen Mines Incorporated in 1908. The company operated the mine until 1916. Except for a brief period of operation by leasers in 1918 the property was idle until acquired by the Yellowstone Mining Company Limited in 1922, however, the company carried on operations for only about a year. Messrs. Lavigne, Stayner & associates acquired the property in 1928 and in 1930 formed Queen Mines Limited, however, operations ceased later in the year.

In 1933 Sheep Creek Gold Mines Limited was formed by a consolidation of the Queen Mining & Milling Company and the Midnight Gold Mining Syndicate, owners of the Midnight and Vancouver claims. A new 50 ton mill was put into operation in May 1935 and operated more or less continuously until the mine was closed in 1951. The company name was changed in 1956 to Sheep Creek Mines Limited.

Beginning in 1961 leasers made intermittent shipments of silica ore from the dumps, the ore being in demand as a silica flux.

The company name was changed in September 1965 to Aetna Investment Corporation Ltd.

The Sheep Creek mining camp consists of auriferous sulphide mineralization within a regional system of quartz veins controlled by

CAPSULE GEOLOGY

faults. The camp hosts four distinct fault/fracture systems. All productive veins are associated with faults trending northeast and dipping southeast. The veins are particularly productive where they cross the axis of the two regional, northerly trending anticlines which dominate the geology of the camp. In addition there are a few northwest trending strike slip faults, north trending normal faults and flat faults, on which the hanging wall has been thrust westwards.

Ore occurs in shoots and is almost without exception confined to parts of fault zones in which one or both walls are quartzite. Other parts of the veins are either too narrow or low grade to be economic. The ore shoots are found at the intersection of northeast faults with quartzite stratigraphy, particularly the Upper Nugget and Upper Nevada members of the Quartzite Range Formation (correlative with rocks of the Hamill Group). The underlying Motherlode Member quartzite is, without obvious reason, almost completely barren of economic gold mineralization. The veins contain a quartz gangue containing pyrite with lesser amounts of pyrrhotite, chalcopyrite, galena, sphalerite and rare visible gold. Precious metal grades are exceedingly variable and zones of high grade appear to be distributed randomly. Such zones or ore shoots are rarely greater than a few of tens metres in size.

Throughout the camp, economic mineralization is found within a vertical range of less than 500 metres in any given vein and from north to south in the camp this vertical range occurs at progressively lower elevations. At the north end of the camp near Reno Mountain the economic zone lies at about 1675 to 2150 metres elevation and at the south end near Mount Waldie the zone is entirely below 915 metres above sea level. The veins may occur above the economic zone but are generally too narrow and below the zone the veins usually persist but are commonly wider and of lower grade. Higher grades of greater than 150 grams per tonne are generally restricted to the top of the zone.

The Queen property includes four east trending veins which are north to south the Yellowstone (082FSW052), Queen, Midnight (082FSW050) and Alexandra (082FSW51) veins. The Queen vein crosscuts the western anticline and the mine shaft is within the Nugget and Nevada Members of the Quartzite Range Formation. To the west, the quartzites are in contact with Lower Cambrian Laib Formation limestones and the vein dies out in the softer sediments. To the east, the vein crosscuts argillites and quartzites of the Lower Cambrian Reno Formation (correlative with rocks of the Hamill Group). The ore shoots are within quartz gangue carrying free gold, pyrite and some sphalerite and galena. Wall rocks are predominantly quartzite. The vein is crosscut by two lamprophyre dykes intruded along fault zones.

Several ore shoots were developed on the Queen property which produced 653,165 tonnes of ore intermittently from 1902 to 1970. It has been reported that from 1900 to 1938 production was from the Queen vein; thereafter it includes production from other veins mined by Sheep Creek Gold Mines. From the total tonnage mined 9,453,383 grams of gold, 3,121,527 grams of silver, 7,769 kilograms of lead and 3,063 kilograms of zinc were recovered.

CAPSULE GEOLOGY

This property is located on Waldie creek near its junction with Sheep Creek. The Kootenay Belle (082FSW046) property adjoins on the northeast. Other associated properties are the Yellowstone, Queen, Vancouver and Midnight (082FSW052, 048, 049 and 050).

The Alexander vein occurs in quartzite of the Lower Cambrian Quartzite Range Formation (correlative with rocks of the Hamill Group). The vein, typical of the Sheep Creek camp, is a northeast trending quartz vein along a fault zone which has about 3 metres dextral movement. The vein is for the most part narrow and little more than a fissure but locally is up to 30 to 50 centimetres wide. Two small ore shoots in the order of 13 and 4 metres long respectively, were intersected and a small amount of ore was produced which contained pyrite and galena in a quartz gangue. Oxidation of the vein extends to all the old working levels. Two quartz porphyry sills, which are a combined 5 metres thick, intruded the sedimentary succession and are exposed in the underground workings. See the Queen occurrence (082FSW048) for a summary of the general geology of the Sheep Creek camp.

CAPSULE GEOLOGY

This property is located on Waldie creek near its junction with Sheep Creek. The Kootenay Belle (082FSW046) property adjoins on the northeast. Other associated properties are Queen, Vancouver, Midnight and Alexander (082FSW048-051, respectively).

The Yellowstone claim was staked in 1896 by T. Bennett. Development of the property commenced late in the summer of that year by Yellowstone Mines Limited and in the three succeeding years all its own ore had been developed.

Leasers began development work on the Queen property (082FSW048) in about 1900; the Holmes Syndicate carried on development work during part of 1902; the Queen claim (Lot 1076) was Crown-granted to Messrs. Turner and Scully that same year.

In 1903 W. Waldie, one of the owners, began development of the property and also obtained a lease on the Yellowstone mill. Waldie completed purchase of the property in 1905, acquired the Yellowstone group in 1907, and sold the combined property to Queen Mines Incorporated in 1908. The company operated the mine until 1916. Except for a brief period of operation by leasers in 1918 the property was idle until acquired by the Yellowstone Mining Company Limited in 1922, however, the company carried on operations for only about a year. Messrs. Lavigne, Stayner & associates acquired the property in 1928 and in 1930 formed Queen Mines Limited, however, operations ceased later in the year.

In 1933 Sheep Creek Gold Mines Limited was formed by a consolidation of the Queen Mining & Milling Company and the Midnight Gold Mining Syndicate, owners of the Midnight and Vancouver claims. A new 50 ton mill was put into operation in May 1935 and operated more or less continuously until the mine was closed in 1951. The company name was changed in 1956 to Sheep Creek Mines Limited.

CAPSULE GEOLOGY

Beginning in 1961 leasers made intermittent shipments of silica ore from the dumps, the ore being in demand as a silica flux. The company name was changed in September 1965 to Aetna Investment Corporation Ltd.

The Yellowstone is one of four east-west trending quartz-sheer veins identified in some references as part of the Queen property. The Yellowstone lies on the east limb of the western anticline of the Sheep Creek Camp. It is within quartzites and argillites of the Lower Cambrian Reno Formation (correlative with rocks of the Hamill Group) which are in contact to the east with quartzites of the Lower Cambrian Quartzite Range Formation argillites of the Lower Cambrian Laib formations argillites. Along the Laib-Reno formation contact is an intrusive sill (?) of quartz-porphyry which extends along a north-south trend through most of the Sheep Creek camp.

Mineralization consists of brown iron oxides (limonite?) with pyrite, free gold and some sphalerite and galena in a quartz gangue. The vein is less than a metre wide and is normally very narrow. It commonly splits into several fissures. Almost all recorded production was achieved in 1900 and 1901 when an ore shoot about 40 metres long produced about 15,400 tonnes of ore containing 169 kilograms gold and 86 kilograms silver. The north wall of the shoot was quartzite and the south wall was argillite. The eastern extension of the shoot was marked by a change from quartzite to argillite in the north wall.

Refer to the Queen mine (082FSW048) for a summary of the Sheep Creek mining camp.

Arakis Mining Corporation drilled 10 holes (257 metres) in 1988. Nugget Mines Ltd. conducted geophysical and geochemical surveys in 1998 and 1999.

CAPSULE GEOLOGY

acquired the property from Kootenay Ore Hill Gold Mines and G. Birtsch in 1939. A 488-metre crosscut was driven from the Queen No. 5 level to Ore Hill ground. From this crosscut 85 metres of drifting, 404 metres of crosscutting, and 349 metres of diamond drilling was completed in 1940. A geological survey was reported by the company on Ore Hill ground in 1947.

The vein occurrence at the Ore Hill deposit crosscuts limestone and schist of the Lower Cambrian Laib Formation as well as quartzites and argillite of the Lower Cambrian Reno Formation (correlative with rocks of the Hamill Group). Several adits with over 1000 metres of underground development occur on the property. Between 1906 and 1940, a total of 2,241 tonnes of ore were mined and 88,612 grams of gold, 168,424 grams of silver, 80,257 kilograms of lead and 75,651 kilograms of zinc were recovered.

South of the adits a trench exposes limestone in fault contact with schists. The fault strikes 050 degrees and dips 75 degrees southeast. A one metre wide lamprophyre dyke is injected along the fault and there is about 30 centimetres of fine-grained galena, sphalerite, pyrrhotite and pyrite on the footwall side, within highly altered limestones. North of this exposure, in the adits, the vein is about 45 centimetres wide within quartzite but narrows along strike as it crosscuts argillites. No mineralization is reported in the quartzite section.

In the Sheep Creek camp, limestone hosted mineralization is similar but not identical to quartzite hosted mineralization. Limestone hosted vein deposits occur along the same northeast trend as the productive quartzite veins and the gold-silver mineralization occurs in a similar ore shoot environment. However, lead and zinc are more common in the limestone deposits and mineralization commonly occurs in the wallrocks as replacement sulphides accompanied by quartz. Higher grade zones within limestone are rarely greater than a few tens of centimetres wide while in quartzites the ore shoots may be several metres wide. All production from veins in limestone has been made from levels fully 600 metres in elevation above similarly productive quartzite hosted deposits. Exploration within limestone at elevations comparable to quartzite hosted occurrences has been disappointing.

CAPSULE GEOLOGY

The property is located at 1676 metres elevation at the head of Billings Creek, a northerly flowing tributary of Sheep Creek, some 12 kilometres southeast of Salmo.

The showings were staked in 1901. A cross-cut adit was driven by F.E. Collins and J. Miller during the period 1906-08 and some ore was shipped. Vancouver Financial Corporation acquired the property and incorporated Sheep Creek Summit Gold Mines, Limited in May 1910. Some high-grade ore was shipped during 1910-11. The company charter (Sheep Creek) was surrendered in 1914.

Five claims, the Summit (Lot 10010), Gold Crown (Lot 10014), Gold Crown Fr. (Lot 10047), Independence (Lot 10012), and Independence Fr. (Lot 10048) were Crown-granted to J.B. O'Brian in 1914. Lessors W.B. De Witt & associates held the property in 1914 and some ore was put through a small mill on the adjoining Ore Hill property (082FSW053). W.B. Poole & associates held the Summit and Ore Hill properties during 1919-20 but no work was reported on the Summit at that time.

McCuaig Red Lake Gold Mines Limited purchased the Summit property in 1934 but there is no report of work done. In 1937 the property was purchased from McCuaig by Kootenay Ore Hill Gold Mines, Limited, owner of the adjoining Ore Hill property. Some mining was done on the Summit group in the spring of 1938 while under lease to H.D. Forman; the ore was treated at the Ore Hill mill.

The working to 1934 comprised a glory-hole at about 1706 metres elevation, 2 adits between 1646 and 1676 metres elevation totalling about 194 metres of crosscuts and drifts, and several caved adits at about 1585 metres elevation.

The Summit occurrence is a quartz-siderite vein deposit which contains erratically distributed pyrite, galena and sphalerite within a narrow fault zone striking 55 degrees and dipping southeast. The fault crosscuts Lower Cambrian, Laib Formation limestones and schists close to a granitic intrusion of the Middle to Late Jurassic Nelson

CAPSULE GEOLOGY

Intrusions. Most of the mine production was from a 20 metre long "Glory Hole". Production from 1906 to 1938 totalled about 1094 tonnes which contained 27,059 grams of gold, 37,883 grams of silver, 13,728 kilograms of lead and 12,988 kilograms of zinc.

In the Sheep Creek Camp, limestone hosted mineralization is similar but not identical to quartzite hosted mineralization. Limestone hosted vein deposits occur along the same northeast trend as the productive quartzite veins and the gold-silver mineralization occurs in a similar ore shoot environment. However, lead and zinc are more common in the limestone deposits and mineralization commonly occurs in the wallrocks as replacement sulphides accompanied by quartz. Higher grade zones within limestone are rarely greater than a few tens of centimetres wide while in quartzites the ore shoots may be several metres wide. All production from veins in limestone has been made from levels fully 600 metres in elevation above similarly productive quartzite hosted deposits. Exploration within limestone at elevations comparable to quartzite hosted occurrences has been disappointing.

Sultan Minerals Inc. prospected the area in 1996.

QUANTITY: 14254 Tonnes
YEAR: 1987

COMMODITY: Gold
GRADE: 10.2800 Grams per tonne

COMMENTS: Present reserves; not including low-grade material or possible reserves in areas of difficult access. Average gold grade.

REFERENCE: George Cross News Letter No.217 (November 12), 1987.

CAPSULE GEOLOGY

Detailed information on the Bonanza vein system is limited. A mineralized vein strikes about 80 degrees and crosscuts quartzites of the Lower Cambrian Quartzite Range Formation near the westerly contact with the Lower Cambrian Reno Formation (both formations are correlative with rocks of the Hamill Group). The quartzite is hard, white and the vein bifurcates with some brecciation between the branches but mostly on the northerly branch. Visible gold is reported in the quartz vein which may be over a metre wide locally but has very scarce disseminated sulphides. Minor limonite is reported. Refer to the Queen mine (082FSW048) for a description of the Sheep Creek mining camp.

The Bonanza North and South veins are developed by four adits on the Dip claim. About 17 tonnes were shipped in 1910 but the value of the shipment was not reported (Minister of Mines Annual Report 1910, page 110). In 1963, a total of 14 tonnes were mined, from which 124 grams of gold, 2,861 grams of silver and 118 kilograms of lead were recovered.

Results of 1982 sampling indicate that there is an ore shoot above and below the second level on the North vein. Potential is indicated at depth where the productive horizon is projected to below

CAPSULE GEOLOGY

an elevation of 914 metres. In 1983, 2720 tonnes of proven and possible ore at a grade of 18.86 grams per tonne gold was outlined on the North Bonanza vein (Assessment Report 11249). A later estimate of the ore on the property was reported to be 14,254 tonnes grading 10.28 grams per tonne gold (George Cross News Letter No.217 (November 12), 1987).

of Sheep Creek mining camp.

Gold values occur in a fissure that strikes approximately 075 degrees, with steep south dip, across the lower part of the Reno Formation close to the contact with the Quartzite range Formation to the east. The showing in the upper adit has been described as a quartz vein, 0.6 metre wide, carrying free gold. Oxidation has removed any sulphide mineralization originally present in the fissure.

CAPSULE GEOLOGY

The property is located on the south side of Porcupine creek some 7 kilometres southeast of Ymir.

The showings were discovered in the late fall of 1927 by J. Thexton, who staked the Rainy Day, Lucky Sunday and Success claims. Work by the owner in 1928 included trenching and driving three short adits.

New Jersey Zinc Exploration Company (Canada) Ltd, which acquired the nearby Jackpot property in 1948, subsequently restaked the showings as the Elm group of 9 claims. Work by the company in the 1950's included geological mapping, bulldozer trenching and a small amount of diamond drilling.

The Elm showing is located on Porcupine Creek, just east of the Oxide showing (082FSW022). Workings comprise two adits and a few trenches.

The area is underlain by argillite, slate, quartzite and limestone of the Lower and Middle(?) Ordovician Active Formation which have been intruded by granitic rocks of the Middle to Late Jurassic Nelson Intrusions.

Mineralization consists of small lenses of pyrite, pyrrhotite and sphalerite hosted in steeply dipping limestone. The limestone is around 100 metres thick and bounded to the east and west by black argillites. Some skarnification of the limestones is reported near intrusive contacts. Mineralization is locally associated with fluorite, and scheelite has also been locally noted.

CAPSULE GEOLOGY

The Udiville property is located at approximately 1067 metres elevation on the east side of Bennett Creek, a north-flowing tributary of Sheep Creek, 10 kilometres southeast of Salmo. The property, including the Udiville, Udiville No. 2 and Udiville No. 1 claims (Lots 15851-15853 respectively), was owned by J. Sapples of Salmo. Exploration and development work to 1928 included open cuts, a shallow prospect shaft inclined at 55 degrees, and an adit driven 3 metres easterly at shallow depth; no mineralization was found in the adit. Mentor Exploration and Development Co., Limited acquired the property in 1977. Magnetic and geochemical soil surveys were carried out; the magnetic survey outlined a moderately sharp anomaly on the northwest corner of the Udiville claim. A synclinal structure of Lower to Middle Ordovician Active Formation argillites and Lower Cambrian Laib Formation carbonates is

CAPSULE GEOLOGY

intruded by granite of the Middle to Late Jurassic Nelson Intrusions. Within the Reeves Member limestone of the Lower Cambrian Laib Formation is an area of disseminated sphalerite, galena and pyrite mineralization within dolomitized limestone away from the granitic intrusive. The irregularly mineralized zone has widths of up to 1.8 metres. A sample across 1.4 metres assayed 0.34 grams gold, 13.7 grams silver, 0.4 per cent lead and 10.8 per cent zinc. Another sample collected from a trench in 1983 assayed 15.2 per cent lead, 3.89 per cent zinc and 4.0 grams per tonne silver (Assessment Report 11662).

Upslope from the lead-zinc mineralization is an outcrop of garnet-diopside skarn in limestone next to the granite contact where there is minor disseminated scheelite and molybdenite.

REFERENCE: Mentor Exploration and Development Company Ltd. 1977 Annual Report.

CAPSULE GEOLOGY

The property is located at approximately 975 metres elevation on the west side of Bennett Creek, a north flowing tributary of Sheep Creek, 9.6 kilometres southeast of Salmo.

The Little Keen, Last Chance and Lucky Jim claims were staked in 1932 by Jack Sapples of Salmo as a molybdenum prospect. Exploration work was done in open cuts and strippings. H.L. Batten and associates of Vancouver optioned the property in 1939 and carried out open cutting and stripping. The option was given up that same year. The property, together with additional claims staked by Joe Gallo, was optioned in 1942 by Bralorne Mines, Limited. Exploration work was directed towards the tungsten showings and included a winze sunk to 5 metres. The option was given up in January 1943. The Consolidated Mining and Smelting Company of Canada Limited optioned the property in 1943. Considerable trenching was carried out before the option was dropped in September of that same year.

Canadian Exploration, Limited carried out trenching on the property in 1946. Ground lying between this group and the Emerald

CAPSULE GEOLOGY

mine to the southwest was staked by the company. In 1951 the property was under option to Boleen Mines Limited, however, no work was reported. The property included the Victory, Victory Fr., Last Chance (Lots 15842- 15844 respectively), and Lucky Jim (Lot 15846) claims. Victory Tungsten Ltd. optioned the property from J. Sapples in 1952. A diamond drilling program, carried out mainly on the Last Chance and Victory Fr. claims, was concentrated in a zone 137 metres long between elevations of about 914 and 1005 metres. Diamond drilling to the end of July 1953 totalled over 4572 metres in 64 holes; drilling continued until the end of October. This work indicated 82,000 tons grading 0.54 per cent WO₃ (Mentor Exploration and Development Co., Limited, 1947 Annual Report, p. 11). Canadian Exploration, Limited, the owner of adjacent ground, carried out geological work on the property in 1958.

Mentor Exploration and Development Co., Limited acquired an option on the property in 1977; included was adjacent ground as well as the nearby Udiville (082FSW058) and Amco properties. Work on the larger property in 1977-82 included geochemical soil surveys (2,832 samples), a magnetometer survey over 22 line kilometres, a scintillometer survey over 14 line kilometres and 842 metres of diamond drilling in 3 holes. Geological mapping and a geochemical rock survey were carried out in 1983. The company abandoned the option on December 1, 1984.

Black argillites containing beds of grey, finely crystalline limestone of the Lower to Middle Active Formation, are host to skarn zones where they are intruded by tongues of granite of the Middle to Late Jurassic Nelson Intrusions. Sediments near the granite contact are highly altered to skarns containing pyroxene, amphibole, calcite and titanite with disseminations of scheelite and molybdenite. The alteration rapidly diminishes away from the contact.

Locally, a limestone band is highly altered to garnet and tremolite and, within a width of about 6 metres, contains scheelite, molybdenite, pyrite and pyrrhotite. The main showing is estimated to contain about 74,382 tonnes of 0.42 per cent tungsten (Actual grade is 0.54 per cent WO₃. Conversion used for WO₃ to W is 1.2611.) (Mentor Exploration and Development Company Limited 1977 Annual Report in EMR MIN BULL MR 223 B.C. 23). Patchy molybdenite mineralization was also identified in skarn north of the tungsten showing and as disseminations in the Nelson granite.

CAPSULE GEOLOGY

The Middle Cambrian Nelway Formation in the area of Russian Creek, south of the Pend d'Oreille River, is host to disseminated sphalerite.

There are two mineralized exposures. The first is immediately west of Russian Creek and about 215 metres from the United States border. Honey colored sphalerite occurs as finely disseminated grains in a grey and white banded limestone of the upper Nelway Formation. The sphalerite tends to occur in bands and surface oxidation is present from a few centimetres up to about a metre in thickness. The grade of this occurrence is low and the extent is unknown.

The second showing is to the east and near the top of a small knoll about 185 metres from the United States border. A nearly white, crystalline limestone near the top of the Middle Nelway Formation contains a few pockets of limonitic gossan. Mineralization is spotty but one sample is reported to have assayed more than 20 per cent zinc (Bulletin 41, page 94).

Lead	21.6000	Per cent
Zinc	1.3000	Per cent

COMMENTS: The sample width is 4.57 metres.

REFERENCE: Geological Survey of Canada, Memoir 172.

CAPSULE GEOLOGY

Disseminated, stringers and massive sulphide mineralization is associated with quartz gangue within lensoidal masses or shoots along the shear zone known as the Black Bluff fault. The fault is interpreted as a thrust zone with Lower to Middle Ordovician black and graphitic argillites of the Active Formation to the west and upper Laib Formation phyllites, argillites, quartzites and minor limestones to the east.

Sulphides include pyrite, sphalerite and galena within quartz zones of highly variable width and extent although the mineralization appears related to disconnected shoots rather than to well defined planar structures. A 4.5-metre thick lens containing 1.8 metres of latite dyke on the hanging wall assayed 2.74 grams per tonne gold, 442.3 grams per tonne silver, 21.6 per cent lead and 1.3 per cent zinc (Geological Survey of Canada, Memoir 172, page 82).

CAPSULE GEOLOGY

A fissure vein striking 290 degrees with a steep to near vertical dip is associated with the Black Bluff Fault and is host to quartz gangue containing galena, tetrahedrite, pyrite, sphalerite and chalcopyrite. The width of the vein averages 5 centimetres but locally may be as wide as 50 centimetres. The vein crosscuts dolomites and limestones of the Middle Cambrian Nelway Formation as well as phyllites and quartzites of the Lower Cambrian Laib Formation. The country rock also includes several diorite dykes which are pre-veining in age. Near surface and to a depth of about 5 metres the vein is highly weathered and contains cerussite, chalcocite, covellite, malachite and azurite. There is some cross fracturing and quartz veining on a north trend with steep west dips. The vein carries silver and gold values but mineralization is highly erratic ranging from trace up to in the order of 65 grams per tonne gold or better and as high as 13 kilograms silver per tonne from selected grab samples (Minister of Mines Annual Report 1938).

From six years between and 1938 and 1963 (inclusive), there was a total of 55 tonnes mined from which was recovered 2,456 grams of gold, 65,191 grams of silver 2,318 kilograms of lead and 1,115 kilograms of zinc. Most of the production was from 1938 when 34 tonnes were mined.

REFERENCE: Property File - Obolus Resources Inc., Prospectus, Nov. 1988.

CAPSULE GEOLOGY

The property is located at 914 metres elevation on the south side of Porcupine Creek, about 2 kilometres east of the Salmo River and 3.2 kilometres east-southeast of Ymir. The Nevada property (082FSW064) adjoins to the southwest. The very similar Blue Nellie showing (082FSW065) is just to the north. The property includes the Maple Leaf workings comprising ten short adits and several open cuts.

CAPSULE GEOLOGY

The Porcupine (Lot 4634), the first claim staked in the Ymir area, was located by Messrs. Lloyd and Thompson in 1895. Considerable work was done in an adit driven in 1897. The Porcupine and Franklin (Lot 4635) were Crown-granted to J.S. Clute in 1901. Claims adjacent to the northwest were Crown-granted that same year to The Rio Grande Gold and Silver Mining Company, Limited Liability; in later years these claims were divided between the Porcupine and adjacent Nevada properties.

In 1925 the Porcupine group, owned by E. Haukedahl, E. Gille, and Nels Peterson, of Ymir, comprised 7 claims including in addition to the above, the Sunrise claim, and the Champagne (Lot 5131) which had been Crown-granted to the Rio Grande company. Exploration work was reported in open cuts and old adits. The Porcupine was reported re-Crown-granted in 1925 to N.H. Peterson. The Franklin, Champagne, and Sunrise (Lot 4385) were re-Crown-granted to Haukedahl and Peterson in 1926.

The property was bonded in 1926 by R.K. Waite for Cleveland Ohio interests. Cleveland Mines, Limited was incorporated in September of that year but no activity was reported other than the shipment of a few tons of ore. Intermittent prospecting and development by Haukedahl and Peterson continued until about 1930; work to date included numerous open cuts and about 129.8 metres of underground work in 5 adits.

Late in 1937 the property was optioned by C. Wolf and E.H. Carlson, of Spokane, who carried out 84 metres of drifting the following year. A Spokane syndicate, Maple Leaf Gold Mining Co. Inc. was organized to continue the development work. In 1939 underground work totalled 49 metres of drifting and 18 metres of crosscutting; an additional 38 metres of drifting was reported in 1944. The company in 1948 held the Ambassador, Easter, and Sun Fr. claims in this vicinity. An adit was driven during the year and a small amount of ore shipped.

Duval International Corporation held the Porcupine and adjacent claims in 1968; geological mapping and sampling was reported.

The Porcupine, Franklin, and Champagne claims were owned in 1976 by I. Urquhart, c/o Cochran Consultants Ltd. Geological mapping, and sampling of trenches, dumps, and adits was reported in 1976 and 1978.

The area is underlain by Lower Cambrian metasediments near the contact with the southern tongue of the Nelson batholith of the Middle to Late Jurassic Nelson Intrusions. The metasediments comprise quartzite, schist, argillite and slate. These have been intruded by granodiorite and late stage lamprophyre dykes.

Irregular quartz veins occupy steeply dipping shear zones in argillite adjacent to their contacts with granodiorite and are associated with silicified zones. The shear zones are up to 3 metres wide with the best mineralization restricted to less than a metre. At least five veins have been poorly documented on the property. Mineralization consists of pyrite, galena, sphalerite and trace pyrrhotite hosted by quartz gangue. These sulphides occur as disseminations, stringers and small pods. Sulphides, particularly pyrite, also occur as disseminations within the wallrocks of the veins and shears. Width, strike and dip are variable although all of the showings have proven to be limited in size. Traces of chalcopryrite and tin are recorded.

Production for the showings is uncertain; 16 tonnes yielding 31 grams gold, 5381 grams silver and 1052 kilograms copper (which makes origin suspect) is recorded for the Porcupine for 1926; 24 tonnes yielding 72 grams gold, 7216 grams silver, 648 kilograms lead and 1738 kilograms zinc is recorded for the Maple Leaf in 1948; and 69 tonnes of crude ore yielding 31 grams of gold, 5910 grams of silver, 482 kilograms lead and 895 kilograms zinc is reported shipped in 1971 from the Maple Leaf.

A grab sample of quartz containing pyrite and sphalerite (PORC 3) taken in 1988, from the vicinity of the workings at 845 metres elevation, assayed 0.9 grams per tonne gold and 33.4 grams per tonne silver.

CAPSULE GEOLOGY

The property is located at 1097 metres elevation on the south side of Porcupine Creek, about 1.6 kilometres east of the Salmo River and 3.2 kilometres south-southeast of Ymir. The Porcupine property (82 F/6, Ag 2) adjoins to the northeast.

The Nevada claim (Lot 3504) was located in July 1898 by J.B. Stover and Crown-granted in 1899 to R.C. Pollett. The Imperial claim (Lot 3025), adjoining to the southeast, was Crown-granted to G.F. Whiteman in 1898. The Victor, Emerald, and Porcupine claims (Lots 2906-2908 respectively), extending south from the Imperial, were Crown-granted to P. Thompson, A. Johnson & associates in 1902. The Sandaulphon, Gorgina, Champagne, and Rio Grande Fr. (Lots 4639, 5130-5132 respectively), located adjoining to the north of the Nevada claim, were Crown-granted to The Rio Grande Gold and Silver Mining Company, Limited Liability in 1901; the Champagne claim in later years became part of the Porcupine property.

In about 1907 the Rio Grande Fr., Gorgina, and Sandaulphon claims were purchased at a tax sale by O. and C. Anderson, of Ymir. The Nevada and Imperial claims were acquired in 1911 by Messrs. Grobe and MacLeod, of Ymir. Development work to 1915 totalled about 98 metres of drifts and crosscuts in 4 adits. Work on the Rio Grande Fr. included about 122 metres of drift and crosscuts in one adit; a lower adit was being extended in 1915. Further development work was reported in 1917. The Imperial claim was re-Crown-granted in 1918 to D.E. Grobe. Sampling was reportedly carried out on the property in the 1930's by Wesko Exploration and Development Company, Limited.

MINFILE NUMBER: **082FSW064**

CAPSULE GEOLOGY

In 1937 some development work was carried out by David Grobe of Spokane; a small shipment of ore was reported under the name of J.A. Armes, of Vancouver, as owner.

The property was bonded in 1926 by R.K. Waite for Cleveland Ohio interests. Cleveland Mines, Limited was incorporated in September of that year but no activity was reported other than the shipment of a few tons of ore. Intermittent prospecting and development by Haukedahl and Peterson continued until about 1930; work to date included numerous open cuts and about 130 metres of underground work in 5 adits.

Late in 1937 the property was optioned by C. Wolf and E.H. Carlson, of Spokane, who carried out 84 metres of drifting the following year. A Spokane syndicate, Maple Leaf Gold Mining Co. Inc. was organized to continue the development work. In 1939 underground work totalled 49 metres of drifting and 18 metres of crosscutting; an additional 38 metres of drifting was reported in 1944. The company in 1948 held the Ambassador, Easter, and Sun Fr. claims in this vicinity. An adit was driven during the year and a small amount of ore shipped. Duval International Corporation held the Porcupine and adjacent claims in 1968; geological mapping and sampling was reported. The Porcupine, Franklin, and Champagne claims were owned in 1976 by I. Urquhart, c/o Cochran Consultants Ltd. Geological mapping, and sampling of trenches, dumps, and adits was reported in 1976 and 1978.

The Nevada showings are located on the south side of Porcupine Creek, about 3.2 kilometres southeast of Ymir. The Porcupine showings (082FSW063) adjoin to the northeast.

The area is underlain by metasediments of the Jurassic Ymir Group intruded by Middle to Late Jurassic granite and granodiorite of the Nelson Intrusions.

Two types of mineralization occur on the property: 1) veins and 2) shear zones.

A number of irregular quartz veins strike 050 to 080 degrees and dip 60 to 75 degrees south. The veins occur at and near the margins of the intrusives, hosted mainly in schist and argillaceous quartzite. The veins are 15 to 75 centimetres wide and contain quartz with sheared or schistose wallrocks. Mineralization consists of scattered patches and disseminations of fine-grained pyrite, galena, sphalerite and common limonite.

Shear zones are developed along a north trend of about 40 degrees, with dips in the order of 80 degrees southeast. The shears are up to 3 metres wide and contain stringers of quartz in sheared wallrock. Mineralization is sparse and includes galena, sphalerite and pyrite. Silicification is locally developed at and near granite contacts. Gold and silver values are low and sporadic.

A shipment of 9 tonnes in 1937 contained 62 grams of gold, 1773 grams of silver, 546 kilograms of lead and 381 kilograms of zinc.

CAPSULE GEOLOGY

This property is located at 1067 metres elevation on the west slope of Jubilee Mountain about 1.6 kilometres southeast of Ymir. The Centre Star claim was located in 1900 and Crown-granted to J.S.C. Fraser & associates in 1905. No further activity was reported from the property until 1934. At this time Wesko Exploration and Development Company, Limited, acquired the Centre Star group consisting of the Centre Star, Redman, Twilight, Cold Island, Crowfoot, and Blind Canyon Crown-granted claims, and ten adjoining claims held by location. Exploration and development work was carried on through 1935 and in 1936 a 100 ton per day concentrator was put into operation. During 1936 the company name was changed to Wesko Mines, Limited. The concentrator operated until August 1938 at which time the ore reserves were exhausted. A very limited diamond drilling program failed to locate additional ore and the mine closed late in the year. Lessees carried on small scale intermittent salvage operations from 1940 until 1950. The mine has been developed by over 2012 metres of drifts, crosscuts and raises on 5 main levels and several subsidiary levels. The Centre Star mine is located on the west slope of Jubilee Mountain, about 1.6 kilometres northeast of Ymir. The mine has been developed by over 2000 metres of drifts, crosscuts, and raises on 5 main levels and several secondary levels. Mining operations started

CAPSULE GEOLOGY

in 1936 and by 1938 reserves were exhausted; intermittent salvage operations were carried on from 1940 to 1950.

The area is underlain by Jurassic Ymir Group sediments. The sheared and altered argillites and quartzites are intruded by the Nelson batholith comprising granite and granodiorite of the Middle to Late Jurassic Nelson Intrusions. Prominent shear zones, 5 to 10 metres wide, trending 30 to 55 degrees east with vertical or steep southeast dips, crosscut the host rocks. On the property, two such parallel shear zones occur about 122 metres apart.

Mineralization occurs in a broad contact zone consisting of sheared and altered argillites and quartzite intruded by granite. Ore shoots occur in veins, up to 8 metres wide, along fault fissures striking 280 to 300 degrees and dipping steeply northwest.

The deposit comprises a 152 metre long mineralized vein, dipping steeply northwest, occurs within a 1 to 2-metre wide fracture. The vein strikes 60 to 80 degrees east, diagonally between the two major northeast trending shear zones, and is terminated by shears. Ore shoots with an easterly pitch are developed at the intersection of the vein with northwest trending fractures. The fractures also host sulphides but they contain negligible to zero gold. Tongues of intrusive granite are close to the ore shoots.

Gangue consists of quartz and brecciated, siliceous country rock fragments, with pyrite, galena, sphalerite and pyrrhotite. Pyrrhotite is less common in the upper levels. Near surface, the vein is oxidized with limonite, manganite and pyromorphite stained by cerussite.

The average grades from 51,458 tonnes of production were 7.5 grams per tonne gold, 57.3 grams per tonne silver, 1.88 per cent lead and 0.93 per cent zinc (Assessment Report 11753).

CAPSULE GEOLOGY

fire in April 1899.

Vancouver interests were negotiating for the property in 1903. Dundee Cold Mine, Limited was incorporated in Vancouver in July 1904 to acquire the property. Some rehabilitation work was done in 1903 and lessees worked for a short period in 1905.

The Dundee, Dundee Fraction, and M.S. claims (Lots 7241- were Crown-granted to Dundee Cold Mining and Milling Company, of Everett, Washington, which was registered in British Columbia in 1905. The location of these claims relative to the Dundee property is not known.

Work resumed in June 1910 when an adit "Dundee adit" was begun on the Old Bill claim some 274 metres below the collar of the shaft. By 1915 when work ceased the adit had been driven as a crosscut for 568 metres, and for 333 metres of drifting on the vein.

The Mining Corporation of Canada, Limited optioned the property late in 1919 and some exploration work was carried out in 1920. The option was dropped in 1921.

Ymir Dundee Gold Mining Company, Limited, incorporated June 1934, acquired the property under agreement from Dundee Gold Mine, Limited and development work was begun in driving a raise. Operations continued until mid 1935.

Ymir Yankee Girl Gold Mined, Limited, owner of the adjacent Yankee Girl mine, acquired a lease and bond on the property early in 1940. A crosscut was begun from the Yankee Girl main (376 metres) level to connect with the raise from the Dundee adit. Some 660 metres of raising on the Dundee supplied most of the ore milled during 1941 and to the end of 1942 when the mine closed. Lessees owned pillar and stope remnants in 1950. The workings to date comprised 8 levels over a vertical range of 305 metres.

Yankee Dundee Mines Limited was incorporated in November 1952 by Ralph Sostad and associates to develop the Yankee Girl and Dundee mines, however no work was reported on the Dundee. The company name was changed in 1963 to Dundee Mines Limited.

Burlington Mines Ltd., (of which Ralph Sostad was a director) acquired 36 claims comprising the Dundee and Yankee Girl properties from Dundee Mines Limited by an agreement dated July 1966. No work was reported on the Dundee.

The Dundee mine is located on the north side of Oscar Creek, 3 kilometres east-northeast of Ymir. This property was one of the first to be developed in the Ymir area; gold was initially discovered on the Dundee in 1896. The Dundee and Yankee Girl (082FSW068) mines were amalgamated in 1940. A crosscut was developed from the Yankee Girl 1235 level to connect with the raise from the Dundee adit. The Dundee mine closed in 1942 and no further work has been reported. The Yankee Girl vein occurs 300 metres to the north.

The area is underlain by Jurassic Ymir Group slate, argillite and argillaceous quartzites intruded by granodiorite of the Middle to Late Jurassic Nelson Intrusions. The contact with a southern tongue of the Nelson batholith occurs about 400 metres to the east. The area is strongly faulted with the faults forming a conjugate set. One set, striking 290 degrees and dipping 60 to 70 degrees north, hosts mineralized veins.

The Dundee vein, a strong fault-fissure striking 060 to 070 degrees east and dipping 60 to 70 degrees northwest, cuts both the sediments and intrusive. The zone has well-defined walls and varies from 2 to 6 metres in width. On the hanging wall, 30 to 60 centimetres of fault gouge is present and the footwall is granite. The vein hosts sheared country rock fragments in a quartz gangue containing pyrite, galena, and sphalerite, in order of abundance. The vein, parallel to the Yankee Girl vein, has been traced on surface for many hundreds of metres. At surface, the vein is 4 metres wide and increases with depth. The vein is offset and intersected by lamprophyre dykes.

Production at the Dundee was principally from a 33-metre long ore shoot in the vein where it crosscuts a tongue of granodiorite. The ore bearing sections of the vein are up to 4 metres wide. Sulphide mineralization is less abundant where the vein crosscuts sediments. The Dundee vein is paralleled by the Blue vein which generally hosts less gold and dips less steeply.

Production from the Dundee has been included with the Yankee Girl, however, this property had only a limited production of 2717 tonnes with grades in the order of 10 grams per tonne gold and 170 grams per tonne silver. Inferred reserves are 872,000 tonnes at approximately the same grade as the material mined (George Cross News Letter No. 215, 1983). There are 360,000 tonnes of reported material left on the dumps (George Cross News Letter No. 212, 1983).

Kingsvale Resources Ltd. optioned the property in 1988 and conducted trenching and sampling; they dropped the option in 1989.

CAPSULE GEOLOGY

was initially discovered on the Yankee Girl in 1899. The Yankee Girl and Dundee (082FSW067) mines were amalgamated in 1940. A crosscut was developed from the Yankee Girl 1235 level to connect with the Dundee adit. The Dundee vein occurs 300 metres to the south.

The area is underlain by Jurassic Ymir Group slate, argillite and argillaceous quartzites intruded by granodiorite of the Middle to Late Jurassic Nelson Intrusions. The contact with a southern tongue of the Nelson batholith crosscuts the area. The area is strongly faulted with the faults forming a conjugate set. One set hosts mineralized veins.

The Yankee Girl vein, averaging 1.5 metres in width, has a maximum width of 9 metres with productive sections never wider than 4 metres. The vein fissure, striking 060 to 070 degrees and dipping 55 to 70 degrees south, hosts quartz gangue with fragments of brecciated and altered granodiorite and schist. Mineralization consists of pyrite, galena and sphalerite with values in gold, silver and cadmium. The values are erratically distributed. Ore occurs in well-defined shoots which generally rake to the east. The Spur vein, equally rich, branches off the Yankee Girl vein on the footwall and is parallel to it for 250 metres.

The Lakeview cataclastic zone/vein is the largest mineralized fault on the property. Average gold values from drifting on the vein at the Yankee Girl junction were 3.4 grams per tonne gold (Assessment Report 14719). The Lakeview zone, more than 15 metres wide, exhibits intense deformation, banding, flow characteristics and brecciation. Fractures are filled with quartz and mineralized with disseminated and irregular masses of pyrite and minor disseminated sphalerite. The zone is hosted in granitic rocks varying in composition from granite to diorite. Argillic alteration is common. Drilling on the Lakeview zone in 1985 was disappointing.

Two other mineralized veins, the Bonus (120 metres north of the Yankee Girl) and Cannon veins, were identified in the Wildhorse crosscut in 1954. The Bonus vein is parallel to the Yankee Girl. A sample taken from a section of the Bonus vein, where it is 2 metres wide, assayed 15.43 grams per tonne gold, 9.94 grams per tonne silver, 2.65 per cent zinc and 1.2 per cent lead (Assessment Report 14719). A sample across 1 metre in the Cannon vein averaged 13.0 grams per tonne gold (George Cross News Letter No.145, 1988).

Production from the Yankee Girl and parallel veins totalled 370,616 tonnes with a grade of approximately 8.6 grams gold and 44.5 grams silver per tonne. Lead constitutes an average of 1.5 per cent and zinc assays about 2.8 per cent.

Kingsvale Resources Ltd. optioned the property in 1988 and conducted trenching and sampling; they dropped the option in 1989.

The property is located at approximately 1097.2 metres elevation on the north side of Oscar Creek, 1.6 kilometres east of Ymir.

The Yankee Girl, Canadian Girl, and Atlin claims were staked in October 1899 by Messrs. Graham, Grobe, McLeod, Masterton, and Lovell. Development work was done in a series of open cuts, a shaft, and an adit ("Overland Tunnel") which gained a depth of 15 metres on the vein. In 1904 the Atlin and adjacent Nome and Yukon claims were held by Pat Daly, A. Parr, Wm. Coffey and associates. The Atlin-Nome workings included a shaft to 18 metres with a 15-metre crosscut to the north, and a 96-metre crosscut adit and drifts on the vein. On the Yukon claim an adit had been driven 75 metres. The Yankee Girl (Lot 7712) and Canadian Girl (Lot 7072) were Crown-granted in 1907 to David Grobe, Donald McLeod, James Cronin, and Eber Moore. The Yukon Fr. (Lot 5303) was Crown-granted to Messrs. Daly, Coffey, Hughes and Ryan. In 1910 the Atlin (Lot 4800) and Atlin Fr. No. 2 (Lot 9336) were Crown-granted to William Coffey.

The property was bonded in 1907 by a syndicate of American interests. About 305 metres of development work was carried out and a tram line was built from the Yukon claim to the wagon road. The bond was given up in August of that same year. Early in 1908 the property was bonded by H.L. Rodgers, representing New York interests, and development work began in driving the 1235 (No. 4) level adit from the Old Bill claim of the adjacent Dundee property (82 F/6, Au 10). Operations were transferred to Yankee Girl Gold Mines, Limited which was incorporated in South Dakota and registered in British Columbia in 1909.

The Yankee Girl, Canadian Girl and Yukon Fraction were optioned in 1911 by Hobson Silver-Lead Company, Limited of Spokane, which was controlled by Fort Worth Texas interests. An aerial tram 1829 metres long was built from the 1235 level to the railroad at Ymir. Development work continued in the 1235 level and ore was shipped to smelters at Greenwood, Grand Forks, and Trail, the high silica content of the ore making it desirable for fluxing purposes. The company ceased operations in 1919. Ownership of the property was transferred to Texas Yankee Girl Mines, Limited, which was registered

CAPSULE GEOLOGY

in British Columbia in 1920.

The Mining Corporation of Canada, Limited optioned the property in the spring of 1920 and carried out 628 metres of drifting and crosscutting and 204.2 metres of raising in known areas of the mine. The option was given up later in the year. No further activity was reported until 1926 when O.C. Thompson and associates optioned the property and incorporated Yankee Girl, Limited. The mine was reopened and some ore shipped during the year. In May 1927 The Porcupine Goldfields Development and Finance Company, Limited optioned the property. Further development work was carried out and diamond drilling was done to test for ore below the 1235 level. Enterprise Consolidated Mining Company, Limited optioned the property in March 1928 from Texas Yankee Girl Mines, Limited. The company name Enterprise) was changed to Yankee Girl Consolidated Mines, Limited. Further development work was done in the upper levels of the mine. The workings at that time included 2 shafts, 5 adits and 10 levels totalling some 5486 metres of openings. In the fall of 1928 a new crosscut adit was begun on the Ymir (Wildhorse) Creek side of the mountain 233 metres below the 1235 level. When work was suspended late in 1929 the Wildhorse adit had been driven 869 metres.

Early in 1933 E.P. Crawford, F.R. Weekes and associates took over the property under an agreement with Texas Yankee Girl Mines, Limited and incorporated Ymir Yankee Girl Gold Mines, Limited in May 1934. The property included 5 Crown-granted claims, the Yankee Girl, Canadian Girl, Lakeview, Black Diamond, Yukon Fr., and Klondyke No. 1 Fr. The company installed a 100 t.p.d. mill which began production in January 1935. A winze was sunk to 91 metres below the 1235 level, extending the workings to a depth of 495 metres and comprising eleven levels. The company continued operations during 1938 while lessees carried out the mining of ore remnants in pillars and stopes in the less accessible parts of the mine. In 1939 the company carried out a salvage mining operation in pillars and stope remnants. A crosscut adit was driven from the 1235 adit level to the Dundee ore zone in 1940. The mill operated on Dundee ore, and on mill tailings from former operations, until June 1942 when the company ceased work. Lessees operated the mill until near the end of the year, treating backfill from old stopes. Lessees continued intermittent mining and clean up operations into 1950.

Yankee Dundee Mines Limited was incorporated in November 1952 to develop the Yankee Girl and Dundee properties. Rehabilitation and extension of the Wildhorse adit began and in 1954 the adit reached a length of 1417 metres. At 1247 metres from the portal the Bonus vein was intersected and drifted on for 20 metres. At 1417 metres the Yankee Girl vein was encountered and drifted on for 14 metres. In December 1954 a raise was started on the vein but only driven 11 metres when work stopped.

Newmont Mining Corporation of Canada Limited optioned the property in August 1960. Diamond drilling was done in 2 holes to test the Bonus vein. The option was given up in December.

Cayzar Athabaska Mines Limited in August 1961 optioned the property from Yankee Dundee and drove a raise on the Yankee Girl vein for 143.5 metres to intersect the old workings at the 1625 level. Drifting totalling 126 metres and some 678 metres of diamond drilling in 5 holes was done on the Yankee Girl vein from the Wildhorse adit. The option was given up in 1965. The company name (Yankee Dundee) was changed in 1963 to Dundee Mines Limited.

Burlington Mines Ltd. by an agreement dated July 1966 acquired from Dundee Mines 24 Crown-granted claims. Rehabilitation and maintenance work was done in the Wildhorse adit. The company name was changed to Burlington Mines & Enterprises Ltd. in 1970 and to Burlington Gold Mines Ltd. in 1974.

REFERENCE: George Cross News Letter No.216, 1988.

CAPSULE GEOLOGY

The Two Star showing is located 32 kilometres south of Nelson, just east of Ymir. Development began on this property in 1933.

The area is underlain by granodiorite of the Middle to Late Jurassic Nelson Intrusions, a small pendant of Jurassic Ymir Group argillite occurs near the showing.

The occurrence is on the strike extension of the Yankee Girl (082FSW068) and Dundee (082FSW067) vein systems. The occurrence comprises a vein in a strong quartz filled shear which strikes 055 degrees within argillite. The vein is wide and hosts pyrite and fine-grained galena and sphalerite.

Kingsvale Resources Ltd. optioned the property in 1988 and conducted trenching and sampling; they dropped the option in 1989. The sampling program in 1988 from the Evening Star shaft resulted in an average assay of 10.11 grams per tonne gold and 118.27 grams per tonne silver over 2.4 metres (George Cross News Letter No.216, 1988). Assays to the west of the shaft were higher.

There has been no recorded production from this occurrence although there has been a great deal of surface and underground development.

CAPSULE GEOLOGY

The May Blossom showing is located on the west side of the Salmo River, 3.5 kilometres southwest of Ymir. The showing is east of the Free Silver showing (082FSW277). The claim was staked in 1897 and development includes a shaft and an adit.

The property is located at 1372 metres elevation on the west side of the Salmo River, 3.5 kilometres southwest of Ymir.

The Free Silver claim (Lot 2902) was staked in June 1896 by J.M. McLaren and Crown-granted in 1902 to P.W. Thompson and associates. Adjacent ground was subsequently staked as the Ruby, Silver Fr., Victor, Royal, and Galena claims (Lots 2904 - 2906', 5322, 4553 respectively). Further activity was reported in 1908 and 1915 when the property was owned by T. Bennett, J.H. Schofield and associates; the only work reported is trenching.

The May Blossom claim (Lot 5666), which adjoins and lies east of the Free Silver claim, was staked in May 1897 by W. Birmingham. Subsequent staking included the May Day (Lot 13468), May Flower, Big Diamond, and Electric claims. Early development work was by American interests under the name May Blossom Mining & Milling Company. By

CAPSULE GEOLOGY

1915, the claims were held by J.F. Harbottle and associates. Development work to date included a 12-metre vertical shaft and a 69-metre adit on the May Blossom claim.

Washington interests, under the name Gibraltar Mining Company, optioned the May Blossom and Free Silver groups in 1921 but no work was reported. Harbottle and associates held the May Blossom group until 1930 or later.

The Free Silver claim was owned in 1977 by R. Spain, of Trail; prospecting of old trenches was reported.

The area is underlain by sedimentary and volcanic rocks of the Lower Jurassic Elise and Hall formations of the Rossland Group. These have been intruded by Tertiary rhyolite dykes and monzonite of the Middle Eocene Coryell Intrusions.

A quartz vein carrying some galena, pyrite, and chalcopyrite occurs at the contact between a quartz monzonite porphyry and an augite porphyry sill of the Elise Formation. The vein is reported to be narrow (about 1 to 4 centimetres) but is silicified and "altered" (?) for about 0.5 metre on each side of the vein. The vein strikes 322 degrees and dips 82 degrees northeast. Galena occurs as narrow stringers and reportedly assays up to 1371.2 grams per tonne silver and has low gold values.

Later reports identify some scheelite in skarn mineralization and some molybdenite in the quartz veining. The records indicate that the mineralization is not extensive and the best accumulation of sulphides was the galena rich material near the portal.

"A few hundred pounds of manganese ore was reported shipped", but the source is not identified.

CAPSULE GEOLOGY

The Ronoke showings are located 7 kilometres northeast of Ymir on Ymir Creek. The claims were crown granted in 1901 and several open cuts and 3 adits have been developed.

The area is underlain by biotite granodiorite of the Middle to Late Jurassic Nelson Intrusions. Metamorphosed sediments of the Lower and Middle Ordovician Active Formation (Pend d'Oreille schists) occur in a roof pendant within the Nelson batholith.

The occurrence comprises two showings, the upper (on Lot 3402) and the lower (Lot 3718).

The lower showing, on the south side of the creek, comprises the dumps for 2 caved adits and a few open cuts. Mineralization consists of quartz veinlets with disseminated pyrite and traces of galena and chalcopyrite in silicified, rusty altered hornblende-biotite schist and quartzite. Intrusives host minor disseminated pyrite. An average of 6.9 grams per tonne gold (based on a price of \$35.00 per ounce) was calculated from 5 assays across 12 metres (Assessment Report 6141).

The upper showing, 300 metres upstream from the lower showing on

CAPSULE GEOLOGY

the north side of the creek, consists of a small outcrop and a caved adit. Mineralization is similar to the lower showing and is reported to "replace" or follow certain beds within the schists. Graphite is locally abundant. An assay of 39 grams per tonne gold came from this zone (also based on \$35.00 per ounce) (Assessment Report 6141).

REFERENCE: Property File - Yukon Spirit Mines Ltd., Prospectus, Sept. 1989.

CAPSULE GEOLOGY

The Tamarac deposit is located 5 kilometres northeast of Ymir on the southern slopes of Mt. Elise. The claims were staked in 1896. Production of approximately 232 tonnes has been reported for 1901, 1905, 1933 and 1959.

The mineralization is hosted in a major northwest trending, dextral shear zone within schistose-albite-porphyrific granite of the Middle to Late Jurassic Nelson Intrusions. Augite basalt flows and breccia flows of the Lower Jurassic Elise Formation, Rosslund Group also occur in the area. Lamprophyre dykes cut both the schistose granitic rocks and the mineralized quartz veins.

The Tamarac fissure-vein forms a typical "S" shaped secondary shear or tension gash which strikes about 005 degrees and dips 30 degrees west. The vein parallels the Ymir-Goodenough veins (082FSW074) and is confined within the northwest trending shear (which is about 40 metres wide). The vein consists of quartz gangue with disseminated pyrite, arsenopyrite, and minor free gold. Ore shoots, with a northwest rake, have been identified at the bends in the vein where dilation has been greatest. Disseminated pyrite and arsenopyrite also occur within the wallrocks but gold values decrease with distance from the vein. Fault gouge is present on the hanging and footwall side of the vein.

Numerous quartz veins cut the pluton at surface. A vein striking 082 degrees is visible in the ceiling of a collapsed adit. At least three other gold bearing quartz veins occur in the mine area. These strike between 320 and 090 degrees and dip 40 to 60 degrees north.

Reserves for the Tamarac vein have been calculated as 440,640 tonnes possible grading 4.5 grams per tonne gold, 63,180 tonnes probable grading 2.25 grams per tonne gold and 55,890 tonnes proven grading 5.1 grams per tonne gold (Property File - Yukon Spirit Mines Ltd. Prospectus, Sept. 1989). A central higher grade portion of the Tamarac vein is estimated as containing 30,000 tonnes grading 10.4 grams per tonne (Property File - Yukon Spirit Mines Ltd. Prospectus, Sept. 1989).

A sample of a north striking vein, near the 1 Level raise, assayed 4.2 grams per tonne gold over 1 metre (Property File - Yukon Spirit Mines Ltd., Prospectus, Sept. 1989). A sample from an east striking vein at the Powell shaft assayed 4.182 grams per tonne gold over 0.15 metre (Property File - Yukon Spirit Mines Ltd. Prospectus, Sept. 1989).

Tamarac claim (lot 3802) is located at the 1372 metres elevation, 1.6 kilometres east of the Salmo River and 3.2 kilometres north of Ymir. The main claims are the Tamarac and Racatam.

Adjacent ground to the north has been variously held as the Plymott claim (Lot 2399); later Crown-granted as the Pharoah Fr. (Lot 15180), and the Lone Pine claim which was reportedly restaked in 1932 as the Pathfinder and later Crown-granted as the Rainbow Fr. (Lot 12267). The showings were staked in September 1896 by J. W. Handen. The Kenneth Mining and Development Company, Limited Liability began work on the property in 1897 and 5 claims, the Tamarac, Racatam, October, October Fr. and Dinner Bucket (Lots 3802- 3806 respectively) were Crown-granted to the company in 1899. Adjacent ground to the south and east was subsequently Crown-granted as the King Solomon Fr. (Lot 12269) and Queen of Sheba Fr. (Lot 15181). About 168 metres of development work was done in a crosscut and drift from which two mineralized vein segments were partially explored by raises and winzes. Tamarac Mines, Limited was incorporated in July 1900 to

CAPSULE GEOLOGY

acquire the property and about 76 metres of underground work was carried out that year. A 1524-metre tramline to the railway was completed in 1901 and several small ore shipments to the Hall Smelter at Nelson were made before the tramline was destroyed by a forest fire in 1902. Underground development to that date totalled about 488 metres. Lessees shipped a small tonnage to the Boundary Falls Smelter in 1905 but the operation proved unprofitable.

By 1928 the property had been acquired by E.W. Widdowson of Nelson, and limited rehabilitation carried out. Late in 1932 A.T. Powell, of Nelson, optioned the property and began work in an old shaft on a separate vein about 37 metres north of the adit portal. The Pathfinder claim adjoining the Tamarac claim on the north, was staked in August 1932 by D.T. Graney, of Ymir, who drove a 34-metre crosscut adit. The claim was subsequently acquired by Powell, who carried out development work on the combined property from November 1932 until March 1933 when work ceased; several shipments of ore were made to the Tacoma Smelter in February and March. In 1935 Widdowson optioned the property to W.G. Wilkins and associates but little work was reported. Balsam Gold Mines, Limited optioned the property in the latter half of 1936 and intermittent work to early 1938 included rehabilitation of the workings, driving a new adit at a lower elevation, and 61 metres of diamond drilling. In 1958 rehabilitation work was begun by owners George Powell and Lewis Lunde, who incorporated Tamarac Mines Ltd. March 1959. In October of that year an option was given to Pacific Western Metals Ltd. Bulldozer stripping was reported and about 200 tons of ore carrying \$30.00 per ton in gold were crushed and beneficiated. Greenwood Explorations Ltd. optioned 9 Crown-granted from Tamarac Mines Ltd. in August 1979. Trenching, geological mapping, and a geochemical soil survey were carried out. Work during 1980 included diamond drilling in 1-8 holes. Proven, probable and possible reserves were estimated at 630,000 short tons grading 3.5 grams per tonne gold (Northern Miner, December 25, 1980).

CAPSULE GEOLOGY

The Protection (Goodenough) deposit is located 5 kilometres northeast of Ymir, just to the southwest of the Ymir deposit (082FSW074). Exploration dates back to 1895 and the deposit has a long production history from the turn of the century to the 1970's. The Protection occurrence may be the western extension of the Ymir vein but the latter is much wider although other characteristics are similar. These veins have a similar trend as the Ymir veins but are higher grade. The Tamarac (082FSW072), Protection, Ymir (082FSW074) and Good Hope (082FSW075) all appear to be located along the same shear related vein system although the same vein or shear may not be continuous through all properties. The deposit is hosted by Lower Jurassic Ymir Group schist, argillite and quartzite. Augite basalt flows and flow breccias of the Lower Jurassic Elise Formation (Unit Jel), Rossland Group occur just to the west and the contact with the Middle to Late Jurassic Nelson batholith is to the east. Pyrite is disseminated in quartz veins and throughout the sedimentary rock. Mineralization is confined to a shear zone. The shear crosscuts the sedimentary stratigraphy which strikes 035 degrees with a 70 degree northwest dip.

Mineralization occurs in a system of two quartz filled

CAPSULE GEOLOGY

fissure-veins striking 015 to 026 degrees and 028 degrees respectively within argillites and quartzites. The veins converge to the southwest and are about 30 metres apart in the showing area. The veins are highly variable in width but average 1 to 2 metres and they may be a single well defined vein or several veinlets within a distinctive, crushed shear zone. Mineralization occurs as distinct ore shoots apparently related to the intersection of Jurassic granitic dykes with the veins. The gangue is predominantly quartz with some calcite stringers, brecciated wallrocks and a few grains of brown tourmaline. Auriferous pyrite is the main economic sulphide and is associated with galena and sphalerite and minor free gold. Cadmium is reported to occur with the sulphides in minor amounts. With depth the vein appears to carry more chalcopyrite and less gold. The veins are associated with parallel and crosscutting faults in addition to lamprophyre, felsite, and granitic dykes all related to the Nelson Intrusions.

Production between 1898 to 1970 totalled 14,788 tonnes grading 22 grams per tonne gold, 170 grams per tonne silver, 4.5 per cent lead and 4.6 per cent zinc. It is suggested that 85,500 tonnes of ore remain in the old stopes (Assessment Report 15524).

The property is located at 1219 metres elevation on the north side of Ymir Creek, 4.8 kilometres northeast of Ymir.

The Goodenough Fractional claim was staked in June 1898 by Alex Gayette. Development work in shaft sinking to a depth of about 20 metres was carried out in 1899 under the name Ymir Gold Mining Company. There is no record of this company as a Canadian incorporation.

By 1917 the Goodenough Fr. (Lot 13025) and Surprise claims were owned by O.A. Lovell and O. Poulin. In about 1921 owners Lovell, McDonald, and associates began development work on the property, which then consisted of the Goodenough, Demaricott, and Little Nell claims. An adit was driven about 41 metres. Early in 1924 P.J. O'Brien, of Kettle Falls, Washington, optioned the property and development work continued.

The Porcupine Goldfields Development & Finance Company, Limited, optioned the property in 1925 and began development work in a new adit. The option was given up near the end of 1926. Mr. O.D. Firth who was manager for the above company optioned the property and in July 1927 incorporated Goodenough Mines, Limited. A third adit was begun during the year.

Enterprise Consolidated Mining Company, Limited, optioned the Goodenough and adjacent Ymir (82 F/6, Au 9) properties early in 1928. Several hundred metres of development work was done in the lower adit before the option was given up. The owners, Jackson, McDonald, and associates, then resumed development work in the upper levels. Small amounts of ore were shipped to Trail, the ore commanding a very favourable smelting rate due to the high silica content. A new surface discovery in 1930 was explored by a new (No. 4) adit. During the 1928-1932 period the owners shipped about 9,000 tons of ore.

J.F. Coats, of Vancouver, acquired the property near the end of 1932 and incorporated a private company Ymir Gold Mines, Limited. The adjoining Ymir, property was optioned. Some development work was reported in 1933-34. Ymir Consolidated Gold Mines, Limited, was incorporated in September 1934 to acquire and operate the Ymir and Goodenough properties. A 125 ton-per-day mill was installed at the Ymir property in 1925 and operated from July to November, milling ore from both properties; the Goodenough ore was trucked to the mill. Intermittent milling operations continued until August 1939 and development work continued until April 1940. The workings at that time totalled about 1829 metres of drifts crosscuts and raises on 6 levels over a vertical distance of 213 metres. Lessees worked the property to 1943, mining small ore remnants. By 1944 the Goodenough was owned by L.S. Davidson, of Vancouver. Lessees worked the property during the year. Production of some 2,900 tons during the period 1944-1953 is listed under the name Protection.

Americonda Mines Limited, incorporated October 1956, acquired options on the Goodenough and Ymir properties and small amount of development work was carried out during the period 1957-1959.

Hyrock Goodenough Mines Ltd., incorporated August 1960, carried out limited exploration work and shipped 11 tons of ore; work was suspended in October 1960.

In 1964 the Goodenough Fr. Crown-grant and 4 recorded claims were owned by A.L. Weber, of Flushing, N.Y. Some rehabilitation work was reported.

Silver Dawn Mines Ltd. in 1970 prospected the workings for scheelite and shipped a small amount of ore. Lessees mined and shipped a small amount of ore in 1973.

CAPSULE GEOLOGY

The property is located at the 1372 metres elevation on the west side of Huckleberry (north fork of Wild Horse) Creek, 5.6 kilometres northeast of Ymir.

The Ymir, Rockland, and Mugwump claims, staked in July and August 1895 by Joseph and Jerome Petrie and Oliver Blair, were in May

CAPSULE GEOLOGY

1897. The Golden Horn and Robertson and Nora Fractions were staked in 1896 by Petrie, Wood, and Robertson and Crown-granted (Lots 1711, 1712, 2301, respectively) in 1897 and 1898. The Poutney and Lawrence Fractions were staked by the operating company in 1897 and Crown-granted (Lots 2302 and 2303) in 1898.

The property was acquired in November 1896 by The London and British Columbia Goldfields Limited. A program of extensive underground development was begun. A mill was built at the 1036-metre elevation, with a 732-metre tramway to No. 3 adit. A subsidiary company, The Ymir Gold Mines, Limited, was incorporated in London, England, in August 1898 to be the operating company. An 80-stamp mill was put into operation in 1900 and a cyanide plant for treating the tailings was installed in 1901. The No. 10 level crosscut was collared just above the mill and by 1902 had been driven 657 metres to intersect the vein 305 metres below the outcrop. Development work in the upper levels was done in Nos. 2 and 3 adits, and on Nos. 4 and 5 levels from a winze from No. 3 adit. No. 10 level was connected by a raise to the winze from No. 3 adit. Little ore was found below the 7th level. By 1904 the milling operation was reduced to 40 stamps. Production gradually decreased until the mine closed in 1908. During 1907-08 considerable surface exploration was carried out in search for the source of mineralized float occurring further up the mountain. On No. 2 level a crosscut was driven 244 metres into the hill in search for a parallel vein. On No. 10 level the vein was drifted on for 335 metres to the east.

Ymir Gold Mines, Limited, a private company incorporated in February 1933 by J.F. Coats and associates of Vancouver to acquire the adjacent Goodenough property (082FSW073), acquired an option on the Ymir mine but no work was reported under this agreement.

Ymir Consolidated Gold Mines, Limited, was incorporated in September 1934 to acquire and operate the Ymir, and Goodenough properties. Some high-grade ore was known to occur in the Goodenough, and sampling in the Ymir reportedly indicated large blocks of low-grade ore. On the basis of this the company installed a 125 ton-per-day mill at the Ymir property in 1935. The Goodenough ore had to be trucked to the mill. The mill operated from July 18th to November 30, 1935, mainly on Goodenough ore. Exploration in the east end of the upper Ymir workings located a small ore shoot and the mill resumed operating in June 1937 at 30 tons-per-day; milling operations continued into May 1938 when the company ceased operations. Lessees worked the property intermittently from 1937 to 1944, mining from pillars, stops remnants, and dumps.

Americonda Mines Limited, incorporated October 1956s held options on the Ymir and Goodenough properties. Only limited work on the Goodenough was reported during 1956.

Silver Dawn Mines Ltd. apparently held the Ymir and Goodenough properties in 1970. Some adits were rehabilitated and the workings prospected for scheelite.

The Ymir property was owned in 1973 by Murray Zulps and associates, of Vancouver. Some rehabilitation work was reported and a small amount of ore shipped. Issa Fahel optioned the 7 Crown-granted claims of the Ymir group from Zulps and associates in July 1975. This agreement to purchase was assigned to Junex Resources Ltd. in September 1975.

The deposit is hosted by Lower Jurassic Ymir Group schist, argillite and quartzite. Felsic dykes (up to 1 metre wide) strike 030 degrees and dip 74 degrees northwest crosscutting the host rocks. Augite basalt flows and flow breccias of the Lower Jurassic Elise Formation (Unit J1), Rosslund Group occur just to the west and the contact with the Middle to Late Jurassic Nelson batholith is about 1 kilometre to the east.

Pyrite is disseminated in quartz veins and throughout the sedimentary rock. Mineralization is confined to a shear zone trending northeast at 065 degrees with a 60 to 70 degree dip to the northwest. The shear crosscuts the sedimentary stratigraphy which strikes 035 degrees with a 70 degree strike-slip dip. Economic mineralization occurs as lenses with an easterly pitch and frequently contains narrow bands or inclusions of argillite.

The main ore zone, the Bonanza shoot, was about 146 metres long by 3 to 12 metres wide, averaging 4 metres in width. This zone was mined to a vertical depth of about 153 metres. Ore minerals consisted of pyrite, galena, and sphalerite and, near the surface where the vein is oxidized, cerussite and free gold are common. Below 150 metres depth quartz became more prominent and at about 300 metres ore mineralization is confined to streaks within the quartz. Ore material gradually decreased along strike to the east but to the west the vein was terminated by a fault.

The Protection (082FSW073) occurrence may be the western extension of the Ymir vein but the latter is much wider although

CAPSULE GEOLOGY

other characteristics are similar.

The host rocks are crosscut by lamprophyre dykes, numerous faults and are complexly folded. However, there is no evidence of granitic intrusives associated with the ore zone as is common at some nearby deposits. The Tamarac (082FSW072), Protection (082FSW073), Ymir, and Good Hope (082FSW075) all appear to be located along the same shear related vein system although the same vein or shear may not be continuous through all properties.

The best assay from drilling in 1986 (DDH Y86-1) was from a 2-metre intersection (68 to 69 metres) from a drill hole east of the main shaft and below the No. 7 level workings. This assay was 6.5 grams per tonne gold, 38.05 grams per tonne silver, 1.33 per cent lead and 0.70 per cent zinc (Assessment Report 15524). It is suggested that 85,500 tonnes of ore remains in the old stopes.

Total production from 1895 to 1970 is 327,646 tonnes with a grade of about 10 grams per tonne gold and 34 grams per tonne silver. Combined lead and zinc content was about 1.7 per cent.

CAPSULE GEOLOGY

The Good Hope occurrence is located on Huckleberry Creek 5 kilometres northeast of Ymir. The claims were Crown granted between 1900 and 1905. Exploration was primarily done by the Ymir-Good Hope Mining Co. on the X-ray, Wild Horse and Annie Maud Crown Grants.

The area is underlain by slate, shale, argillite, limestone, quartzites, and their contact metamorphosed equivalents, of the Lower Jurassic Ymir Group. The metamorphic rocks consist of mica schists, graphitic schists, andalusite-mica schists, biotite schists, talc schists and paragneissic rocks. These have been intruded by porphyritic granite and dykes and sills ranging in composition from aplite to lamprophyre of the Middle to Late Jurassic Nelson Intrusions. Silicification of the sediments in contact with the granite intrusions is common.

The showing consists of a number of parallel shear-related quartz veins hosted by argillite and schist which strike north with moderate to steep west dips. The quartz veins parallel the foliation and bedding of the sediments. Granite is observed to form the footwall of the main vein. Individual veins are up to about 0.60 metre wide but are usually 0.15 to 0.30 metre wide. The veins are

CAPSULE GEOLOGY

discontinuous and locally occur as a sort of quartz stockwork or reticulating quartz veinlets within zones of brecciated sediments or granite. Fault gouge is common.

Mineralization is sporadic but consists mainly of pyrite, minor pyrrhotite, sphalerite, galena and minor chalcopyrite within a blue to white quartz gangue. Quartz gangue is most common but siderite is locally associated with sphalerite.

Metal values are low and sporadic although selected grab samples have contained as high as 90 to 100 grams per tonne gold (Geological Survey of Canada Paper 51-4). Minor cadmium, silver and zinc values are also present. Minor production totalling 41 tonnes yielding 902 grams of gold and 3,950 grams of silver is reported for this occurrence.

CAPSULE GEOLOGY

The Blackcock mine is located 9.7 kilometres northeast of Ymir on Wild Horse Creek. The deposit was discovered in 1896.

The area is underlain by granodiorite of the Middle to Late Jurassic Nelson Intrusions, argillite of the Lower Jurassic Ymir Group occurs as a roof pendant within the Nelson batholith.

The deposit is comprised of an east trending vein system hosted primarily in argillite but also in granodiorite. The vein is irregular in width but tends to be wider to the west and narrower to the east where it becomes a system of thin streaks and fissures within a zone about 1.5 metres wide. The vein, striking 090 to 110 degrees and dipping 60 to 75 degrees north, has been traced on surface for 204 metres. The vein contains quartz gangue with thin,

CAPSULE GEOLOGY

discontinuous streaks of pyrite, galena, sphalerite and pyrrhotite. The mineralization is not confined to the sheared vein, but it is present in the silicified granodiorite hanging and footwall rocks as irregular masses and disseminations of pyrite, galena, and sphalerite. Abundant sericite has formed along foliation (?) or shear planes within the vein.

A weighted average assay indicates that the vein hosts about 16 grams per tonne gold over a width of 4.73 metres including both vein and wallrock (Ministry of Mines Annual Report 1928, page 332).

Approximately 2600 tonnes of ore mined from the Blackcock vein produced 31,850 grams of gold, 97,260 grams of silver, 43,163 kilograms of lead and 36,821 kilograms of zinc between 1899 and 1942, inclusive. Recent rehabilitation of the old mine workings and construction of a 243 metre crosscut has intersected a mineralized zone about 12 metres wide, with undetermined length and depth, hosting low gold values.

The best assay from drilling in 1986 on the Glitter claims was from DDH 86-001; the intersection from 8.2 to 9.1 metres in porphyritic and vuggy granodiorite assayed 0.92 grams per tonne gold and 7.9 grams per tonne silver (Assessment Report 15844).

CAPSULE GEOLOGY

The Wilcox mine is located on the north side of Ymir Creek, 30 kilometres southeast of Nelson. Production is recorded for 1901-1905, 1910-1911 and 1931-1943. There are three main tunnel levels comprising 1829 metres of development.

The area is underlain by granodiorite of the Late to Middle Jurassic Nelson Intrusions (Nelson batholith). Northeast trending roof pendants of Lower Jurassic Ymir Group metasediments occur within the batholith.

The Wilcox occurrence consists of a number of parallel quartz veins, emplaced along minor shears, striking 075 to 080 degrees and dipping 70 to 90 degrees north. The veins are hosted by greenish grey, fine to coarse-grained granitic rocks. The three major veins are the Fourth of July, Little Willcock, and Willcock veins, all of which crosscut the granitic foliation. To the west, the veins terminate against a roof pendant of schists. Disseminated mineralization continues into the granite for up to 4.9 metres and spreads into "T" or "L" shaped zones. The massive white bull quartz veins contain up to 30 per cent sulphides consisting of irregular masses and disseminations of pyrite, pyrrhotite, minor sphalerite, galena and arsenopyrite. Free gold is common. High grade material occurs in the hanging wall side above the #1 tunnel and the ore generally occurs in tabular shoots with an east pitch. Although the

CAPSULE GEOLOGY

vein is on average 45 centimetres wide, ore shoots may be up to 2 metres in width and 10 to 20 metres long. Wall rocks are locally silicified and may contain ore grade disseminated sulphides. In many places a fault gouge of decomposed feldspar accompanies the ore.

The two Fourth of July veins, extending onto the Willcock claim, strike 95 to 115 degrees and dip 50 to 55 degrees north. These veins are 0.10 to 0.20 metres wide and are separated by 20 metres of foliated granodiorite. Mineralization consists of minor disseminations and stringers of pyrite and occasional clusters of galena. A chip sample (#J-07) assayed 27.8 grams per tonne gold, 561.4 grams per tonne silver, 1.95 per cent lead and 0.124 per cent zinc (Assessment Report 14555).

Production totalled 14,555 tonnes yielding 241,982 grams of gold, 526,635 grams of silver, 98,224 kilograms of lead and 30,649 kilograms of zinc.

COMMODITY Gold GRADE 74.7000 Grams per tonne
COMMENTS: Highest assay of samples collected from the shaft and dump material
(Sample FHTDD-3) of the No.3 vein.
REFERENCE: Assessment Report 16464.

CAPSULE GEOLOGY

The Foghorn occurrence is located 10 kilometres northeast of Ymir. Workings comprise several open cuts, short adits and inclined shafts on 3 veins, the No. 1, No. 2 and No. 3.

The area is underlain by porphyritic and gneissic granodiorite (Nelson batholith) of the Middle to Late Jurassic Nelson Intrusions which host north-northeast trending pendants. The pendants comprise Lower Jurassic Ymir Group sediments striking 010 to 082 degrees. The sediments have been metamorphosed to quartz-biotite schist and biotite schist. The veins and country rocks are crosscut by lamprophyre dykes.

The granodiorite is host to several northeast trending, faulted quartz veins of variable dip and strike. The veins are in the order of 20 to 30 centimetres wide on average. The veins contain quartz

CAPSULE GEOLOGY

with pyrite and are sheared. Breccia and fault gouge 5 to 10 centimetres wide is common. Quartz near surface is vuggy and small crystals of quartz are noted. Manganite is common in the veins with some limonite. The granitic host rock is kaolinized locally.

The No. 1 vein, the most northerly and highest vein, strikes 008 degrees and dips 52 degrees west. The footwall is aplitic granodiorite grading into gneiss and the hanging wall is normal granodiorite. The granodiorite contains small angular veins of honey-combed and, locally, iron stained quartz. These vary from 0.15 to 0.60 metre in width.

The No. 2 vein, the most southerly and lowest vein, is exposed in an open cut 76 metres lower than the No.1 vein. The No. 2 vein strikes 040 degrees and dips 45 to 50 degrees north. The vein in the face shows 0.03 metre of quartz hosting pyrite and limonite with several centimetres of oxidized and kaolinized granitic vein rock.

The No. 3 vein, traversing the area in between No.1 and No.2, is exposed by 3 surface cuts, a shaft and an adit. The vein exposed is 0.5 to 1 metre wide and both walls are in granodiorite. The vein strikes 033 degrees and dips 053 degrees north and is truncated by a lamprophyre dyke. This vein reportedly carries the best gold values. Samples collected from the collar of the shaft and from dump material near the portal assayed up 74.7 grams per tonne gold (Sample FHTDD-3), (Assessment Report 16464).

Records indicate a zone 2.75 metres wide of high grade galena and a 14 metre zone of low grade galena (about 7.5 per cent) within what is referred to as the "long tunnel". It is unclear which vein each of these zones may be associated with.

CAPSULE GEOLOGY

The Gold Cup occurrence is located on the west side of Mt. Elise, 6 kilometres north of Ymir. Some underground development was done in the early 1900's.

The area is underlain by metamorphosed, Lower Jurassic Elise Formation (Rossland Group) porphyritic andesite (augite porphyry) and andesitic agglomerates which have been intruded by Middle to Late Jurassic granite of the Nelson Intrusions.

Quartz veins, usually 45 to 75 centimetres wide, crosscut the volcanics and at lower levels the granitic intrusive. The veins generally strike 090 degrees with dips variable from steeply north to steeply south. The quartz gangue contains pyrite, chalcopyrite,

CAPSULE GEOLOGY

bornite, covellite and rare native gold. Weathered zones also contain malachite, limonite and tetrahedrite. A grab sample indicated values in the order of 20 grams per tonne gold and 145 grams per tonne silver (Geological Survey of Canada Memoir 94). No analysis for copper is reported.

For 1925, 24 tonnes producing 1,244 grams of gold is reported.

COMMENTS: Highest values from samples taken from a tunnel near the centre of an anomaly.

REFERENCE: George Cross News Letter, No.99, 1988.

CAPSULE GEOLOGY

The Dumas occurrence is located on the south side of Clearwater Creek about 9.5 kilometres northeast of Ymir. Drifting on the vein began in 1898 and development work ceased in 1914 and the property was idle until 1980.

The area is underlain by argillite, schist, sericite schist, andalusite schist and argillaceous quartzite of the Lower Jurassic Ymir Group. These have been intruded by granodiorite of the Middle to Late Jurassic Nelson Intrusions (Nelson batholith) and lamprophyre dykes and sills. The contact with the Nelson batholith is about 300 metres to the east of the showing.

Mineralization occurs at the contact of the argillaceous

CAPSULE GEOLOGY

sediments and the Nelson batholith. Mineralization consists of a network of quartz veins hosted in argillites and containing galena, sphalerite and tetrahedrite.

Two drifts have been developed on a quartz vein 1 to 1.3 metres wide. The vein strikes north-south and dips 58 degrees east in black argillite and sericite schist. The vein exposed in the lower drift is highly pyritic but the material stockpiled at the portal gave low assay values. At the upper adit, several tonnes of material containing veinlets and disseminations of pyrite, galena, sphalerite and traces of tetrahedrite are stockpiled. Samples from this material has an average assay of 1.55 per cent lead, 1.29 per cent zinc, 62 grams per tonne silver and 16 grams per tonne gold (Assessment Report 16800). The highest values from samples taken from a tunnel near the centre of an anomaly were 133.35 grams per tonne gold, 719.9 grams per tonne silver, 21 per cent lead and 14 per cent zinc (George Cross News Letter, No.99, 1988). The anomaly is 914 metres long, 30 to 91 metres wide, has an indicated depth of more than 107 metres and is open at both ends.

A 1.8 metre thick quartz vein cuts highly shattered black argillite at the western edge of the property. The vein hosts disseminated pyrite which is oxidized. The vein strikes 060 degrees and dips 52 degrees north. A sample assayed 0.01 per cent lead, 0.01 zinc, 6.2 grams per tonne silver and 0.2 grams per tonne gold (Assessment Report 16800).

CAPSULE GEOLOGY

The Old Timer showing is located 8 kilometres northeast of Ymir on the south side of Clearwater Creek. Exploration and development of the workings took place between 1900 and 1928.

The area is underlain by argillite, siltstone, grit, limestone, chert and wacke of the Jurassic Ymir Group. The Nelson batholith of the Middle to Late Jurassic Nelson Intrusions occurs just to the east of the workings.

Argillites and schists host a northeast trending quartz vein within a shear zone approximately parallel to the schist/granite contact. The vein is in the hanging wall of the 2 to 3 metre wide shear zone which contains irregular masses of mineralized quartz and

CAPSULE GEOLOGY

gouge material. The vein is hosted in sediments to the southwest but follows the contact to the northeast. The irregular Old Timer vein (now called the West zone) is, on average, 1.4 metres wide and has been traced for 125 metres along strike. Significant mineralization occurs over at least a 50 metre strike length and consists of pyrite, galena, sphalerite and chalcopyrite. A rare chlorophosphate of lead, pyromorphite (Pb,C1) Pb₄ (P04)₃, is found within the oxidized portion of the vein.

The Pathfinder vein (developed by a tunnel) also occurs in the vicinity.

In 1980, 22.6 tons of vein material was shipped and contained 3.97 grams per tonne gold and 85.8 grams per tonne silver (Assessment Report 12593). Channel sampling across 2 metre widths in 1987, assayed between 2.3 to 20.74 grams per tonne gold, 6.86 to 37.71 grams per tonne silver and combined lead/zinc of 0.4 to 1.1 per cent (Property File - Golden Glory Resources Ltd., Prospectus, July, 1988).

A northeast trending geochemical anomaly, the East zone, was outlined in 1987, 150 metres east of West zone.

CAPSULE GEOLOGY

observed in the footwall and blocky fine-grained greenish quartzites are in the hanging wall.

Mineralization consists of disseminated grains and irregular clusters of chalcopyrite and pyrite with minor bornite. The sulphide zones are highly irregular with no distinct boundaries. Folds in the hanging wall to the east of the zone have axes that plunge 10 degrees northeast. Small faults and feldspar porphyry dykes crosscut the skarn and host sediments.

Production totals 45,352 tonnes, recovering 7,651 grams of gold, 950,010 grams of silver and 672,630 kilograms of copper. The ore also contained traces of nickel and cobalt.

Work in 1966 delineated a second skarn about 0.8 kilometre west of the original open pit.

The original discovery was made here in 1890 and mining was carried on intermittently between that time and 1918. The workings were mainly open glory holes and these are still accessible.

Following the closing of the mine in 1918, little work was done on the property until 1955. In that year some diamond drilling was done. In the latter part of 1956 the Finley Company of Reno, Nevada, obtained an option. A few thousand tons of material was broken for mill feed but no regular mining program evolved.

In 1956, Swift Copper Mines Limited acquired 18 mining claims covering the property and in addition acquired a complete mill rated at 200 to 300 tons, located about 11.2 kilometres from the mining property.

Development in 1960 consisted of mapping, stripping, sampling, and other surface work, including a limited amount of Packsack drilling.

During 1961 a zone about 152 metres long was stripped by bulldozer and two old adits uncovered. In 1962 the Great West Mining Corporation Ltd. of Vancouver put down twelve diamond-drill holes, six in the vicinity of the workings, and six in a group about 610 metres west-southwest of the workings. Four holes of the latter group intersected a body of skarn about 12 metres thick mineralized with chalcopyrite and pyrite.

COMMENTS: Siliceous grey rock containing 2 to 3 per cent pyrite and 3 per cent malachite from the dump by the Alma N shaft.
REFERENCE: Assessment Report 19503.

CAPSULE GEOLOGY

The Star and Alma N occurrences are located 8 kilometres southwest of Nelson. The occurrences were discovered around 1897.

A mineralized shear zone occurs within Lower Jurassic Elise Formation (unit Jel) volcanics of the Rosslund Group at and near the contact with Jurassic pseudodiorite (monzonite ?) and pyroxenite of unknown affinity (Eagle Creek?). The Elise Formation comprises augite basalt flows, flow breccias and subvolcanic intrusions. The zone and showings occur at the northern extension of the Silver King shear zone (Silver King mine, 082FSW176).

The Star occurrence consists of an irregular quartz vein, a few centimetres to one metre wide, which follows the shear zone striking 010 degrees with a vertical dip. The quartz is mineralized with pyrite, chalcopyrite, some malachite, and traces of galena. Sulphides are also disseminated within the sheared country rock on either side of the quartz vein. The vein is hosted in sheared and potassically altered monzonite(?). Mineralization occurs over an 800 by 200 metre area. A grab sample of highly sheared sericitic volcanic rock containing trace pyrite from the shaft assayed 0.76 grams per tonne gold, 0.0623 per cent copper, 0.0085 per cent zinc and 0.0145 per cent lead (Assessment Report 19503).

The Alma N showing, about 800 metres southeast of the Star, is reported to consist of a mineralized zone about 12 metres wide hosted in potassically altered monzonite(?) at the contact. Two shafts were sunk on the showing and a small shipment of sorted ore is thought to have come from this showing. A grab sample of siliceous grey rock containing 2 to 3 per cent pyrite and 3 per cent malachite staining from the dump by the shaft assayed 0.66 grams per tonne gold, 0.0944 per cent copper, 0.02 per cent lead and 0.035 per cent zinc (Assessment Report 19503).

The Ron area (grid) hosts similar mineralization to the west of these workings.

This is possibly a "conformable gold" occurrence.

Pacific Sentinel Gold Corporation drilled the property in 1990.

CAPSULE GEOLOGY

The Eureka workings are located about 7 kilometres southwest of Nelson, south of Kootenay Lake. The area was explored at the turn of the century. Production from 1905 to 1954 totalled 8995 tonnes yielding 1,124,747 grams silver, 19,190 grams gold, 159,170 kilograms copper and 713 kilograms lead. Production in 1956 was included with Queen Victoria (082FSW082).

The area is underlain by Jurassic pseudodiorite, pyroxenite or monzonite (?) of unknown affinity (Eagle Creek?) and mafic to intermediate flows and tuffs of the Lower Jurassic Elise Formation, Rossland Group. The Silver King shear zone has been truncated to the south of the showing by the metamorphic (intrusive ?) rocks.

The mineralization was originally documented as occurring in rafts or remnants of limestone of the Lower Jurassic Rossland Group which are incorporated into the diorites and granites of the Middle to Late Jurassic Nelson Intrusions. Two veins, closely associated with the limestones, host chalcopyrite, azurite, malachite, chrysocolla with minor galena, bornite, and native silver in a quartz-carbonate gangue. The veins are both slightly larger than 1 metre wide and are oxidized to the lowest levels of the underground workings. Sulphide mineralization also occurs in the limestone as well as the quartz veins. The main vein has a strike of 308 degrees

CAPSULE GEOLOGY

with a dip of 85 degrees to the northeast. The veins produced a few thousand tonnes of copper ore which graded five to ten per cent copper with 5 to 7 grams of gold and 50 to 70 grams of silver. Better grades were observed in the limestone hosted portions of the system than in the siliceous sections.

More recent work describes a shear related quartz-carbonate vein system hosting 1 to 5 per cent pyrite, chalcopyrite and bornite and up to 5 per cent sphalerite, galena and hematite. The veins are hosted in occasionally sericitic monzonite and monzosyenite. Mapping in the area defines the host rock as pseudodiorite (Open File 1989-11). This is possibly a "conformable gold" occurrence.

A representative grab sample from the area of the Alhambra workings in 1989 assayed 1.75 grams per tonne gold, 173 grams per tonne silver, 0.82 per cent copper, 1.08 per cent lead and 1.50 per cent zinc (Assessment Report 19503).

Pacific Sentinel Gold Corporation drilled the property in 1990. GEO Resources drilled in the area in 1997. See also the Kenville (082FSW086).

The Eureka property is located at the head of Eagle Creek on Lot 5552, about 6 kilometres southwest of Nelson at an elevation of 823 metres. It covers over 50 acres and consists of 10 claims and fractions: Eureka, Toronto, Champion, Imperial, Cold Hill, Gold Leaf, Gold Leaf Fraction, Athambra Fraction, Viking Fraction, and Viking Junior Fraction.

By 1896, Eureka had been opened up and in 1902, J.P. Swedberg received a Crown grant for the property. In 1904, 2 ledges had been opened up by 2 shafts, 27 and 23 metres long, and an incline of 12 metres. More than 37 metres of drifting and sinking was done.

The following year, the property was bonded to J.A. Kirkpatrick and other Nelson men who extended the working shaft by 15 metres and did 610 metres of drifting.

The property was owned by the Eureka Copper Mines, Limited, in 1906. They worked it until 1912, carrying the shaft down another 15 metres, doing 463 metres of drifting and 213 metres of crosscutting, driving a tunnel for about 244 metres and constructing a raise.

In 1912, Eureka was under lease and bond to British Columbia Copper Company, Limited, who installed a small boiler, an ore concentrator and a hoist driven by a gasoline engine. They also sunk a winze 30 metres, and carried out 61 metres of drifting and 183 metres of raising.

In 1915, the property was secured under lease and bond to Keffer & Johns. Shortly after they turned the bond over to Pingree Mines, Limited, who drove a tunnel for about 61 metres.

A short aerial tramway 329 metres long and another 914 metres long were installed in 1917 to alleviate the expense of hauling the ore by wagon. The same year, 60.9 metres of cross-cutting and 61 metres of open cuts on the surface showing were made and a new compressor and hoist were brought to the mine, but not yet installed.

In 1918, the property was operated under lease by Inland Mining Company, Limited, of Walla Walla, Washington. The following year, Vincent Development Company, also of Walla Wan, held the property under lease and bond. The Granite - Poorman mill was leased and flotation equipment installed. Development work consisted of advancing the main drift and continuing a long crosscut for 37 metres. In 1920 they dropped their option.

Nothing was reported to have happened on this property until 1945 when Kenville Gold Mines Ltd., who owned the Granite - Poorman property, took over neighbouring properties on the northern slopes of Toad Mountain, including Eureka. This company cleaned out old adit portals, except those which were seriously caved, surveyed most of the accessible workings and did a considerable amount of surface drillings on its extensive holdings.

In 1950, Copper Leaf Mines Limited started a raise, reopened the 76.2 metres level for 182.8 metres, rehabilitated the old shaft and located the old winze. The following year they purchased the property from Kenville Gold Mines Ltd.

In 1953, the property was optioned to Eureka Copper Syndicated who installed a compressor at the portal of the 137 metres adit.

In 1956, Copper Leaf Limited rehabilitated the upper or 76 metres level and then concentrated their efforts on the south end of the workings where 3 stopes were carried up the pillar for a total distance of 34 metres. A stope was also carried up the pillar from the 46 metres. The Kenville Cold Mines Mill at Nelson was purchased to treat the ore. Reserves were estimated that year at 80,000 tons, grading 0-115 oz. Au/ton; 4-7 oz. Ag/ton; 1.26 per cent copper; 1.6 per cent lead, and 0.4% Mo.

Later in 1956, Finley Company of Reno, Nevada, provided funds

CAPSULE GEOLOGY

and all the operations of Copper Leaf Mines Limited were than carried on under that name.

CAPSULE GEOLOGY

Mines Ltd., Kootenay Gold Exploration Co. Ltd., Inland Mining Co., Granite-Poorman Mines Ltd., Granite-Poorman Gold Mines Ltd., Livingstone Mining Co. Incorporated, and Kenville Cold Mines Ltd.

In 1945 Kenville Gold Mines Ltd. acquired the Granite-Poorman and a number of other properties in the area. A total of over 6096 metres of diamond drilling was done on the Granite-Poorman property, partially from the surface in a search for bidden veins, and the remainder underground to search for extensions of known veins. A 125-ton mill was in operation from 1947 to August 1949.

The mine is developed from two main levels, the 2,570 or lower, and the 2,750 or upper adits. Underground workings are extensive. The five main veins have been stoped for a combined length of over 915 metres.

The mine is one of the oldest, and greatest producers in the district, producing intermittently from 1890 to 1954, with the bulk of production from 1899 to 1912. Production totalled 2029 kilograms of gold, 861 kilograms of silver, 23.5 tonnes of lead, 15 tonnes of zinc, 1.6 tonnes of copper and 37 kilograms of cadmium from 181,395 tonnes mined.

The area is underlain by Jurassic pseudodiorite and pyroxenite of unknown affinity, underlain by volcanic rocks of the Lower Jurassic Elise Formation, Rosslund Group. These have been intruded by granodiorite of the Middle to Late Jurassic Nelson Intrusions (Nelson batholith). A northwest trending system of quartz veins is hosted in pseudodiorite, locally gneissic, intruding greenstone on the east limb of a syncline. The veins, which are weak fault zones, strike 330 to 350 degrees and dip 45 degrees north. The veins are cut by faults, some of which are occupied by lamprophyre dykes. The veins have good continuity along strike and downdip. Significant amounts of ore have been produced from five veins which range from 0.02 to 2 metres in width, averaging about 0.6 metre but are commonly 0.02 to 0.10 metre wide. West to east, over a horizontal distance of 518 metres, they are; the Hardscrabble, Poorman, Greenhorn, Granite (or White), and Beelzebub veins. Lesser veins occur to the east and west. At the Hardscrabble vein, steeply dipping faults drop the eastern block down as much as 15 metres. The largest fault has produced offset of about 100 metres to the left in the Granite and Greenhorn veins. The gangue is milky to glassy quartz with pyrite, chalcopyrite and minor amounts of galena, scheelite, sphalerite and some visible gold. "Rich pockets" of visible gold are reported from earlier development. Where the veins are oxidized limonite is common with some "free gold". Scheelite is widely distributed as individual grains but rarely as significant concentrations in any given zone. Sulphides are commonly disseminated in hanging wall or footwall rocks. Ore shoots, which rake to the south, are formed at the intersection of the main veins with flatter lying offshoots and high gold values in these shoots appear coincident with galena. Host rocks exhibit replacement of plagioclase by soda-potassic feldspar as well as alteration of ferromagnesian minerals to biotite and epidote. Ore production has averaged better than 17 grams per tonne gold with associated silver. The Granite-Poorman produced mainly gold with silver but the mill has been used at various periods to process ores from other properties which may have been richer in base metals. In recent years some of the granitic rock has been used as a construction material (Granite 082FSW342). A 1985 report by P.J. Stantos, stated indicated and inferred resources above the 2570 (main mine adit) level were 294,800 tonnes grading 16.73 grams per tonne gold (www.anglo-swiss.com). In 1995 and 1996, Anglo Swiss Industries Inc. and Teck Corp., Teck as operator, conducted prospecting, diamond drilling (1140 metres in 1995; 1941 metres in 11 holes in 1996) along approximately 475 metres of strike length, and an induced polarization survey on the property.

GEO Resources Ltd. drilled about 1200 metres in 5 holes in 1997 on the White/M.R.S. property, adjacent to the Kenville mine. The objective was to evaluate the northern extension of the mineralized shear at the Eureka mine (082FSW084). West of the Kenville mine, McMahon Resources Ltd. drilled 1200 metres in 1997. Anglo Swiss Resources Inc. plan drilling in 1998.

CAPSULE GEOLOGY

The Venango occurrence is located on the western edge of the Granite-Poorman mine (082FSW086), about 11.5 kilometres west of Nelson. The veins of this occurrence are similar to the Granite-Poorman veins and are part of the same fracture system. Little work was done on the property until 1939.

The area is underlain by Jurassic pseudodiorite and pyroxenite of unknown affinity underlain by volcanic rocks of the Lower Jurassic Elise Formation, Rossland Group. These have been intruded by granodiorite of the Middle to Late Jurassic Nelson Intrusions (Nelson batholith).

A northwest trending system of quartz veins is hosted in pseudodiorite, locally gneissic, intruding greenstone on the east limb of a syncline. The veins, which are weak fault zones, strike 330 to 350 degrees and dip 40 to 45 degrees north. The veins are cut by faults, some of which are occupied by lamprophyre dykes. The veins have good continuity along strike and downdip.

The occurrence consists of two quartz veins along strike with and similar to the Granite-Poorman veins. The quartz gangue hosts pyrite with lesser amounts of chalcopyrite, galena, and sphalerite as irregular concentrations. Free gold was reported and scheelite was found in significant amounts but not recovered. The vein in the stope varies from 10 to 60 centimetres in width and is up to 46 metres in length. This vein is typically "sheeted" by fractures parallel to the walls. Locally, significant concentrations of scheelite were noted (0.3 to 3.39 per cent Wo3) but no tungsten was produced (Property File - Maconachie, 1942). A scheelite lense 15 by

CAPSULE GEOLOGY

3.66 by 0.25 metres was documented near the collar of the shaft. The veins are remarkably consistent along strike with some anastomosing of the vein into narrow, flat lying stringers. The ore shoots plunge to the south at about 30 degrees along the plane of the vein. No major faulting was observed in the underground workings but a large lamprophyre dyke crosscuts the vein in its northern extension.

Production figures are scarce but it is estimated that about 809 tonnes were mined with shipping grades in the order of 14.5 grams of gold and 17 grams of silver per tonne with some lead and zinc.

CAPSULE GEOLOGY

The Royal Canadian and Nevada veins are located 11.2 kilometres west of Nelson. Work on these date back to the late 1800's. Workings on the Royal Canadian consist of 4 adits and on the Nevada, 2 adits and a shaft were developed.

The area is underlain by Jurassic pseudodiorite and pyroxenite of unknown affinity and by volcanic rocks of the Lower Jurassic Elise Formation, Rossland Group. These have been intruded by granodiorite of the Middle to Late Jurassic Nelson Intrusions (Nelson batholith).

The Royal Canadian vein, striking 345 degrees and dipping 60 degrees to 70 degrees northeast, is hosted in psuedodiorite. The vein is 1 to 30 centimetres wide and contains quartz gangue impregnated with pyrite and chalcopyrite. Pyrite is also disseminated in the country rock. The southern portion of the vein is offset a few metres and it is reported that the vein is weaker and the values lower beyond the fault.

The Nevada vein lies about 460 metres to the southwest of the No.4 adit on the Royal Canadian vein. The vein strikes at 080 degrees with a 50 degree southeast dip, almost at right angles to the trend of the Royal Canadian vein. It is located for the most part, at the contact of psuedodiorite with a raft or inlier of schistose volcanics. The Nevada ranges from 0.20 to 1.37 metres in width and hosts stringers and knots of quartz well mineralized with pyrite.

Both veins produced gold, silver and minor lead and zinc. From a total of 113 tonnes (90 tonnes reportedly from the Nevada), 3,359 grams of gold and 3,454 grams of silver were produced. In 1943, scheelite was reported from the Royal Canadian and Nevada groups on 49 Creek. Scheelite was also found in gravels of 49 Creek on the

CAPSULE GEOLOGY

Acorn (082FSW269) occurrence downstream from these claims.

CAPSULE GEOLOGY

The Good Hope occurrence is located on the west side of Bird Creek, 13 kilometres southwest of Nelson. The workings consist of 3 adits and the work dates back to 1911. A number of veins of variable orientation and with spotty mineralization were subjected to prospecting at various times and all are in the immediate vicinity of the Good Hope or Ophir veins.

The area is underlain by volcanic (lapilli tuff) and metavolcanic rocks of the Lower Jurassic Elise Formation, Rossland Group and metasedimentary rocks of the Lower Jurassic Ymir Group. The mineralization occurs along or near the contact.

Parallel quartz veins hosted in east striking fissures and conformable to the regional foliation occur within quartz-mica and quartz-mica-chlorite schist. Bands and lenses of quartz, with

CAPSULE GEOLOGY

interbands of pyritic, siliceous schist are up to about 1 metre wide and strike 085 degrees with a dip of 30 to 45 degrees south. Pyrite and chalcopryrite is reported locally from various veins in the area and some free gold is reported from oxidized portions of the mineralized zones.

Samples taken over 0.06 to 0.30 metre from the footwall vein in the No. 3 adit assayed 61.7 grams per tonne gold, 89.8 grams per tonne silver and 1 per cent copper (Assessment Report 11554).

CAPSULE GEOLOGY

The Miracle showing is located on the east side of Forty Nine Creek, 17.5 kilometres southwest of Nelson. The only recorded work, 10 metres of drifting, was done in 1944.

The area is underlain by augite basalt flows, flow breccias and subvolcanic intrusions of the Lower Jurassic Elise Formation (Unit J_{el}), Rossland Group. These have been intruded by granite of the Middle to Late Jurassic Nelson Intrusions and are cut by the Red Mountain fault.

A geological description is not available but it is assumed to be similar to the May & Jennie showing (082FSW091) immediately to the south. The showing plots right on the trace of the Red Mountain fault and is described as a occurring above Forty Nine Creek road.

Records indicate about 24 tonnes of material yielded about 13.7 grams per tonne gold and 32.9 grams per tonne silver.

CAPSULE GEOLOGY

and 175 metres of drifting carried out. No. 2 adit was driven 114 metres to the vein and 198 metres of drifting was done. A 34-metre raise connected the two level and a 30-metre raise was driven to the surface. Reserves were estimated in 1903 at about 60,000 tons above No. 2 level. Extensive surface work was done on the Red Top claim in IL903 the option was apparently abandoned that same year.

Construction of a 50 ton mill was begun in 1904 by Reliance Gold Mining and Milling Company, Limited, which was incorporated in March of that year. The cyaniding plant proved to be inadequate and the mill operated for only a short period in 1906. The company charter was surrendered in 1914. The mill was dismantled in about 1918.

Two adjacent claims, the Gold Note (Lot 616) and Giant Fraction (Lot 6449) were Crown-granted to A.H. Kelly in 1903 and 1907, respectively. The Gold Note and adjacent claims were owned during the 1919-1921 period by Alex Long and Jeff Steele, of Nelson; in 1921 the claim was part of the High Ore group; the veins were traced along strike for several hundred metres by a series of short adits and open cuts.

The May & Jennie claim was under lease for a short time in 1940 to C.H. Erickson and A. Olsen, of Nelson; some work was reported in reopening the old adits.

Highland Star Mines Limited in August 1973 optioned from R.A. Sostad, of Vancouver, the May & Jennie claim, Mineral Leases covering the Golden Giant, Tip Top, Cold Bell, Giant Fr., and Cold Note claims, and the "49" Nos. 1-15 located claims. Reserves were estimated at 80,000 tons averaging 8.57 grams per tonne gold (indicated) (Northern Miner, Feb. 28, 1974, p. 21).

The May & Jennie Crown-grant and four reverted Crown-grants, owned by Anne Kramer, of West Vancouver, were acquired by Shackelton Petroleum Corporation in about 1980; the company name was changed to Europa Petroleum Ltd in May 1983. No work was reported.

Player Petroleum Inc. in May 1983 acquired the 6 claims comprising the property through separate transactions with Europa Petroleum and L. Leighton, of Nelson. Austin Resources Inc. reportedly carried out geochemical and geophysical surveys under a joint venture agreement early in 1984. The company name (Player) was changed in June 1984 to Player Resources Inc. Work at this time included magnetometer and electromagnetic surveys over 18.4 kilometres, geochemical surveys comprising 709 soil and 64 rock samples, and trenching. An option to earn a 49 per cent interest was given to Yucana Resources Inc. in 1985; drilling work was reported; the option was given up and the property reverted to Europa Petroleum Ltd. in 1986. Aurora Gold Ltd. optioned the property in 1987.

The May & Jennie vein is located on the southwest slope of Forty Nine Creek valley, 8.5 kilometres southwest of Nelson. Development was carried out on this property between 1900 and 1905, comprising 610 metres of underground workings. The workings are caved or flooded and the vein is now only exposed in adit No. 2.

The property is underlain by Lower Jurassic Elise Formation (Rossland Group) augite basalt flows, flow breccias and pyroclastics previously mapped as the Beaver Mountain Formation. Locally, the volcanics have been intruded by dominantly fault controlled late stage, biotite-rich lamprophyre dykes which are probably related to the nearby large granitic stocks and plugs of the Middle to Late Jurassic Nelson Intrusions.

The occurrence consists of quartz-pyrite vein mineralization which is controlled by a major normal fault (the Red Mountain fault) striking 150 to 160 degrees and dipping 80 degrees east. The fault closely follows the trend of the local stratigraphy and schistosity and has numerous associated minor shears. The vein averages about 0.6 to 0.8 metre in width and has been traced for about 345 metres (although it may have a strike length of over 700 metres) along strike on surface. The gangue consists of quartz with minor calcite mineralized by fine to medium grained disseminated pyrite. Wider sections of the fault host massive pyrite with possibly some pyrrhotite and little or no quartz gangue. Locally, a quartz-pyrite rich envelope extends into the footwall stratigraphy. Assays vary from 1 gram to about 36 grams gold. Free gold occurs in near-surface oxidized zones.

Chip sampling across intervals of the exposed vein assayed 0.96 grams per tonne gold across 0.41 metre to 33.1 grams per tonne gold across 0.66 metre (Assessment Report 14417).

CAPSULE GEOLOGY

The Gold Hill occurrence is located on Fortynine Creek, 16 kilometres southwest of Nelson. The area was initially explored in the 1890's. The old workings were re-opened in 1974.

The area is underlain by andesite, lapilli tuff (Unit Je8l), basalt flows, flow breccias and subvolcanic intrusions (Unit Je1) of the Lower Jurassic Elise Formation, Rossland Group intruded by lamprophyre dykes. The two units are separated by the Red Mountain normal fault. Foliation and shearing follow a general northwest trend. The sheared volcanic rocks are chloritic with lesser biotite and sericite.

Mineralization occurs in shears and quartz zones, associated with the margins of lamprophyre dykes, hosted in massive to schistose dark green augite porphyritic andesite. The veins generally parallel the strike and dip of the foliation in the schists. The three mineralized veins identified are strongly fault/shear controlled and contain erratic quartz-plagioclase pegmatitic lenses which host chalcopyrite, bornite, and arsenopyrite. Oxidized portions of the

CAPSULE GEOLOGY

veins host malachite, azurite, and free gold. Historical sampling and mining activities indicate erratic gold values which are locally up to 65 grams per tonne, but appear to average about 10 grams. The gold is associated with about 60 grams per tonne silver and about 1.35 per cent copper.

The highest assay from exploration in 1984 was 207.4 grams per tonne gold, 168.315 grams per tonne silver and 4.24 per cent copper (Assessment Report 13878). A channel sample from trenching on the mineralized structure in 1988 assayed 25.1 grams per tonne gold (George Cross News Letter No.205, 1988).

CAPSULE GEOLOGY

the Le Roi, Centre Star, War Eagle, Iron Mask, Josie, Kootenay Columbia, Nickel Plate, and Crown Point claims. By an agreement of August 1, 1967, Hunstone assigned the agreement to Falaise Lake Mines Ltd. During 1967-1968 Falaise carried out 3194 metres of surface diamond drilling, in 41 holes in the hanging wall of the Le Roi, Centre Star, and War Eagle veins, and magnetometer and electromagnetic surveys over other parts of the property. Based on this drilling, together with the work by Cominco in 1940, the indicated ore reserves in pillars and stope remnants in the upper part of the Le Roi, Iron Mask, and War Eagle workings were estimated at 278,800 tonnes averaging 79 grams per tonne gold, 20.9 grams per tonne silver, and 0.65 per cent copper. In May 1969 an adit was begun at the north edge of the Golden-Born Crown-grant (Lot 1234) and directed towards the 800 level crosscut of the Le Roi workings. The adit, driven for 1310 metres, was completed in October 1970. Underground diamond drilling was carried on into 1971. The option was subsequently dropped.

The southern part of the Rossland area is underlain primarily by volcanic rock of the Lower Jurassic Elise Formation (Rossland Group). These rest unconformably on metasedimentary rocks of the Pennsylvanian and possibly Permian Mount Roberts Formation and are in apparent fault contact with rocks of Unit Cs of Carboniferous age (both Upper Paleozoic units may be correlative with the Milford Group). Locally, the Elise Formation is overlain by coarse conglomerates of the Upper Cretaceous Sophie Mountain Formation.

Four prominent igneous suites intrude these rocks. The Rossland monzonite, recently dated at 190 million years (Early Jurassic), is an east trending intrusive complex centred near the Rossland gold camp. It is cut by the Middle to Late Jurassic Trail pluton (Nelson Intrusions) and by the alkaline Middle Eocene Coryell Intrusions. The Middle Eocene Sheppard Intrusions occur as stocks in the southeastern part of the area and in north-trending felsic dykes; they are also cut by the Coryell Intrusions. Also important is an augite porphyry intrusion known as the Rossland sill that hosts a number of the principal orebodies of the camp. The sill, exposed south of the monzonite and on the east slopes of Red Mountain, intrudes the upper part of the Elise Formation and is considered to be part of that formation.

The Rossland mining camp is the second largest gold-producing camp in British Columbia, with recovery of more than 84,000 kilograms of gold and 105,000 kilograms of silver between 1894 and 1941. These deposits are classified as three main types referred to as the North belt, the Main veins and South belt. The Rossland gold-copper veins are dominantly pyrrhotite with chalcopyrite in a gangue of altered rock with minor lenses of quartz and calcite.

In the North belt, a zone of discontinuous veins extends eastward from the northern ridge of Red Mountain to Monte Cristo Mountain. The veins strike easterly and dip north at 60 to 70 degrees. The largest, on the St. Elmo claims (082FSW134), is in the Rossland sill and is 1 to 2 metres thick.

The Main veins form a continuous well-defined fracture system that trends 070 degrees from the southern slope of Red Mountain northeast to the eastern slopes of Columbia Kootenay Mountain, a distance of over 1 kilometre. More than 98 per cent of the ore shipped from the Rossland camp was produced from these veins, of which more than 80 per cent were from deposits in a central core zone between two large north-trending lamprophyre dykes. These important deposits include the Le Roi, Centre Star (082FSW094), Nickel Plate (082FSW095), War Eagle (082FSW097) and Josie (082FSW147) orebodies. The Main vein system consists of a series of veins, commonly in echelon, that dip steeply north. They are mostly within the Rossland sill or the Rossland monzonite. They crosscut lithologies and early structures, but appear to be cut by the late north-trending faults and associated dykes.

The principal veins of the South belt trend 110 degrees and dip steeply north or south. They are within siltstone lapilli tuff and augite porphyry of the Elise Formation, several hundred metres south of the Rossland monzonite. In addition to the typical copper-gold mineralization of the main veins and North belt, some veins in the south belt also contain sphalerite, galena, arsenopyrite and boulangerite.

The Le Roi deposit, part of the Main vein system, consisted of a series of ore shoots with narrow width or strike length with the greatest dimension on the dip. The ore shoots are strung out along a main fissure, which in general is nonpersistent, and end abruptly against dykes or cross structures. The Le Roi vein system strikes 070 degrees and dips 70 degrees north. The deposit was mined to about 600 metres elevation and explored vertically to a dimension greater than the strike length.

CAPSULE GEOLOGY

The vein system is hosted by the Rosslund monzonite which is comprised of a biotite-hornblende-augite monzonite stock that intrudes augite porphyry of the Rosslund sill. The porphyry occurs more than 450 metres below the footwall of the sill and is therefore older than the monzonite intrusion. The augite porphyry in the mine area is thought to have been a stock or dyke-like feeder for the sill exposed on the surface. The monzonite is fine to medium-grained, grey to green in color and hosts magnetite, apatite, some sphene with chlorite, epidote, pyrite, and pyrrhotite.

The Le Roi vein was formed by mineralization replacing wallrock along well defined fractures and by filling fractures and faults with pyrrhotite and chalcopyrite. The gangue consists of altered host rock with lenses of quartz and calcite. Actinolite forms rosettes of silky green needles between chalcopyrite and pyrrhotite. Minor pyrite occurs as well formed crystals in the pyrrhotite and as disseminations in the host rock. Garnet crystals are associated with the pyrrhotite and chalcopyrite which occur in fractures with quartz.

Native silver has been reported in pyrrhotite rich ore from the Le Roi central zone. It occurs as blebs along the grain contacts of pyrrhotite and at the contacts of pyrrhotite with magnetite and gangue. Small grains of a silver bearing mineral, probably stromeyerite, with heavy surface stain are associated with the silver.

Between 1898 to 1917, 1,791,680 tonnes of ore was mined from the Le Roi deposit from which was recovered: 24,091,170 grams gold, 37,563,105 grams silver, and 21,330,618 kilograms copper. Production from the deposit is reported to have commenced in 1893.

After 1917, between 1918 and 1942, production from the main mines (Centre Star, Josie, Le Roi, War Eagle, White Bear) was combined and recorded as the Rosslund Properties.

is thought to have been a stock or dyke-like feeder for the sill exposed on the surface.

The Rossland monzonite is fine to medium-grained, grey to green in color and hosts magnetite, apatite with minor chlorite, epidote, pyrite, and pyrrhotite. The Centre Star vein was formed by replacing wallrock along well defined fractures with fracture infillings comprised of pyrrhotite and chalcopyrite with a gangue of altered host rock with lenses of quartz and calcite. Minor pyrite occurs as well formed crystals in the pyrrhotite and as disseminations in the host rock. Molybdenite is reported to occur in quartz-rich ore.

The Centre Star - Le Roi vein was mined almost continuously over 1 kilometre. The vein system is comprised of a series of ore shoots which are more or less en echelon in strike and dip. The ore shoots end abruptly against dykes or cross structures. Between 1897 to 1917, 2,065,331 tonnes of ore were mined from the Centre Star portion of the Main vein system. Recovery totalled 34,164,625 grams gold, 23,147,008 grams silver and 13,366,167 kilograms copper.

From 1928 to 1942 production from the deposit was combined with the Le Roi, Josie, War Eagle and White Bear and is reported with the Le Roi data (082FSW093).

The Centre Star, War Eagle and Le Roi claims, located at the northwestern edge of the city of Rossland, formed the nucleus of a property that was subsequently expanded by the Consolidated Mining and Smelting Company of Canada Limited (Cominco) to include some 30 claims and fractions. The three claims were located in 1890 by Messrs. Bourjouis and Morris, the Le Roi claim being recorded in the name of E.S. Topping.

Early development work on the Centre Star claim was reportedly carried out by the Centre Star Cold Lining and Smelting Company, and from about 1902 by the Centre Star Mining Company, Limited. The War Eagle and Iron Mask claims were reportedly developed by the War Eagle Gold Mining Company, and from about 1897 by the War Eagle Consolidated Mining & Development Company, Limited. The Centre Star, War Eagle and Iron Mask mines were acquired by Cominco in 1906.

The Le Roi claim was reportedly developed by a Spokane company, be the Le Roi Mining & Smelting Co., from 1891. The Le Roi Mining Company, Limited, acquired the Le Roi and Black Bear claims in 1898 and the mine operated continuously until it closed in September 1910. The property was acquired by Cominco in 1911.

Cominco purchased the adjoining Josie property in 1923. By 1928 when the company closed the mine the original workings had all been connected underground to form one large mine with a total of about 97 kilometres of underground workings; mining operations were carried on to a depth of about 503 metres.

Groups of lessees, sometimes over 30 in number, extracted remnants of ore from the old surface and underground workings from 1932 until the company closed down the operation in June 1942; Cominco carried out a program of geological mapping during 1940-1941.

In May 1967 Hunstone Ventures Ltd. obtained an option from Cominco on 72 Crown-granted claims, including the mine workings of the Le Roi, Centre Star, War Eagle, Iron Mask, Josie, Kootenay Columbia, Nickel Plate, and Crown Point claims. By an agreement of August 1, 1967, Hunstone assigned the agreement to Falaise Lake Mines Ltd. During 1967-1968 Falaise carried out 3194 metres of surface diamond drilling, in 41 holes in the hanging wall of the Le Roi, Centre Star, and War Eagle veins, and magnetometer and electromagnetic surveys over other parts of the property. Based on this drilling, together with the work by Cominco in 1940, the indicated ore reserves in pillars and stope remnants in the upper part of the Le Roi, Iron Mask, and War Eagle workings were estimated at 278,800 tonnes averaging 7 grams per tonne gold, 20.9 grams per tonne silver, and 0.65 per cent copper. In May 1969 an adit was begun at the north edge of the Golden-Born Crown-grant (Lot 1234) and directed towards the 800 level crosscut of the Le Roi workings. The adit, driven for 1310 metres, was completed in October 1970. Underground diamond drilling was carried on into 1971. The option was subsequently dropped.

CAPSULE GEOLOGY

The deposit is part of the "Main vein" system, in the Rossland mining camp, which forms a continuous well defined fracture system on a regional scale. The Main vein system trends 70 degrees for a strike length in excess of 1.0 kilometre with the veins dipping steeply to the north. Refer to the Le Roi deposit (082FSW093) for a more detailed discussion of the regional geology and the Main vein system.

The Nickel Plate vein system is hosted by the Early Jurassic Rossland monzonite and augite porphyry of the Lower Jurassic Elise Formation (Rossland Group), known as the Rossland sill. The Rossland monzonite is an east-trending stock of biotite-hornblende-augite monzonite. Tertiary lamprophyre dykes, trending northwards, crosscut the monzonite and sill. This dyke is about 70 metres thick and gives a potassium-argon date of 49.6 plus or minus 1.6 million years (Bulletin 74). The dyke appears to control the concentrations of copper and copper-gold ore. It is a dark greenish dyke with pre-dominant crystals of biotite and abundant potassic feldspar. Minor serpentine occurs on blocky joint faces which caused unstable ground when driving the adit.

Sulphide mineralization occurs from the replacement of wallrock along well defined fractures and by infilling fractures and faults with pyrrhotite and chalcopyrite. The gangue consists of minor lenses of quartz and calcite. Minor pyrite occurs as crystals in the pyrrhotite and as disseminations in the host rock.

In 6 years between 1901 and 1913, 18,685 tonnes of ore were mined from the Nickel Plate vein system with recovery totalling: 291,778 grams of gold, 335,787 grams of silver and 209,376 kilograms of copper.

at 278,800 tonnes averaging 7 grams per tonne gold, 20.9 grams per tonne silver, and 0.65 per cent copper. In May 1969 an adit was begun at the north edge of the Golden-Born Crown-grant (Lot 1234) and directed towards the 800 level crosscut of the Le Roi workings. The adit, driven for 1310 metres, was completed in October 1970. Underground diamond drilling was carried on into 1971. The option was subsequently dropped.

The Iron Mask mine is hosted by the Rossland monzonite and the Rossland sill. The Rossland monzonite is an east trending stock which intrudes an augite porphyry sill of the Lower Jurassic Elise Formation (Rossland Group), known as the Rossland sill.

The deposit is part of the "Main vein" system of the Rossland camp which forms a continuous well defined fracture system on a regional scale trending 70 degrees for a strike length in excess of 1.0 kilometre. The Iron Mask deposit is a mineralized cross structure, a zone of enrichment at the intersection of the Iron Mask and Centre Star north veins (082FSW094). Sulphide mineralization consists of the replacement of wallrock along well defined fractures and infilling the fractures or fault system with pyrrhotite, chalcopyrite, and pyrite. Gangue consists mainly of altered wallrock with minor lenses of quartz and calcite.

A vertical shaft driven in 1896 contained high grade ore which averaged 78.86 grams per tonne gold (Geological Survey of Canada Memoir 77, page 103). BC production records show production for the Iron Mask from 1898 to 1901 and again in 1904 when a total of 14,218 tonnes were mined from which 448,059 grams of gold, 434,019 grams of silver and 189,328 kilograms of copper were recovered. The Iron Mask was historically part of the Centre Star-War Eagle Group (082FSW094 and 082FSW097) and other production data may be combined with one of these occurrences.

Refer to the Le Roi deposit (082FSW093) for details of the regional geology and Main vein-type deposit characteristics.

CAPSULE GEOLOGY

The War Eagle mine is part of the "Main vein" system, in Rossland mining camp, which forms a continuous well defined fracture system on a regional scale. The vein system occurs on two general strikes of which the better developed is about 070 degrees. The veins have been traced in excess of 1 kilometre with veins dipping steeply to the north. The less developed vein system is the War Eagle type which strikes 120 degrees and dips 70 degrees north. The War Eagle system is at best only a series of detached ore shoots with marked stepping to the north. The series of ore shoots have narrow widths and short strike lengths with the greatest dimensions down dip. The ore shoots end abruptly against dykes or cross structures.

The system is hosted by the Rossland monzonite, a biotite-hornblende-augite monzonite stock that intrudes augite porphyry of the Lower Jurassic Elise Formation (Rossland Group), known as the Rossland sill. The porphyry is thought to have been a stock or dyke-like feeder for the sill exposed on the surface, prior to the monzonite intrusion.

The veins were formed by mineralization replacing the wallrock along well defined fractures and by filling fractures and faults with pyrrhotite and chalcopyrite. The gangue consists of altered host rock with minor lenses of quartz and calcite. Grayish banded wollastonite is associated with the ore near the altered host rock and gmelinite has been reported, occurring as reddish-white well-formed crystals. Pyrite occurs as well formed crystals in the pyrrhotite and as disseminations in the host rock. Native gold was reported to occur as disseminated fine specks in rusty patches of

CAPSULE GEOLOGY

quartz-rich ore. Minor molybdenite occurs in quartz-rich veins. A brown to black variety of sphalerite was found cutting vein-like through chalcopyrite and pyrrhotite.

Native silver has been identified in pyrrhotite rich ore in the War Eagle mine. It occurs as blebs along grain contacts of pyrrhotite and at the contacts of pyrrhotite with magnetite and gangue. Small grains of a silver-bearing mineral, probably stromeyerite, which develop a very heavy surface stain are associated with the silver.

Between 1898 to 1905, 300,169 tonnes of ore were mined with recovery totalling: 5,659,751 grams gold, 12,036,613 grams silver and 5,021,436 kilograms copper. From 1918 to 1942, production from this deposit was combined with Centre Star (082FSW094), Le Roi (082FSW093), Josie (082FSW147) and White Bear (082FSW114) and reported with Le Roi production (082FSW093) data.

Refer to the Le Roi deposit (082FSW093) for further details of the Rossland mining camp; the Main vein system and the history of work done.

CAPSULE GEOLOGY

The Virginia vein is part of the "Main vein" system, of the Rossland mining camp, which forms a continuous well defined fracture system on a regional scale trending 70 degrees for a strike length in excess of 1.0 kilometre. The Virginia vein is a sulphide ore body which strikes east-west and dips steeply north and averages 7.6 metres in width.

The vein is hosted by the Rossland monzonite, an east-trending biotite-hornblende-augite monzonite stock. The stock intrudes augite porphyry and volcanic rocks of the Lower Jurassic Elise Formations, Rossland Group. The augite porphyry, known as the Rossland sill, intrudes the upper part of the Elise Formation.

Mineralization consists of pyrrhotite and chalcopyrite infilling fractures and/or faults. Gangue consists of altered wallrock with lenses of quartz and calcite. Pyrite occurs as crystals in the pyrrhotite and as disseminations in the host rocks.

In 1899, 95 tonnes of ore were mined from the Virginia vein and 2395 grams gold, 1866 grams silver, and 943 kilograms copper were recovered.

Refer to the Le Roi deposit (082FSW093) for further details of the Rossland mining camp and the Main vein system.

CAPSULE GEOLOGY

The Iron Colt Crown Grant (Lot 796) is underlain by Lower-Middle Jurassic Rossland Group (Elise Formation) siltstone, argillite and hornfelsed siltstone which is intruded by the Early Jurassic Rossland monzonite. The grey to black siltstone and argillite grades into hornfels and forms distinct layers within the volcanic breccias and several horizons grade laterally into sandstone and breccia. The Rossland Group rocks are crosscut by north trending Early Tertiary lamprophyre and diorite dykes which host disseminated pyrite.

The Iron Colt vein is believed to be the easterly extension of the main Le Roi vein (082FSW093). The Iron Colt vein strikes 063 degrees and dips steeply northwards hosting ore which is light grey

CAPSULE GEOLOGY

in color, containing calcite seams, lenses of quartz and chalcopyrite. Arsenopyrite, cobaltite and magnetite were also found in the ore. The 60-centimetre wide vein occurs near the contact of the Rossland metasediments and the monzonite intrusive. The siltstone-argillite sequence strikes 020 degrees and dips 60 degrees west.

Between 1936 and 1937, 20 tonnes of ore were shipped and 186 grams gold and 466 grams silver were recovered.

Drilling in the late 1980's and early 1990's has defined a high-grade zone averaging 1.8 to 2.4 metres in width contained between two dykes 60 metres apart. The zone has been intersected over a vertical extent of about 90 metres and remains open to depth. In 1989, a drill hole intersection assayed 243.43 grams per tonne gold over an estimated true width of 2.6 metres (Vancouver Stockwatch-July 11, 1989).

Refer to the Le Roi deposit for a summary of the Rossland mining camp.

International Silver Ridge Resources Inc. and Pacific Vangold Mines Ltd. have been conducting underground development work and mining on the Iron Colt and Evening Star (082FSW102) properties. During January and June 1995, the companies shipped approximately 1414 tonnes of gold-bearing ore from the Iron Colt to the Kettle River mill at Republic, Washington for custom milling; 21.4 kilograms of gold were recovered. They plan to continue underground drilling throughout the winter (Information Circular 1995-9, page 18).

CAPSULE GEOLOGY

The Monte Cristo veins are part of the "North belt" zone of discontinuous veins in the Rossland mining camp. On a regional scale, the veins appear continuous but in detail they are lenticular and offset by northerly trending faults. The Monte Cristo vein strikes east-west and dips between 70 to 75 degrees north. Refer to the Le Roi deposit (082FSW093) for a summary of the Rossland mining camp.

The vein is hosted by the Early Jurassic Rossland monzonite, a biotite-hornblende-augite monzonite stock which is medium-grained, grey to green in color and hosts magnetite, apatite, some sphene with chlorite, epidote, pyrite, and pyrrhotite. The stock intrudes siltstone, argillite, hornfels and volcanic conglomerate of the Lower

CAPSULE GEOLOGY

Jurassic Elise Formation, Rossland Group. Tertiary lamprophyre dykes and swarms of diorite dykes crosscut the monzonite and host disseminated pyrite.

Mineralization in the vein consists of massive banded pyrrhotite with chalcopyrite and pyrite. Pyrite occurs as crystals in the pyrrhotite and as disseminations in the host rock. The pyrrhotite is auriferous and contains nickel with a trace of cobalt. In 1915, a sample of the pyrrhotite gave 0.13 per cent NiO and trace cobalt (Geological Survey of Canada Memoir 77, page 75). Cobaltite is also found in the ore.

At elevation 1230 metres, Tunnel No. 1 was driven along the main vein which strikes east-west and dips 75 degrees north; it has an average width of 0.76 metres. The sulphide shoot occurs along a major fault and is cut off by a crosscutting sericitic diorite dyke. The pyrrhotite carried low values of gold.

Tunnel No. 2, at elevation 1194 metres, was driven west along a vein which dips 70 degrees north. Ore from this vein assayed 27.08 grams per tonne gold (Geological Survey of Canada Memoir 77, page 109). This tunnel connects with Tunnel No. 1, and a 25 centimetre streak of arsenopyrite was noted in the raise with the pyrrhotite. The shallow underground workings are developed within the northern contact zone of the Rossland monzonite.

CAPSULE GEOLOGY

The Evening Star veins are part of the "North belt" zone of discontinuous veins. On a regional scale the veins appear to be continuous, but in detail they are lenticular and offset by northerly trending faults. On the claim, the veins strike 065 degrees and dip at moderate angles to the northwest. Old shafts and trenches expose a very rusty zone crossing hornfelsic siltstone between rocks of the Early Jurassic Rossland monzonite on the south and the Trail pluton to the north.

The mineralized veins are hosted in siltstone, argillite and

CAPSULE GEOLOGY

hornfelsic siltstone of the Lower Jurassic Elise Formation, Rossland Group. The main vein is wide and irregular, striking 043 degrees and hosting arsenopyrite, pyrite with minor chalcopyrite. The vein is reported to host danaitite and cobaltiferous arsenopyrite. Considerable stoping was done in a parallel vein hosting pyrrhotite and chalcopyrite.

The pyrrhotite almost always carries a determinable amount of nickel and a trace of cobalt. In 1915, a sample of the pyrrhotite from the Evening Star claims assayed 0.67 per cent NiO and 1.58 per cent cobalt (Geological Survey of Canada Memoir 77, pages 75,76). A quartz vein with considerable width was exposed in the Old Cronin tunnel. The quartz vein dips 45 degrees west and hosts molybdenite and free gold. The siliceous ore also carries a high percentage of pyrrhotite and chalcopyrite. Sylvanite, a gold telluride, was also reported. Cobaltite, native bismuth and bismuthinite are also associated with the ore.

Ore from the veins on the Evening Star claim was mined for 4 years between 1896 to 1907 and from 1932 to 1939. A total of 2,859 tonnes of ore were produced with recovery totalling 56,701 grams gold, 21,521 grams silver and 1276 kilograms copper.

In 1980, seven drill holes intersected subeconomic mineralization with the best hole assaying 0.047 grams per tonne gold (Assessment Report 14236). In 1982, extensive underground workings were found to exist on the property with about 18,150 tonnes of waste material in the lower adit. Two composite samples of the dump material assayed 1.44 and 1.03 grams per tonne gold respectively, suggesting that mineralization extends into the wallrock adjacent to the vein system (Assessment Report 14236).

In 1991, a 3-metre drill intersection assayed 27.43 grams per tonne gold and contained a 2.4 metre section grading 1 per cent copper (George Cross News Letter #45, 1991). This drill hole was targeted 107 metres west of, and on strike from, the Evening Star Main zone where 311,000 grams of gold have been drill indicated.

Refer to the Le Roi deposit (082FSW093) for a summary of the Rossland mining camp.

Drill indicated reserves are 907,000 tonnes grading 10.29 grams per tonne gold. Development work, including drifting on the vein, is in progress. Metallurgical testing has been completed and ore will be shipped to the Kettle River mill at Republic, Washington. Over 1670 tonnes of high-grade ore were shipped during June and yielded 19.4 kilograms of gold; the company intended to ship a minimum 1800 tonnes per month (Information Circular 1995-9, page 18).

CAPSULE GEOLOGY

The Red Mountain showing is part of the "Main vein" system, of the Rossland mining camp, which forms a continuous well defined fracture system which strikes 070 degrees for a strike length in excess of 1 kilometre. The Red Mountain Crown grant is underlain by augite porphyry of the Lower Jurassic Rossland Group, Elise Formation, known as the Rossland sill. The sill is intruded by the Early Jurassic Rossland monzonite, an east trending biotite-hornblende-augite monzonite stock. A gradational contact between the two intrusives passes diagonally from the southwest to the northeast corner of the claim.

The showing consists of a vein striking 090 degrees and dipping steeply to the north. The vein, 0.9 to 1.2 metres in width, consists of low grade pyrrhotite with some chalcopyrite in quartz and altered country rock gangue. The vein carries low gold and copper values.

Refer to the Le Roi deposit (082FSW093) for a summary of the Rossland mining camp.

The War Eagle mine is part of the "Main vein" system, in Rossland mining camp, which forms a continuous well defined fracture system on a regional scale. The vein system occurs on two general strikes of which the better developed is about 070 degrees. The veins have been traced in excess of 1.0 kilometre with veins dipping steeply to the north. The less developed vein system is the War Eagle type which strikes 120 degrees and dips 70 degrees north. The War Eagle system is at best only a series of detached ore shoots with marked stepping to the north. The series of ore shoots have narrow widths and short strike lengths with the greatest dimensions down dip. The ore shoots end abruptly against dykes or cross structures.

CAPSULE GEOLOGY

The system is hosted by the Rosslund monzonite, a biotite-hornblende-augite monzonite stock that intrudes augite porphyry of the Lower Jurassic Elise Formation (Rosslund Group), known as the Rosslund sill. The porphyry is thought to have been a stock or dyke-like feeder for the sill exposed on the surface, prior to the monzonite intrusion.

The veins were formed by mineralization replacing the wallrock along well defined fractures and by filling fractures and faults with pyrrhotite and chalcopyrite. The gangue consists of altered host rock with minor lenses of quartz and calcite. Grayish banded wollastonite is associated with the ore near the altered host rock and gmelinite has been reported, occurring as reddish-white well-formed crystals. Pyrite occurs as well formed crystals in the pyrrhotite and as disseminations in the host rock. Native gold was reported to occur as disseminated fine specks in rusty patches of quartz-rich ore. Minor molybdenite occurs in quartz-rich veins. A brown to black variety of sphalerite was found cutting vein-like through chalcopyrite and pyrrhotite.

Native silver has been identified in pyrrhotite rich ore in the War Eagle mine. It occurs as blebs along grain contacts of pyrrhotite and at the contacts of pyrrhotite with magnetite and gangue. Small grains of a silver-bearing mineral, probably stromeyerite, which develop a very heavy surface stain are associated with the silver.

Between 1898 to 1905, 300,169 tonnes of ore were mined with recovery totalling: 5,659,751 grams gold, 12,036,613 grams silver and 5,021,436 kilograms copper.

Refer to the Le Roi deposit (082FSW093) for further details of the Rosslund mining camp and the Main vein system.

CAPSULE GEOLOGY

The quartz-diorite and quartz-diorite breccia are part of the Trail Pluton of the Nelson Intrusions which is comprised of a mass of granodiorite to quartz diorite.

The principal host for the molybdenum mineralization is siltstone that is extensively metamorphosed to various types of hornfels and breccia. The molybdenum zone consists of molybdenite, pyrrhotite and minor chalcopyrite which occurs in randomly oriented fractures in the hornfels breccia and quartz-diorite breccia. Commonly, it lies along margins of breccia blocks and locally is concentrated at junctions between the blocks. The scheelite occurs as fine disseminations and clusters of grains and locally as fine stringers in the rock.

In 1985, a molybdenum reserve calculated for the Golden Queen claim was 17,690 tonnes of 0.17 per cent molybdenum (actual grade is 0.3 MoS₂. Conversion used for MoS₂ to Mo is 1.6681.) (David Minerals, Statement of Material Facts, 1985) This is a recalculation for a Y-shaped body of mineralization, designated as the NGQ zone, located on the northwest corner of the claim, approximately 152 metres east of the A orebody on the Coxey claim (082FSW110).

The Golden Queen claim is located at about 1448 metres elevation on the southerly slope of Red Mountain about 1.6 kilometres northwest of Rossland. The St. Elmo claim adjoins to the north, at the summit of the mountain, and the Novelty claim (Lot 958) joins to the south. The Coxey claim (see 82 F/4, Mo 1) joins to the west.

The Golden Queen claim (Lot 994) was Crown-granted in 1896 to J. Garrison but there is no record of early work on the claim. The St. Elmo claim (Lot 923) was Crown-granted in 1896 to F.C. Loring. Development work continued until 1901 and included about 701 metres of drifts and crosscuts in 2 adits. Further activity was reported in 1908 when a small amount of ore was shipped under the name J.P. Johnson.

No further activity was reported until 1941 when the St. Elmo workings were reopened by A. Grubsic and Ike Glover. Scheelite was discovered in the old workings in 1942 and the Consolidated Mining, Smelting and Power Company Limited examined the property under an option agreement.

Northwood Mining Limited optioned the Golden Queen, St. Elmo, and Surprise (Lot 693) claims from Messrs. Grubsic and Glover in August 1964 and the Gertrude claim (Lot 690) from William Keane. By an agreement of September 1964 Northwood assigned the above 4 Crown-granted claims to McKinney Gold Mines Limited. Geophysical and geochemical surveys were started late in 1964. The geochemical survey of the Golden Queen and St. Elmo claims was continued in 1965. Some bulldozer stripping was done and numerous showings sampled. In addition, 47 vertical diamond drill holes totalling 1471 metres were drilled in the northwestern part of the Golden Queen and western part of the St. Elmo claim. Surface stripping and diamond drilling between elevations of 1472 and 1515 metres on the northwest corner of the Golden Queen claim, and about 152 metres east of the "A" orebody on the Coxey claim, delimited a Y-shaped body of mineralization (designated the NGQ Zone) containing an indicated 68,000 tons averaging 0.24 per cent molybdenite. Near the western boundary of the St. Elmo claim a mineralized zone (designated the NSE Zone) as outlined, which to a depth of 23 metres contains about 73,000 tons averaging 0.33 per cent molybdenite. Scurry-Rainbow Oil Limited optioned the property in December 1966, the option included the Novelty claim (Lot 958). Drilling by Scurry in 1967 tested the eastern part of the breccia complex on the Golden Queen and St. Elmo claims and the full width of the Novelty claim. Of the 14020 metres of diamond drilling in 174 holes, most was done on the adjacent Giant claim (see 82 F/4, Mo 3). Further diamond drilling was done by Scurry in 1968. Under the terms of the agreement Scurry earned a 50 per cent interest in the property. The company name (McKinney) was changed in March 1967 to Continental McKinney Mines Limited. Based on the drilling on this property, and on the adjacent Giant property, independent consultants in 1967 calculated the indicated-reserves available for open pit operations in 5 separate orebodies at 810,540 tons averaging 0.39 per cent molybdenite. In addition, some 88,000 tons of possible ore of various grades are indicated below open pit limits. Continental McKinney in May 1973 amalgamated with Trinat Resources Ltd., Gundex Holdings Ltd., and Modoc Holdings Ltd., under the name Chandalar Resources Limited. A geochemical soil survey was carried out by Mine Finders, Inc., of Lakewood Colorado in 1973. Chandler Resources abandoned its interest in the property prior to 1975; Scutty-Rainbow sold its interest in 1975. David Minerals Ltd. optioned the Golden Queen, St. Elmo, Surprise, and Novelty claims from J.D. Turcotte of Christina Lake, subject to a prior agreement between Turcotte and M. Delich of Rossland. From the exploration work done by Scurry Rainbow on the Golden Queen and St. Elmo (1971)

CAPSULE GEOLOGY

there were outlined 237,000 tons grading 0.273 per cent MOS2 (Geol. Rept. for David Minerals in SMF 268/80, 24/12/80). In 1981, David Minerals diamond drilled 22 holes here and in the Giant, California, Novelty, Gold King areas. (See 82 F/4, Mo 3). Reserves were re-calculated by J.M. Stitt (1980) as follows: Golden Queen - 19,500 tons at 0.30% MOS2 St. Elmo - 65,100 tons at 0.28% MOS2- (Report by J.L. Deleen (1983) - in David Minerals Statement of Material Facts, 11/07/85).

CAPSULE GEOLOGY

The Giant claim is located at 1295 metres elevation on the southwesterly slope of Red Mountain about 1.6 kilometres northwest of Rossland. The claim is adjoined to the north and east by the Novelty claim (Lot 958) and to the southeast by the California (Lot 956). The Gold King claim (Lot 1061) lies about 91 metres west of the Giant claim.

The Giant, Novelty, California, and Gold King claims were Crown-granted in 1896 to G.W. Coplin, T.F. Wren, Chas. Warren and D.M. Lennard, respectively. Very little development work was reported on the Gold King. On the Novelty claim a shaft was sunk to

CAPSULE GEOLOGY

12 metres and 2 short adits driven. The Giant and California were developed by two companies, the Giant Gold Mining Company and the California Gold Mining Company, which were organized in Spokane. Development work continued into 1903 and included, on the Giant, 2 shafts totalling about 61 metres and 152 metres of drifts and crosscuts, and, on the California, about 304.8 metres of drifts and a 51.2 metre shaft.

The Giant-California Mining Company, Limited was incorporated in 1907 as successor to the above companies. The property was apparently optioned by The Granby Consolidated Mining, Smelting and Power Company, Limited. Development work during 1907-1908 was confined to the California claim in search for the extension of the ore zone from its adjacent Annie claim held by Le Roi No. 2, Limited. A 36-metre crosscut and a 91 metre shaft were driven to connect with the Le Roi No. 2 workings. In 1914 the Le Roi No. 2, Limited secured a bond on the Giant and California and some development work was reported in 1914 and 1915. The Cal-Roi Mining Company, Limited was incorporated in 1921 to acquire the property but no work was reported.

Cascade Molybdenum Mines Ltd. was incorporated in October 1964 to acquire 9 Crown-granted claims (Gold King, Evening, etc.). The Giant claim was acquired on a 20-year lease from Cominco Ltd. During 1965 the company explored several zones of mineralization by 30 diamond drill holes totalling 2624 metres on the Giant, by 15 holes totalling 1159 metres on the Evening, by 7 holes totalling 920 metres on the Gold King, and by 3 holes totalling 295 metres on the Little Darling. The work on the Giant was localized in two areas, the first in the vicinity of the upper adit at about 1295 metres elevation, and the second a breccia zone to the northeast of the first at 1356 metres elevation. In 1966 approximately 9144 metres of AX wireline drilling in 17 holes was done, mainly on the Giant claim.

Reserves on the Giant claim were estimated at 558,375 tons. The company reported total indicated open pit reserves at 1,078,233 tons averaging 0.282 per cent molybdenite and 1.16 grams per tonne gold.

In January 1967 Cascade Molybdenum and Scurry-Rainbow Oil Limited agreed to a joint exploration program. During the year the full width of the breccia complex on the Giant and adjoining Novelty claim, and the eastern part of the breccia on the Golden Queen and St. Elmo claims (see 82 T/4, Mo 2), was tested by diamond drilling totalling 14020 metres in 174 holes, mainly on the Giant claim. Scurry thereby earned a major share position (282) in Cascade and assumed the management of that company. Based on the drilling by Scurry on this property, and on the adjoining Golden Queen-St. Elmo property, independent consultants calculated the indicated reserves available for open pit operations in 5 separate orebodies at 810,540 tons averaging 0.39 per cent molybdenite. In addition, some 88,000 tons of possible ore of various grades are indicated below open pit limits. In 1970 Red Mountain Mines Limited carried out trenching on the Novelty claim. Mine Finders, Inc. of Lakewood Colorado carried out a geochemical soil survey over the property in 1973. Scurry-Rainbow sold its interest in Cascade Molybdenum in 1975. The company name (Cascade) was changed in June 1975 to New Cascade Minerals Ltd., and in January 1976 to Maloney Steel Ltd.

David Minerals Ltd. by an agreement of August 1980 acquired the property from Maloney Steel for 12,000 shares, subject to a 5 per cent net smelter interest in Giant claim in favour of Cominco Ltd. Drilling was carried out on the Novelty claim in 1981. From the exploration done by Cascade there were estimated 1,070,280 tons grading 0.282 per cent MOS₂ and 1.16 grams per tonne gold on the Giant and Novelty (1967) or 778,500 tons grading 0.340 per cent MOS₂ and 1.98 grams per tonne gold (1971). (Geol. Rept. for David Minerals in SMF 268/80, 24/12/80).

Undiluted drill indicated reserves on the Novelty Main Zone were reported as 85,000 tons at 5.14 grams per tonne gold, 0.380 per cent MOS₂, 0.126 per cent cobalt (J.L. Deleen (1984) - in David Minerals Statement of Material Facts, 11/07/85, p. 7).

The Novelty area is underlain by siltstone, hornfelsed siltstone, hornfels and a breccia complex of the Pennsylvanian and possibly Permian Mount Roberts Formation. The characteristics of the mineralization and its association with the Middle to Late Jurassic Trail pluton, especially its upper and western margins, point to its classification as a porphyry-type deposit (Bulletin 74).

The siltstone is intruded by lenticular masses of andesite, irregular bodies of quartz diorite and quartz diorite breccia, and late, steeply dipping mafic dykes which trend northward. The quartz-diorite and quartz-diorite breccia are part of the Trail Pluton of the Nelson Intrusions which is comprised of a mass of granodiorite to quartz diorite. A set of faults trend 160 degrees

CAPSULE GEOLOGY

and are downthrown on the west.

Molybdenite, usually without other sulphides, occurs in randomly oriented fractures in all types of hornfels breccia and in granodiorite breccia. Commonly, it lies along the margins of breccia blocks and locally is concentrated at junctions between the blocks. Pyrrhotite, and locally pyrite, are disseminated in hornfels and also occur in fractures and as massive lenses between breccia fragments. Its distribution seems to be independent of the distribution of molybdenite.

In the Novelty pit, fractures in siliceous hornfels contain arsenopyrite, cobalt minerals, bismuthinite, and uraninite (Bulletin 74, page 49; Thorpe, 1967, pages 15,32). Grab samples of molybdenite from the Giant-Coxey area assayed 0.017 to 0.20 per cent uranium (Geological Survey of Canada Economic Geology Series No. 16, 1952).

Undiluted drill indicated reserves on the Novelty main one were reported as 77,110 tonnes at 5.14 grams per tonne gold, 0.22 per cent molybdenite, 0.126 per cent cobalt (Actual grade is 0.38 per cent MoS₂. Conversion used for MoS₂ to Mo is 1.6681.) (J.L. Deleen, 1984 - in David Minerals Statement of Material Facts, July 11, 1985; National Mineral Inventory - 082F4 Mo3).

In addition, 47 vertical diamond drill holes totalling 1471 metres were drilled in the northwestern part of the Golden Queen and western part of the St. Elmo claim. Surface stripping and diamond drilling between elevations of 1472 and 1515 metres on the northwest corner of the Golden Queen claim, and about 152.4 metres east of the "A" orebody on the Coxey claim, delimited a Y-shaped body of mineralization (designated the NGQ Zone) containing an indicated 68,000 tons averaging 0.24 per cent molybdenite. Near the western boundary of the St. Elmo claim a mineralized zone (designated the NSE Zone) as outlined, which to a depth of 23 metres contains about 73,000 tons averaging 0.33 per cent molybdenite.

Scurry-Rainbow Oil Limited optioned the property in December 1966, the option included the Novelty claim (Lot 958). Drilling by Scurry in 1967 tested the eastern part of the breccia complex on the Golden Queen and St. Elmo claims and the full width of the Novelty claim. Of the 14020 metres of diamond drilling in 174 holes, most was done on the adjacent Giant claim (see 82 F/4, Mo 3). Further diamond drilling was done by Scurry in 1968. Under the terms of the agreement Scurry earned a 50 per cent interest in the property. The company name (McKinney) was changed in March 1967 to Continental McKinney Mines Limited. Based on the drilling on this property, and on the adjacent Giant property, independent consultants in 1967 calculated the indicated-reserves available for open pit operations in 5 separate orebodies at 810,540 tons averaging 0.39 per cent molybdenite. In addition, some 88,000 tons of possible ore of various grades are indicated below open pit limits.

Continental McKinney in May 1973 amalgamated with Trinat Resources Ltd., Gundex Holdings Ltd., and Modoc Holdings Ltd., under the name Chandalar Resources Limited. A geochemical soil survey was carried out by Mine Finders, Inc., of Lakewood Colorado in 1973. Chandler Resources abandoned its interest in the property prior to 1975; Scutty-Rainbow sold its interest in 1975. David Minerals Ltd. optioned the Golden Queen, St. Elmo, Surprise, and Novelty claims from J.D. Turcotte of Christina Lake, subject to a prior agreement between Turcotte and M. Delich of Rossland. From the exploration work done by Scurry Rainbow on the Golden Queen and St. Elmo (1971) there were outlined 237,000 tons grading 0.273 per cent MOS₂ (Geol. Rept. for David Minerals in SMF 268/80, 24/12/80). In 1981, David Minerals diamond drilled 22 holes here and in the Giant, California, Novelty, Gold King areas. (See 82 F/4, Mo 3). Reserves were re-calculated by J.M. Stitt (1980) as follows: Golden Queen - 19,500 tons at 0.30% MOS₂ St. Elmo - 65,100 tons at 0.28% MOS₂- (Report by J.L. Deleen (1983) - in David Minerals Statement of Material Facts, 11/07/85).

The Gertrude Crown Grant is underlain by siltstone, hornfelsed siltstone, hornfels and a breccia complex of the Pennsylvanian and possibly Permian Mount Roberts Formation. The succession is thought to have been thrust over the underlying Rossland sill of the Elise Formation, Rossland Group, prior to the intrusion of the Middle to Late Jurassic Trail pluton. Augite porphyry of the Rossland sill may underlie the eastern part of the claim.

The siltstone is intruded by lenticular masses of andesite, irregular bodies of quartz diorite and quartz diorite breccia, and late, steeply dipping mafic dykes which trend northward. Small scale

CAPSULE GEOLOGY

faults parallel to this trend step the older rocks down on the west. The quartz-diorite and quartz-diorite breccia are part of the Trail pluton of the Nelson Intrusions which is comprised of a mass of granodiorite to quartz diorite.

A little mineralization is reported to occur in the vicinity of a granitic dyke. At a shaft near the dyke there is a few streaks of ore along bedding planes and in the granitic rock itself. Seams of calcite are present. The ore on the shaft dump consist of pyrrhotite, chalcopyrite, pyrite, arsenopyrite and a little molybdenite. Sphalerite, native bismuth and bismuthinite are also associated with the ore.

The characteristics of the mineralization in this area and its association with the Trail pluton, especially its upper and western margins, point to its classification as a porphyry-type deposit (Bulletin 74).

In 1991, drilling was initiated on the Gertrude claim in order to test for the strike extension of the War Eagle/Number One vein (082FSW097). One drill interval graded 14.06 grams per tonne gold over 5 metres (George Cross News Letter No.65, April 4, 1991).

Pacific Vangold and International Silver Ridge plan work (surface drilling and drifting from existing workings to intersect the vein), where proven reserves are estimated at 44,447 tonnes grading 7.9 grams per tonne gold (Information Circular 1995-9, page 18).

CAPSULE GEOLOGY

The Giant claim is located at 1295 metres elevation on the southwesterly slope of Red Mountain about 1.6 kilometres northwest of Rossland. The claim is adjoined to the north and east by the Novelty claim (Lot 958) and to the southeast by the California (Lot 956). The Gold King claim (Lot 1061) lies about 91 metres west of the Giant claim.

The Giant, Novelty, California, and Gold King claims were Crown-granted in 1896 to G.W. Coplin, T.F. Wren, Chas. Warren and D.M. Lennard, respectively. Very little development work was reported on the Gold King. On the Novelty claim a shaft was sunk to 12 metres and 2 short adits driven. The Giant and California were developed by two companies, the Giant Gold Mining Company and the California Gold Mining Company, which were organized in Spokane. Development work continued into 1903 and included, on the Giant, 2 shafts totalling about 61 metres and 152 metres of drifts and crosscuts, and, on the California, about 305 metres of drifts and a 51-metre shaft.

The Giant-California Mining Company, Limited was incorporated in 1907 as successor to the above companies. The property was apparently optioned by The Granby Consolidated Mining, Smelting and Power Company, Limited. Development work during 1907-1908 was confined to the California claim in search for the extension of the ore zone from its adjacent Annie claim held by Le Roi No. 2, Limited. A 366-metre crosscut and a 91-metre shaft were driven to connect with the Le Roi No. 2 workings. In 1914 the Le Roi No. 2, Limited secured a bond on the Giant and California and some development work was reported in 1914 and 1915. The Cal-Roi Mining Company, Limited was incorporated in 1921 to acquire the property but no work was reported.

Cascade Molybdenum Mines Ltd. was incorporated in October 1964 to acquire 9 Crown-granted claims (Gold King, Evening, etc.). The Giant claim was acquired on a 20-year lease from Cominco Ltd. During 1965 the company explored several zones of mineralization by 30 diamond drill holes totalling 2624 metres on the Giant, by 15 holes totalling 1159 metres on the Evening, by 7 holes totalling 920 metres on the Gold King, and by 3 holes totalling 295 metres on the Little Darling. The work on the Giant was localized in two areas, the first in the vicinity of the upper adit at about 1295 metres elevation, and the second a breccia zone to the northeast of the first at 1356 metres elevation. In 1966 approximately 9144 metres of AX wireline drilling in 17 holes was done, mainly on the Giant claim.

Reserves on the Giant claim were estimated at 558,375 tons. The company reported total indicated open pit reserves at 1,078,233 tons averaging 0.282 per cent molybdenite and 1.16 grams per tonne gold.

In January 1967 Cascade Molybdenum and Scurry-Rainbow Oil Limited agreed to a joint exploration program. During the year the full width of the breccia complex on the Giant and adjoining Novelty claim, and the eastern part of the breccia on the Golden Queen and St. Elmo claims (see 82 T/4, Mo 2), was tested by diamond drilling totalling 14020 metres in 174 holes, mainly on the Giant claim. Scurry thereby earned a major share position (282) in Cascade and assumed the management of that company. Based on the drilling by Scurry on this property, and on the adjoining Golden Queen-St. Elmo property, independent consultants calculated the indicated reserves available for open pit operations in 5 separate orebodies at 810,540 tons averaging 0.39 per cent molybdenite. In addition, some 88,000 tons of possible ore of various grades are indicated below open pit limits. In 1970 Red Mountain Mines Limited carried out trenching on the Novelty claim. Mine Finders, Inc. of Lakewood Colorado carried out a geochemical soil survey over the property in 1973. Scurry-Rainbow sold its interest in Cascade Molybdenum in 1975. The company name (Cascade) was changed in June 1975 to New Cascade Minerals Ltd., and in January 1976 to Maloney Steel Ltd.

David Minerals Ltd. by an agreement of August 1980 acquired the property from Maloney Steel for 12,000 shares, subject to a 5 per cent net smelter interest in Giant claim in favour of Cominco Ltd. Drilling was carried out on the Novelty claim in 1981. From the exploration done by Cascade there were estimated 1,070,280 tons grading 0.282 per cent MOS₂ and 1.16 grams per tonne gold on the Giant and Novelty (1967) or 778,500 tons grading 0.340 per cent MOS₂ and 1.98 grams per tonne gold (1971). (Geol. Rept. for David Minerals in SMF 268/80, 24/12/80).

Undiluted drill indicated reserves on the Novelty Main Zone were reported as 85,000 tons at 5.14 grams per tonne gold, 0.380 per cent MOS₂, 0.126 per cent cobalt (J.L. Deleen (1984) - in David Minerals Statement of Material Facts, 11/07/85, p. 7).

The Giant Crown grant is underlain by the Pennsylvanian and possibly Permian Mount Roberts Formation siltstone, hornfelsed siltstone, hornfels and a breccia complex. The siltstone is rusty,

CAPSULE GEOLOGY

sooty and massive or thinly bedded with minor disseminated pyrrhotite and pyrite. The hornfels and hornfelsic siltstones are thinly laminated, massive cherty rocks, which locally contain brown garnet and epidote.

The succession is thought to have been thrust over augite porphyry of the underlying Rosslund sill of the Elise Formation (Rosslund Group) prior to the intrusion of the Middle to Late Jurassic Trail pluton (Nelson Intrusions). The siltstone is also intruded by the Early Jurassic Rosslund monzonite and monzonite breccia as well as by the syenitic Middle Eocene Coryell Intrusions and associated syenite dykes. Lenticular masses of andesite and late, steeply dipping, north-trending lamprophyre and diorite dykes have also invaded the siltstone.

Two types of mineral deposits occur on the property. The initial underground workings were on a narrow easterly dipping vein mineralized with sulphides of cobalt, nickel, arsenic, iron and molybdenum, all with gold. The molybdenum zone developed in later work occurs in breccia and consists of molybdenite, pyrrhotite, and minor chalcopyrite.

The mineralized vein strikes north and dips steeply to the east. Sulphides infill along a sheared dyke and comprise ore shoots which end abruptly against cross structures. Native gold occurs in impregnations of arsenopyrite, pyrrhotite, pyrite, molybdenite and bismuthinite near the dyke. The pyrrhotite is the most abundant ore mineral and carries determinable amounts of cobalt and nickel. Cobaltite is also present. Bismuthinite and native bismuth occurs in particles or aggregates up to a few centimetres in diameter and is found associated with the pyrrhotite and frequently is found with visible gold. Microscopic magnetite forms a thin rim or coatings around arsenopyrite grains which are associated with molybdenite, pyrrhotite, and chalcopyrite.

Between 1898 to 1913, 4,131 tonnes of ore was shipped from the Giant and California claims (082FSW113). From this ore, 113,246 grams gold, 23,265 grams silver, and 1,330 kilograms of copper were recovered (Geological Survey of Canada Memoir 77, page 141). Included in these figures are 3,940 tonnes of ore shipped from the Giant claim before operations were suspended in 1903.

Later work discovered molybdenum-gold mineralization essentially within the breccia complex. The hornfels and hornfelsic siltstone comprises a breccia with angular blocks ranging up to 30 metres across. The matrix between the blocks is comprised of fine silicates, quartz and calcite, garnet or scheelite. Molybdenum occurs in randomly oriented fractures in the hornfels breccia. It commonly lies along the margins of the breccia blocks and locally, is concentrated at junctions between the blocks. Pyrrhotite, chalcopyrite, pyrite, and arsenopyrite are disseminated in the hornfels and occur in fractures and as massive lenses between breccia fragments. The sulphide distribution seems independent of the distribution of the molybdenite.

In 1966, 17 drill holes indicated open pit reserves on the Giant claim were 50,700 tonnes of molybdenite averaging approximately 0.282 per cent molybdenite and 1.16 grams per tonne gold. In 1971, the indicated reserves for the Novelty and Giant claims were 706,177 tonnes averaging 1.9 grams per tonne gold, 0.20 per cent molybdenite. Actual grade is 0.34 per cent MoS₂ (David Minerals Limited, Statement of Material Facts, Dec. 24, 1980). Conversion used for MoS₂ to Mo is 1.6681.

The characteristics of the molybdenite mineralization and its association with the Middle to Late Jurassic Trail pluton, especially its upper and western margins, point to its classification as a porphyry-type deposit (Bulletin 74).

CAPSULE GEOLOGY

The CoxeY mine is underlain by the Pennsylvanian and possibly Permian Mount Roberts Formation siltstone, hornfelsed siltstone, hornfels and a breccia complex. The siltstone is rusty, sooty and massive or thinly bedded with minor disseminated pyrrhotite and pyrite. The hornfels and hornfelsic siltstones are thinly laminated, massive cherty rocks, which locally contain brown garnet and epidote. The succession is thought to have been thrust over augite

CAPSULE GEOLOGY

porphyry of the underlying Rossland sill of the Elise Formation (Rossland Group) prior to the intrusion of the Middle to Late Jurassic Trail pluton (Nelson Intrusions). The siltstone is intruded by lenticular masses of andesite, irregular bodies of quartz diorite and quartz diorite breccia, and late steeply dipping dykes which trend northward. The quartz diorite is assumed to be part of the Trail pluton.

Steeply dipping faults, trending 160 degrees, offset the orebodies. One such fault separates the A from the B orebodies, another passes between the A and upper A orebodies, and yet another passes between the A and E orebodies. From the offset of the orebodies the faults are assumed to be downthrown on the west. The Headwall fault, between the A and upper A orebodies, is followed by a lamprophyre dyke which is locally sheared along the fault. The quartz diorite breccia is also offset 45 to 50 metres to the right along this fault. Potassium-argon dating of biotite from the Headwall lamprophyre dyke gave an age of 49.0 plus or minus 1.6 million years (Bulletin 74).

The molybdenum mineralization occurs essentially within the Mount Roberts Formation breccia complex. The hornfels and hornfelsic siltstone comprises a breccia with angular blocks ranging up to 30 metres across. The matrix between the blocks is comprised of fine silicates, quartz, calcite, garnet or scheelite. Molybdenite, usually without other sulphides, occurs in randomly oriented fractures in all types of hornfels breccia and in the quartz diorite breccia. Commonly, it lies along the margins of breccia blocks and locally is concentrated at junctions between the blocks. Rarely, these junctions also contain drusy quartz, scheelite, hornblende or epidote. Pyrrhotite, chalcopyrite and pyrite are disseminated in the hornfels and also occur in fractures and as massive lenses between breccia fragments. The sulphide distribution seems independent of the distribution of molybdenite. Arsenopyrite is a predominant mineral with molybdenite and chalcopyrite in the Coxey-Novelty vein (082FSW107). Microscopic magnetite rims the arsenopyrite grains.

Between 1966 to 1972, 1,035,509 tonnes of ore was mined from the open pits and produced 1,748,871 kilograms of molybdenum. In 1982, the indicated reserves for the orebodies on the Coxey and Nevada claims was calculated to be 244,917 tonnes of 0.22 per cent molybdenite. Actual grade is 0.37 per cent MoS₂ (Filing Statement 139/82, David Minerals Limited). Conversion used of MoS₂ to Mo is 1.6681. Some of this material is reported to carry gold but estimates of the average grade cannot be made from the data available.

Scheelite occurring as medium to coarse grains, is scattered throughout the breccia complex. Rarely, it forms spectacular clusters of grains between fragments. Its occurrence is erratic and company records indicate the highest grades were found in the E and F orebodies on the Mountain View claim (082FSW140), where the grade was about 0.10 per cent WO₃ (tungsten trioxide).

The characteristics of the molybdenite and scheelite mineralization and its association with the Middle to Late Jurassic Trail pluton, especially its upper and western margins, point to its classification as a porphyry-type deposit (Bulletin 74).

The property is located on the west slope of Red Mountain about 18 kilometres northwest of Rossland. It consists of 10 claims, the Coxey, Nevada, Mountain View, Ontario, Good Friday, Peak, High Ore, Ophir, Jumbo, and Sam Hayes. Most of these claims were Crown-granted during the period 1895-97 and were well known in the early days of the Rossland camp.

Development work on the Coxey was begun in 1897 by Messrs. Cook & Johnson. In 1899 Montreal Goldfields Ltd. prospected the property for gold and copper. Development work consisted of two tunnels, a shaft, and several open cuts. The Coxey claim was reportedly worked by lessees Williams and Ruffner during the first World War but it is not known what development work was done at that time.

Late in 1963 Torwest Resources acquired the group of 10 claim. During 1964, 59 diamond drill holes were put down on the Coxey claim, 53 on the A or east zone and 6 on the B or west zone. Stripping on the B zone traced the mineralization for over 213 metres.

Metal Mines Limited optioned the property in September 1964 and early in 1965 they assigned one half of their interest in the project to Canadian Nickel Company Limited, the exploration arm of The International Nickel Company of Canada Limited.

At the end of 1964 ore reserves were estimated at 400,000 tons grading 0.5 per cent molybdenite.

Thirty-four drill-holes put down by Metal Mines Limited late in 1964 reportedly confirmed the results of the Torwest drilling. Red Mountain Mines Limited was formed in April 1965 to operate the property. The new company was owned by Torwest Resources (60 per

CAPSULE GEOLOGY

cent), Metal Mines (20 per cent), and Canadian Nickel (20 per cent). Mining was by open pit. A 400 ton per day mill began operating April 24, 1966. Reserves at that time were estimated at 800,000 tons averaging 0.45 per cent molybdenite.

The property was financed to production jointly by Canadian Nickel Company and Consolidated Canadian Faraday Limited.

Mining was done initially in the A zone. Mill capacity was increased to 600 tons per day by 1969 and 750 tons per day by 1970. The mine closed in December 1970 due to lack of ore. The discovery of the E zone late in 1970 permitted the resumption of milling in February 1971. The mine closed in January 1972. After closing, The International Nickel Company engaged Min Finders Inc., of Lakewood Colorado to carry out an extensive exploration program based on a porphyry model of mineralization. Geochemistry, geophysics and deep drilling were carried out in the mine area between 1972 and 1974.

In 1980-81 David Minerals Ltd acquired the property from AJM Explorations Ltd. and AJM Mill Ltd. and also acquiring the interests of Hunstone Ventures Ltd. and those of Inco Limited, Consolidated Canadian Faraday and Teck Corporation. The 1980 agreement included purchase of the 600 tpd mill. In 1981 the company drilled 9 short holes just south of the mine area. Reserves were reported as drill indicated 270,000 tons at 0.37 per cent MOS2 on the Coxe and Nevada claims (David Minerals Ltd., FS 139/82, p. 3, 1982).

CAPSULE GEOLOGY

The Jumbo claim, located about 3.2 kilometres northwest of Rossland, was staked by A.D. Coplen in 1892 and Crown granted to J.A. Finch & associates in 1895. The Jumbo Gold Mining Company of Spokane operated the mine from 1896 until it closed in 1906. Development work, totalling over 244 metres of tunnel was carried on in three adits. Further work was done on the property during 1934-36 by Mr. Slubowski and associates. Lessees worked the property, owned by Mrs. C.F. Smith of California, during 1942.

Late in 1963 Torwest Resources (1962) Limited acquired a group of 10 claims, including the Jumbo and Coxey. Some diamond drill holes were put down on the presumed extension of the oreshoot on the Jumbo. (See: Coxey; Area, 82F/4, Ref. Mo 1).

The Jumbo Crown Grant is underlain by siltstone, hornfelsed siltstone, hornfels and a breccia complex of the Pennsylvanian and possibly Permian Mount Roberts Formation. The siltstone is rusty, sooty and massive or thinly bedded with minor disseminated pyrrhotite and pyrite. The hornfels and hornfelsic siltstones are thinly laminated, massive cherty rocks, which locally contain brown garnet and epidote.

CAPSULE GEOLOGY

The succession is thought to have been thrust over augite porphyry of the underlying Rosslund sill of the Elise Formation (Rosslund Group) prior to the intrusion of the Middle to Late Jurassic Trail pluton (Nelson Intrusions). The siltstone is also intruded by the Early Jurassic Rosslund monzonite and monzonite breccia as well as by the syenitic Middle Eocene Coryell Intrusions and associated syenite dykes. Lenticular masses of andesite and late, steeply dipping, north-trending lamprophyre and diorite dykes have also invaded the siltstone.

A vein along a minor shear, ranging up to 9 metres or more in width, is mineralized with pyrrhotite, arsenopyrite, molybdenite, bismuthinite and native gold in a gangue comprised mainly of quartz with ankerite and calcite. The gold values were highest where the vein is crosscut by syenite dykes. The bismuthinite occurs in particles or aggregates up to a few centimetres in diameter and usually shows perfect cleavage with a lustre that is intermediate between lead-grey and tin-white. Pyrrhotite and other sulphides are associated with the native bismuth and bismuthinite in the country rock. It is often seen as a thin film along cracks and fractures. Visible free gold is frequently found with native bismuth.

Between 1903 to 1906, 28,829 tonnes of ore was mined and produced 415,878 grams of gold. And, between 1934 to 1942, approximately 1965 tonnes were mined and produced 19,719 grams gold and 12,347 grams silver.

The molybdenum mineralization occurs within the breccia complex which is comprised of angular blocks of siltstone and hornfelsic siltstone ranging up to 30 metres across. Molybdenite occurs in randomly oriented fractures in the breccia and locally, is concentrated at the junctions between the blocks. Pyrrhotite, pyrite and minor chalcopryrite with arsenopyrite also occur within fractures in the breccia and as massive lenses between the fragments. Magnetite is found in the ore as microscopic particles associated with the arsenopyrite-molybdenite. The magnetite adjoins or surrounds the arsenopyrite grains with a thin rim or coating. Hematite is represented only by pseudomorphs of magnetite.

Molybdenite occurrences are spatially related to the the Middle to Late Jurassic Trail pluton, especially its upper and western margins. In the region, both skarn and porphyry molybdenum mineralization occur along the margins of the Nelson Intrusions (Fieldwork 1990, pages 21-31). The characteristics of the molybdenite mineralization on Red Mountain indicate classification as a porphyry-type deposit (Bulletin 74, page 52). The copper-gold vein-type mineralization is apparently younger than the porphyry/skarn events.

CAPSULE GEOLOGY

The Gold Hill claim is underlain by Pennsylvanian and possibly Permian Mount Roberts Formation rocks comprised of a coarse sedimentary breccia that grades to the east into a grayish to green, thinly laminated sandstone that, still farther east, grades into thinly bedded grey siltstone and argillite. A mass of Middle Eocene Tertiary Coryell Intrusions, comprised of syenite to monzonite, intrudes these older rocks; the eastern portion of the claim is reported to be underlain by syenite porphyry.

On the claim, the Mount Roberts bedded rocks strike northwards and dip steeply to the west. The host rock is black argillite with some coarser, banded, brown rock that resembles an ash bed or a tuff. Mineralization consists of a series of quartz stringers or veinlets containing pyrrhotite with some calcite along with the quartz. Drusy cavities are present in the quartz. Arsenopyrite was also reported to occur with the vein pyrrhotite. Disseminated pyrite is also present.

In 1894, 9 tonnes of high grade ore were shipped from a quartz vein and 31,103 grams of silver was recovered.

CAPSULE GEOLOGY

The Giant claim is located at 1295.4 metres elevation on the southwesterly slope of Red Mountain about 1.6 kilometres northwest of Rossland. The claim is adjoined to the north and east by the Novelty claim (Lot 958) and to the southeast by the California (Lot 956). The Gold King claim (Lot 1061) lies about 91 metres west of the Giant claim.

The Giant, Novelty, California, and Gold King claims were Crown-granted in 1896 to G.W. Coplin, T.F. Wren, Chas. Warren and D.M. Lennard, respectively. Very little development work was reported on the Gold King. On the Novelty claim a shaft was sunk to 12 metres and 2 short adits driven. The Giant and California were developed by two companies, the Giant Gold Mining Company and the California Gold Mining Company, which were organized in Spokane. Development work continued into 1903 and included, on the Giant, 2 shafts totalling about 61 metres and 152 metres of drifts and crosscuts, and, on the California, about 304.8 metres of drifts and a 51.2-metre shaft.

The Giant-California Mining Company, Limited was

CAPSULE GEOLOGY

incorporated in 1907 as successor to the above companies. The property was apparently optioned by The Granby Consolidated Mining, Smelting and Power Company, Limited. Development work during 1907-1908 was confined to the California claim in search for the extension of the ore zone from its adjacent Annie claim held by Le Roi No. 2, Limited. A 365.7-metre crosscut and a 91.4-metre shaft were driven to connect with the Le Roi No. 2 workings. In 1914 the Le Roi No. 2, Limited secured a bond on the Giant and California and some development work was reported in 1914 and 1915. The Cal-Roi Mining Company, Limited was incorporated in 1921 to acquire the property but no work was reported.

Cascade Molybdenum Mines Ltd. was incorporated in October 1964 to acquire 9 Crown-granted claims (Gold King, Evening, etc.). The Giant claim was acquired on a 20-year lease from Cominco Ltd. During 1965 the company explored several zones of mineralization by 30 diamond drill holes totalling 2624 metres on the Giant, by 15 holes totalling 1159 metres on the Evening, by 7 holes totalling 920 metres on the Gold King, and by 3 holes totalling 295 metres on the Little Darling. The work on the Giant was localized in two areas, the first in the vicinity of the upper adit at about 1295 metres elevation, and the second a breccia zone to the northeast of the first at 1356 metres elevation. In 1966 approximately 9144 metres of AX wireline drilling in 17 holes was done, mainly on the Giant claim.

Reserves on the Giant claim were estimated at 558,375 tons. The company reported total indicated open pit reserves at 1,078,233 tons averaging 0.282 per cent molybdenite and 1.16 grams per tonne gold.

In January 1967 Cascade Molybdenum and Scurry-Rainbow Oil Limited agreed to a joint exploration program. During the year the full width of the breccia complex on the Giant and adjoining Novelty claim, and the eastern part of the breccia on the Golden Queen and St. Elmo claims (see 82 T/4, Mo 2), was tested by diamond drilling totalling 14020 metres in 174 holes, mainly on the Giant claim. Scurry thereby earned a major share position (282) in Cascade and assumed the management of that company. Based on the drilling by Scurry on this property, and on the adjoining Golden Queen-St. Elmo property, independent consultants calculated the indicated reserves available for open pit operations in 5 separate orebodies at 810,540 tons averaging 0.39 per cent molybdenite. In addition, some 88,000 tons of possible ore of various grades are indicated below open pit limits. In 1970 Red Mountain Mines Limited carried out trenching on the Novelty claim. Mine Finders, Inc. of Lakewood Colorado carried out a geochemical soil survey over the property in 1973. Scurry-Rainbow sold its interest in Cascade Molybdenum in 1975. The company name (Cascade) was changed in June 1975 to New Cascade Minerals Ltd., and in January 1976 to Maloney Steel Ltd.

David Minerals Ltd. by an agreement of August 1980 acquired the property from Maloney Steel for 12,000 shares, subject to a 5 per cent net smelter interest in Giant claim in favour of Cominco Ltd. Drilling was carried out on the Novelty claim in 1981. From the exploration done by Cascade there were estimated 1,070,280 tons grading 0.282 per cent MOS₂ and 1.16 grams per tonne gold on the Giant and Novelty (1967) or 778,500 tons grading 0.340 per cent MOS₂ and 1.98 grams per tonne gold (1971). (Geol. Rept. for David Minerals in SMF 268/80, 24/12/80).

Undiluted drill indicated reserves on the Novelty Main Zone were reported as 85,000 tons at 5.14 grams per tonne gold, 0.380 per cent MOS₂, 0.126 per cent cobalt (J.L. Deleen (1984) - in David Minerals Statement of Material Facts, 11/07/85, p. 7).

The California Crown Grant is underlain by the Pennsylvanian and possibly Permian Mount Roberts Formation consisting of siltstone, hornfelsed siltstone, hornfels and a breccia complex. The siltstone is rusty, sooty and massive or thinly bedded with minor disseminated pyrrhotite and pyrite. The hornfels and hornfelsic siltstones are thinly laminated, massive cherty rocks, which locally contain brown garnet and epidote.

The succession is thought to have been thrust over augite porphyry of the underlying Rosslund sill of the Elise Formation (Rosslund Group) prior to the intrusion of the Middle to Late Jurassic Trail pluton (Nelson Intrusions). The siltstone is also intruded by the Early Jurassic Rosslund monzonite and monzonite breccia as well as by the syenitic Middle Eocene Coryell Intrusions and associated syenite dykes. Lenticular masses of andesite and

CAPSULE GEOLOGY

late, steeply dipping, north-trending lamprophyre and diorite dykes have also invaded the siltstone.

The workings of the No. 1 tunnel were started on a pyritic vein following a contact between diorite and quartzite (Mount Roberts Formation?). The tunnel, driven about 100 metres by 1915, crosscut a 15 centimetre wide vein of arsenopyrite that ran as high as 35 per cent arsenic. A shaft, started on a vein striking north and dipping east, contained unspecified economic minerals. Quartzite contains specks of chalcopyrite and abundant pyrite. In places such mineralization is concentrated in definite bands 18 to 33.5 metres in width which as rule follows micaceous syenite porphyry (pulaskite). A sample taken from the California claim for a thesis study contained arsenopyrite, pyrite and sphalerite (Thorpe, 1967).

The California vein was mined in conjunction with the Giant vein system (082FSW109). In 7 years between 1898 to 1913, 4131 tonnes of ore was shipped from the California and Giant claims. From this ore, 113,246 grams gold, 23,265 grams silver, and 1330 kilograms of copper were recovered.

CAPSULE GEOLOGY

The White Bear deposit is associated with the "Main vein" system, of the Rossland mining camp, which forms a continuous well defined fracture system on a regional scale, striking 070 degrees for a length in excess of 1 kilometre. The White Bear mine, along with The Centre Star (082FSW094), Le Roi (082FSW093) and War Eagle (082FSW097) mines are all connected underground and constitute one large mine with a total of about 97 kilometres of underground workings. Refer to the Le Roi deposit (082FSW093) for further details of the Main vein system and the Rossland mining camp.

The White Bear Crown Grant appears to lie on or near the north-trending Rossland fault which divides augite porphyry of the Elise Formation (Rossland Group) on the east from sediments of the Pennsylvanian and possibly Permian Mount Roberts Formation on the west. The augite porphyry, known as the Rossland sill, has intruded the upper part of the Elise Formation. The Mount Roberts succession on Red Mountain is thought to have been thrust over the underlying Rossland sill prior to the intrusion of the Middle to Late Jurassic Nelson Intrusions. The strata are intruded by the Early Jurassic Rossland monzonite, the Rainy Day pluton (Nelson Intrusions), to the west, and by the syenitic Middle Eocene Coryell Intrusions and associated syenite dykes.

By 1902, a shaft passed through a barren package of rocks,

CAPSULE GEOLOGY

described as "altered basic volcanic rock" (Mount Roberts Formation?), up to 150 metres thick and encountered ore-bearing "diorite porphyry" (Geological Survey of Canada Memoir 77, pages 136-137). The diorite porphyry was later interpreted as a marginal facies of the Rossland monzonite (Bulletin 74, page 26).

Mineralization consists of sulphides replacing wallrock along well-defined fractures and infilling fractures and faults with pyrrhotite, chalcopyrite, minor arsenopyrite and pyrite. The pyrite occurs as crystals in the pyrrhotite and as disseminations in the host rock. The gangue is mainly altered wallrock with minor lenses of quartz and calcite.

In 8 years between 1903 to 1920, 17,028 tonnes of ore was mined from the White Bear vein and produced 72,905 grams gold, 229,104 grams silver, and 142,064 kilograms copper. From 1918 to 1942 production from this deposit was combined with the Le Roi, Josie and War Eagle and is reported with the Le Roi (082FSW093) data.

CAPSULE GEOLOGY

The Snowdrop workings lie within greenstone and altered greenstone of the Lower Jurassic Elise Formation, Rossland Group and in dark grey siltstone and sandstone of the Pennsylvanian and possibly Permian Mount Roberts Formation. The veins lie adjacent to the northern contact of a body of serpentinite of probable Permian age which trends easterly and dips steeply to the south. The contact is an east trending fault which is terminated by the Middle Eocene Marron Formation on the west and the Jumbo fault on the east.

On the Snowdrop property, amygdules and small lenticular inclusions of limestone in the greenstone indicate that these rocks are in part, flows. In the upper workings of the Snowdrop mine, the veins are quartz-carbonate filled fissures which trend northeast and dip 50 degrees to the southeast. Other individual veins are not continuous bodies of quartz but rather are tight fractures which contain lenses which pinch and swell and change their attitudes. Widths range from a few centimetres to 0.5 metres in a few places as much as 2.0 metres. Mineralization consists of pockets which host free gold, often in particles visible to the naked eye. Although, occasional concentrations do occur, sulphides are not common in the veins. These sulphides include pyrite, chalcopyrite, and galena. Blades of marcasite were found included in chalcopyrite in ore from the Snowdrop property. Pyrite is also quite widely disseminated in small amounts throughout the wallrock. The only other gangue mineral in addition to the quartz is ankeritic carbonate, which occurs in irregular areas in the vein and occasionally as veinlets in the surrounding rocks. Hematite occurs on the Snowdrop property and is

CAPSULE GEOLOGY

mostly represented as pseudomorphs of magnetite. Also, hematite included in chalcopyrite is completely replaced.

The veins were mined in 1931, 1932, 1937 and 1955 to 1957. Six tonnes of ore were shipped and 6843 grams gold and 16640 grams silver were recovered.

CAPSULE GEOLOGY

Marron Group on the west and the Jumbo fault on the east. Irregular masses of monzonite of the Middle Eocene Coryell Intrusions were encountered in the I.X.L. workings. Also, mafic and lamprophyre dykes, most of which trend northward, are widely distributed. The lamprophyre dykes occupy faults which cut, and in some places, have slightly displaced, the quartz veins.

The Rossland greenstone is very fine-grained, dense, and massive rock of dark green to brownish hue. The original texture has been destroyed by both the development of chlorite and fibrous amphibole and by local silicification and serpentinization. It varies from a highly altered rock with small amounts of serpentine and magnetite to a mottled phase and then a phase which carries abundant, uniform serpentinite and magnetite. The typical massive serpentinite (Permian body) is a very dense black rock with cross-fibre asbestos infilling joints as 0.2 to 0.6 centimetre veinlets and light green talc has developed in the immediate vicinity of the faults. Ten samples of serpentinite taken from this area gave nickel assays of less than 0.24 per cent (Bulletin 74).

On the I.X.L. the three principal veins strike 060 to 080 degrees and dip 35 to 75 degrees to the south. Widths range from a few centimetres to 0.5 metres and in a few places as much as 2 metres. The strongest mineralized zones are less than 100 metres long and have been developed about the same distance up dip. The quartz veins contain free gold, often in particles visible to the naked eye. Mineable pockets of gold are erratically distributed in the veins. Although occasional concentrations do occur, sulphides are not common in the quartz veins. These sulphides include pyrite, chalcopyrite, galena, and sphalerite. Pyrite is also widely disseminated in the wallrock. The only other gangue mineral in addition to the quartz is ankeritic carbonate which occurs in irregular areas in the vein and occasionally as veinlets in the surrounding rocks.

The I.X.L. veins were mined in 53 years between 1899 to 1974 producing a total of 5,248 tonnes of ore were mined. Commodity recovery is recorded at 811,746 grams gold, 270,531 grams silver, 8,255 kilograms copper, 256 kilograms lead, and 154 kilograms zinc. Ore from the I.X.L. claim and Golden Drip claim (082FSW118) was stockpiled and milled between 1977 and 1984. In 1988, a portable mill and concentrator is planned to process an estimated 54,430 tonnes of dump material grading 24.0 grams per tonne gold (George Cross News Letter, September 23, 1988).

CAPSULE GEOLOGY

The property is located at 1067 metres elevation on the east of O.K. Mountain, about 2.4 kilometres west of Rossland. The I.X.L. claim lies to the east and adjoining.

The O.K. claim (Lot 678) was located by J.Y. Cole in June 1892 and Crown-granted in 1896. Underground work by Mr. Cole & associates opened up a large pocket of high-grade free gold-bearing quartz. The O.K. Gold Mining Company, a Spokane, Washington company, which was registered in B.C. in 1895, acquired the property and carried on mining operations until August 1897 when the affairs of the company were ordered wound up. Most of the old underground workings were driven during the period 1893-1896 and include about 305 metres of crosscuts, drifts and raises in 3 adits. During the period 1923-1944 lessees carried out some exploration work each year in search of the downward continuation of the O.K. veins or the extension of the I.X.L. veins.

The O.K. claim was owned by Mrs. J. Pike, of California, and J. Wey and Mrs. Anabelle, of Seattle, in 1953. Some rehabilitation and exploration work was done by lessee M. Doran in 1953 and 1956.

Midnight Consolidated Mines Ltd. was organized in September 1956 to carry out exploration work on the O.K., I.X.L., and Midnight claims. A small amount of drifting was done on the O.K. claim before operations ceased in April 1957.

The O.K. veins lie within greenstone and altered greenstone of the Lower Jurassic, Elise Formation of the Rossland Group. The mine workings pass into dark grey siltstone and sandstone of the Pennsylvanian and possibly Permian Mount Roberts Formation. These rocks lie adjacent to the northern contact of a body of serpentinite, of probable Permian age, which trends east and apparently dips

CAPSULE GEOLOGY

steeply to the south. Many small shear zones along this contact suggest that it is an east trending fault which is terminated by the Middle Eocene Marron Group on the west and the Jumbo fault on the east. It is reported that the gold-bearing quartz veins in the O.K. mine occur only in the greenstone and siltstone to the north and those faults which trapped quartz and precious-metal-bearing solutions did not continue from the greenstone into the serpentinite.

A small intrusion of Middle Eocene Coryell biotite-monzonite was intersected in the lower O.K. adit. Mafic and lamprophyre dykes, most of which trend northward, are widely distributed. The lamprophyre dykes (which range up to 3.0 metres in width), occupy faults which cut the greenstone and monzonite, and in some places have slightly displaced the quartz veinlets.

The greenstone is very fine-grained, dense and massive rock of dark green to brownish hue. The original texture has been destroyed by both the development of chlorite and fibrous amphibole and by local silicification and serpentinization. It varies from a highly altered rock with small amounts of serpentine and magnetite to a mottled phase and then a phase which carries abundant, uniform serpentinite and magnetite. The typical massive serpentinite is a very dense black rock with cross-fibre asbestos infilling joints as 0.2 to 0.6 centimetres veinlets and light green talc has developed in the immediate vicinity of the faults.

The veins are quartz-carbonate fissures which range up to 0.6 metre in width, and strike easterly with moderate to steep dip angles to the north. The veins host free gold, often visible to the naked eye, in mineable pockets that are very erratically distributed along the veins. The mineralized parts of the veins pinch and swell and change their attitudes. Widths range from a few centimetres to 0.5 metre and up to 2 metres in places. The strongest mineralized zones are less than 100 metres long and have been developed for the same distance up the dip. Other sulphides which occur in the quartz and ankeritic carbonate veins are pyrite, chalcopyrite, and galena as well as malachite and azurite. Pyrite is widely disseminated in the host rock.

The O.K. veins were mined in 1909 and from 1933 to 1939. A total of 293 tonnes of ore were mined and 17,916 grams gold, 14,991 grams silver, and 154 kilograms copper were recovered.

CAPSULE GEOLOGY

The Golden Drip workings lie within greenstone and altered greenstone of the Elise Formation of the Lower Jurassic Rossland Group. These lie adjacent to the northern contact of a body of serpentinite, of probable Permian age, which trends easterly and probably dips steeply to the south. Many small shear zones along this contact suggest that it is an east trending fault which is terminated by the Middle Eocene Marron Group on the west and the Jumbo fault on the east.

The greenstone is very fine-grained, dense and massive rock of dark green to brownish hue. The original texture has been destroyed by both the development of chlorite and fibrous amphibole and by local silicification and serpentinization. It varies from a highly altered rock with small amounts of serpentine and magnetite to a mottled phase and then a phase which carries abundant, uniform serpentinite and magnetite. The typical massive serpentinite is a very dense black rock with cross-fibre asbestos infilling joints as 0.2 to 0.6 centimetre veinlets and light green talc has developed in the immediate vicinity of the faults. The serpentinite is brown weathering and stands out as open outcrops with sparse vegetation on the Golden Drip claim and host coatings of green and locally bluish fibrous serpentine. Ten samples taken from the serpentinite exposed in the area gave nickel assays of less than 0.24 per cent (Bulletin 74).

The Golden Dip was mined in conjunction with the I.X.L. (082FSW116).

Workings in the Golden Drip consists of adits and crosscuts which follow discontinuous quartz-carbonate veins or lenses which host free gold and local concentrations of pyrite, chalcopyrite, galena, and sphalerite. The quartz veins are within the Rossland Group rocks and do not pass into the serpentinite.

The veins were mined between 1923 and 1939 producing about 184

CAPSULE GEOLOGY

tonnes of ore from which was recovered 5244 grams gold, 6843 grams silver, 39 kilograms copper, and 186 kilograms lead. Between 1978 and 1982, 33 tonnes of ore were milled and produced 6784 grams gold, 4067 grams silver, 276 kilograms lead and 60 kilograms zinc.

CAPSULE GEOLOGY

The Midnight claim, located on the west side of Little Sheep creek 1.6 kilometres west of Rossland, was Crown-granted in 1897. No work was reported done on the property until leasers began operations in 1925. The claim was owned by T.S. Gilmour in 1930. A small mill (7.3 tonnes/24 hours) was installed on the property in 1932. Leasers continued to work the property until it was purchased by B.A. Lins in 1940. Intermittent operations were carried on by Lins until Kootenay Central Mines Ltd. purchased the property in 1948. Small scale operations were continued by the company or by leasers until 1952. Midnight Consolidated Mines Ltd. acquired the property in 1956.

A private company, headed by Messrs. Thompson and Sheward, began rehabilitation of the workings in 1964. Cinola Mines Ltd. acquired an interest in the Midnight Crown-grant (Lot 1186) and 12 adjacent recorded claims in 1965. The old workings were rehabilitated, short drifts and raises were driven, and diamond drilling totalling 610

CAPSULE GEOLOGY

metres on surface and 914 metres from underground was carried out. In 1966 a new adit (3,100 foot level) was begun 46 metres below the old workings and during 1967 about 305 metres of drifting and raising was done, including a raise to the old workings. Further drifting, raising, and stoping was carried on in 1968 and a small amount of ore shipped. Tull Mines Ltd., incorporated May 1968, agreed to participate in bringing the property to production. Construction of a 90 tonne per day mill was begun late in 1968 but was not completed under the agreement. Federated Mining Corporation Ltd. optioned a 50 per cent interest in the property from Cinola Mines in 1970 and mill construction was completed during the year. Some stope preparation and stoping was done to supply the mill with sufficient ore for recovery tests. Mill tune up operations reportedly began in June 1970 but subsequent modifications were required due to metallurgical problems. The mill operated briefly early in 1971; no production data has been released. All work at the property ceased in September 1971.

The company name was changed in January 1973 to Consolidated Cinola Mines Ltd. During the year about 200 tonnes of ore, mainly cleaned up from the idle mill on the property, was shipped to Trail. A November 1974 agreement between Consolidated Cinola and Sand Mines Ltd. called for the latter company to advance all necessary capital to put the property into production. Consolidated Cinola is to receive 20 per cent, and Federated Mining 10 per cent, of net smelter returns. Underground rehabilitation, development, and diamond drilling was begun. Small shipments of crude ore were made in 1975 and 1976.

Carnelian Mines Ltd. held the property in 1979 and reported a small shipment of crude ore. Tagus Resources Ltd. sub-optioned the property from Carnelian in December 1979; the agreement was abandoned in 1980 following limited diamond drilling and sampling.

The Midnight veins lie within greenstone and altered greenstone of the Elise Formation of the Lower Jurassic Rossland Group. These lie adjacent to the northern contact of a body of serpentinite, of probable Permian age, which trends east and probably dips steeply to the south. Many small shear zones along this contact suggest that it is an east trending fault which is terminated by the Middle Eocene Marron Group on the west and the Jumbo fault on the east.

The greenstone is very fine-grained, dense and massive rock of dark green to brownish hue. The original texture has been destroyed by both the development of chlorite and fibrous amphibole and by local silicification and serpentinitization. It varies from a highly altered rock with small amounts of serpentine and magnetite to a mottled phase and then a phase which carries abundant, uniform serpentinite and magnetite.

The typical massive serpentinite, of the Permian ultramafic body, is a very dense black rock with cross-fibre asbestos infilling joints as 0.2 to 0.6 centimetre veinlets and light green talc has developed in the immediate vicinity of the faults. In 1969, near the northern contact of a mass of serpentinite on the Midnight property along the western side of Little Sheep Creek, samples from underground workings gave several thousand tonnes of serpentinite averaging 0.25 per cent nickel. Selected samples assayed up to 0.45 per cent nickel (Bulletin 74, page 23). The serpentinite hosts pyrite, millerite, and a mineral of the linnaeite group. Chromite is associated with the fine-grained serpentinite. A drift through the serpentinite cut a 15-metre wide mineralized zone grading up to 6.86 grams per tonne gold over its entire length, with up to 17 grams per tonne gold over 4.6 metres (Vancouver Stockwatch, August 21, 1989, page 15).

The principal gold vein on the Midnight claim strikes north to 020 degrees west and dips 65 degrees west in the Rossland Group rocks. The vein ranges from 5 centimetres to 1.5 metres in width and hosts free gold, pyrite, galena, chalcopyrite, and sphalerite in quartz and ankeritic carbonate. The gold is present in very high grade pockets that are erratically distributed along the veins. Other individual veins are not a continuous body of quartz, rather they are tight fractures which every 15 metres or so, contain quartz lenses from 20 to 61 centimetres thick, 15 to 31 metres long, that pinch and swell in both horizontal and vertical sections.

Between 1927 to 1974, 4760 tonnes of ore were mined with the resulting recovery of 218,346 grams gold, 124,383 grams silver, 2097 kilograms lead, 1460 kilograms zinc, and 62 kilograms copper.

Drexore Developments Inc. optioned the property in 1987.

CAPSULE GEOLOGY

The Norway Crown Grant is underlain by a stock of the Middle to Late Jurassic Nelson Intrusions comprised of a granodiorite to quartz diorite. The stock intrudes the Lower Jurassic Elise Formation, Rossland Group comprised of altered siltstone, hornfelsed siltstone, conglomerate, and breccia. These rocks are also intruded by a stock of Early Jurassic Rossland monzonite (recently dated at 190 million years) comprised of a mass of biotite-hornblende-augite monzonite (Andrew, K.P.E., Personal Communication, 1991).

Mineralization on the Norway consists of a quartz vein in the Nelson granitic rocks which hosts gold in places. In 1929, the quartz vein which ranged up to 0.9 metres in width was developed by two adits. The upper adit is about 61 metres in length, while the lower adit followed the vein for some 15 to 18 metres.

In 1936, one tonne of ore was shipped and 156 grams of silver were recovered.

degrees north and hosts 0.5 metres of ore. The ore consists of veinlets, stringers, and impregnations of pyrite, pyrrhotite and chalcopyrite with magnetite traversing the country rock in a gangue of quartz and calcite. Minor scheelite is disseminated in the altered wallrock. In 1906, the average analysis of the ore assayed 8.57 grams per tonne gold, 17.14 grams per tonne silver, and 0.7 per cent copper (Geological Survey of Canada Memoir 77, page 141).

Between 1900 to 1905, 5910 tonnes of ore were mined from the Spitzee system from which was recovered 55,207 grams gold, 97,290 grams silver, and 52,264 kilograms copper.

CAPSULE GEOLOGY

The Deer Park occurrence is hosted by greenstone, volcanic breccia, conglomerate and sandstone sequence of the Lower Jurassic Elise Formation, Rossland Group. The mineralization is considered to be a Rossland-type ore that occurs within the contact aureole of the Early Jurassic Rossland monzonite. The Rossland Monzonite has recently been age dated at 190 million years and consists of a biotite-hornblende-augite monzonite stock. The mineralized veins are considered as part of the South belt vein system. Refer to the Le Roi deposit (082FSW093) for a summary of the Rossland mining camp.

Mineralization consists of massive to semi-massive, pyrite, pyrrhotite and magnetite along the monzonite contact. Abundant fibrous radiating masses of actinolite in a magnetite skarn occur near the massive ore. The low-grade massive pyrrhotite-magnetite ore carries a little copper with traces of gold.

A quartz vein network associated with the monzonite hosts mostly pyrite with some arsenopyrite and free gold, minor calcite, chalc-

CAPSULE GEOLOGY

pyrite, molybdenite and scheelite. The arsenopyrite is nearly always cobaltiferous approaching a danaita composition, and shows unusual twinning in crystals found in the Deer Park veins. The vein system strikes 170 degrees and dips steeply to the north. In 1967, Thorpe identified kobellite, a lead-bismuth sulphide, in the ore from the Deer Park mine. This mineral is a rare sulphosalt, and blades of the kobellite are enclosed in the coarsely granular vein quartz, which also includes minor pyrite, arsenopyrite, pyrrhotite, and chalcopyrite.

The vein system, or ore shoots, terminate abruptly against cross structures. There are several lamprophyre dykes or spessartite dykes with large phenocrysts of hornblende and biotite which traverse the country rock and dissect mineralized ore shoots.

By 1899, 600 metres of underground development had occurred and 16 tonnes of ore had been shipped (Minister of Mines Annual Report 1899, page 599). Statistics on the recovery of minerals from the ore were not reported.

CAPSULE GEOLOGY

The Homestake showings are hosted by the Lower-Middle Jurassic Rossland Group (Elise Formation) augite porphyry. The porphyry is known as the Rossland sill and is dark green with phenocrysts of augite which are partly altered to hornblende. The Rossland Group rocks are intruded by the Early Jurassic Rossland monzonite which consists of a biotite-hornblende-augite monzonite stock. The Homestake veins lie in the zone of thermal metamorphism associated with the monzonite intrusive. The ore in the Homestake vein system, which strikes 100 degrees is classed as transitional-type which is a gradational mineralogy and metal content between the Rossland-type and the South belt-type (Bulletin 74, page 39).

The main mineralized vein on the claim strikes east and dips 70 degrees north and is traceable in excess of 210 metres in length. The ore consists of pyrrhotite, pyrite, sphalerite, galena, marcasite and arsenopyrite in a calcite, quartz and altered country rock gangue. In 1903, the ore assayed an average of 1.37 grams per tonne gold, 96.0 grams per tonne silver, and 0.3 per cent copper (Geological Survey of Canada Memoir 77, page 166).

Another vein strikes 280 degrees and dips steeply to the north

CAPSULE GEOLOGY

and hosts pyrite, pyrrhotite with minor chalcopyrite and magnetite. The vein is 1.8 metres in width and hosts 22.9 centimetres of sulphides on the footwall with 46 centimetres on the hanging wall. The sulphides are part of a magnetite-skarn which occurs in the altered wallrock in a well-defined fracture and/or fault zone. This main fault averages 7.6 centimetres in width. The ore shoots end abruptly against cross structures comprised of lamprophyre and dioritic dykes.

In 3 years, between 1901 and 1908, 236 tonnes of ore were mined and 933 grams gold, 74,927 grams silver, and 91 kilograms copper were recovered.

CAPSULE GEOLOGY

The region of the Monday Crown Grant is underlain by the Lower Jurassic Elise Formation, Rossland Group comprised of banded hornfels, grey to black siltstone, greenstone and a unit consisting of green volcanic conglomerate, breccia and sandstone. Augite porphyry (diorite) of the Rossland sill intrudes the upper part of the Elise Formation and occurs south and east of the Monday property. The southern edge of the Lower Jurassic Rossland monzonite is located approximately 100 metres north of the property. A stock of the Middle Jurassic Coryell Intrusion composed of syenite to monzonite and granite intrudes the strata a few hundred metres to the south.

The Monday vein system lies within the zone of thermal metamorphism associated with the monzonite intrusive and is hosted by the banded hornfels. The ore associated with the Monday veins is classed as Transitional-type which is a gradational mineralogy and metal content between the Main vein-type and the South-belt type (Bulletin 74). Ore generally contains abundant sphalerite, minor galena, and is low in silver.

A shaft was sunk along a vein striking 056 degrees and dipping 75 degrees north. The vein hosts pyrrhotite, pyrite with minor

CAPSULE GEOLOGY

chalcopyrite and crosscuts hornfels and monzonite. Other veins strike between north and 045 degrees and are hosted by hornfelsic siltstone. Mineralization consists of arsenopyrite, sphalerite, galena, pyrrhotite and pyrite.

In 1937, 64 tonnes of ore were mined from veins within the Monday claim from which was recovered 13,468 grams silver, 2,226 kilograms lead and 3,467 kilograms zinc.

CAPSULE GEOLOGY

The Gopher showing is hosted by the augite porphyry (diorite) of the Rossland sill. The sill itself has intruded volcanic conglomerate, breccia, and sandstone of the Elise Formation, Rossland Group. The contact of the sill is poorly defined but appears concordant. The Rossland Group rocks are intruded by the Lower Jurassic Rossland monzonite which is comprised of a biotite-hornblende-augite monzonite stock. The showing lies within the zone of thermal metamorphism associated with the monzonite intrusive.

The mineralized vein lies east of the main fault on the Homestake claim (082FSW123) and, in part, is a continuation of the east Homestake vein system. Mineralization consists of pyrrhotite, pyrite, chalcopyrite, sphalerite and minor arsenopyrite in quartz-calcite gangue. Equidimensional pyrite grains occur as islands in

CAPSULE GEOLOGY

the pyrrhotite. Native bismuth and associated bismuthinite were also reported to occur in the ore. Chip samples taken across 1 metre at the Gopher adit assayed from 8.37 to 10.35 grams per tonne gold and 12.34 to 30.17 grams per tonne silver (Assessment Report 16751).

CAPSULE GEOLOGY

The Tuesday claim is underlain by Lower Jurassic Elise Formation (Rossland Group) banded hornfels and areas of augite porphyry. The rocks lie approximately 100 metres south of the southern edge of the Lower Jurassic Rossland monzonite within the zone of thermal metamorphism associated with the intrusion. On the west side of the property, the Middle Eocene Coryell Intrusion comprised of a monzonite to syenite stock intrudes the Rossland Group rocks. In 1983, potassium-argon dating of biotite from the Coryell Intrusions yielded an age of 49.1 to 49.9 million years (Bulletin 74). A widespread heating effect due to the intrusion may have caused a resetting of the potassium-argon ratios in the Rossland monzonite biotite which also gave a Tertiary age. A Uranium/Lead age date of zircon from the Rossland monzonite gave an age of 190 million years (Andrew, K.P.E, personal communication, March 1991).

The ore associated with veins in the vicinity of the Tuesday Crown grant are classified as Transitional-type, which is a gradational mineralogy and metal content between the Main vein-type and the South belt-type (Bulletin 74, pages 37-41; Minister of Mines Annual Report 1949, page 147). A Transitional-type vein is defined as those which host pyrrhotite, chalcopyrite, pyrite, sphalerite,

CAPSULE GEOLOGY

minor galena and are low in silver. However, commodities reported associated with the showings are gold, silver and copper (Bulletin 74 - Mineral Deposit table in pocket).

CAPSULE GEOLOGY

The Sunset skarn deposit is hosted by the Early Jurassic Rossland monzonite which intrudes the Lower Jurassic Elise Formation (Rossland Group) volcanics and greenstone. The host rock is comprised of a biotite-hornblende-augite monzonite stock which is medium-grained, grey to green in color and hosts magnetite, apatite, some sphene with chlorite, epidote and pyrite.

The ore from the Sunset tunnel is contained in a magnetite-skarn and consists of massive pyrrhotite and magnetite with a fair amount of chalcopyrite intermixed in a quartz and altered monzonite gangue. The massive magnetite shows good octahedral cleavage. A shaft was sunk on a 15 centimetre vein of ore. The ore was mined and shipped in 1898 and 1908 to the Trail smelter. A total of 30 tonnes of ore produced 373 grams gold, 809 grams silver and 99 kilograms copper.

SAMPLE TYPE: Drill Core
COMMODITY
Silver 31.2000 Grams per tonne
Gold 22.7700 Grams per tonne
COMMENTS: From a 2-metre drill interval.
REFERENCE: Assessment Report 16751.

CAPSULE GEOLOGY

The North shear zone occurs between the Homestake-Gopher and Bluebird-Mayflower shear zones. The shear occurs mainly in the southeast portion of the Gopher Crown Grant, and continues northwest through the Maid of Erin Crown Grant to the Robert E. Lee Crown Grant where the Robert E. Lee/Maid of Erin (082FSW131) occurrence is located (Assessment Report 16751, page 23, Figure 5, Map 2).
The North prospect occurs in green volcanic conglomerate, breccia and sandstone of the Lower Jurassic Elise Formation, Rossland Group. The Rossland Group rocks are intruded within a few hundred metres to the north by the Early Jurassic Rossland monzonite which is a stock comprised of a biotite-hornblende-augite monzonite. The deposit occurs in a shear zone that strikes approximately 070

CAPSULE GEOLOGY

degrees, dips either vertically or steeply to the southeast, and is traceable for 400 metres. The shear zone appears to be cut off to the west by the Gopher Creek fault. The structure is continuous to the northeast as far as the Robert E. Lee/Maid of Erin occurrence (082FSW131) and possibly beyond.

The mineralization consist of pyrrhotite, chalcopyrite, arsenopyrite, pyrite and sulphosalts. Two hundred metres to the northeast sphalerite appears as part of the mineral assemblage. The form of mineralization varies from disseminations and veinlets in the volcanics to massive sections up to 1 metre wide. The sulphides are usually accompanied by silicification.

Chip samples across 1 metre intervals taken from trenches across the structure gave values averaging 12.17 grams per tonne gold and 33.25 grams per tonne silver (Assessment Report 16751, page 23). Six diamond-drill holes tested this zone in 1985/1986 with the best intersection grading 22.77 grams per tonne gold and 31.20 grams per tonne silver (Assessment Report 16751, page 23).

CAPSULE GEOLOGY

The Mabel-Paul Boy vein strikes east-west and dips approximately 65 degrees north, hosting pyrrhotite, pyrite, and chalcopyrite in a quartz-calcite gangue. The vein is hosted in the Early Jurassic Rossland monzonite which is comprised of a biotite-hornblende-augite monzonite stock that intrudes the Lower Jurassic Rossland Group (Elise Formation) siltstone, volcanics and augite porphyry sill. A Tertiary lamprophyre dyke, the Spokane dyke, dated at 47.2 to 49.3 million years, crosscuts the monzonite.

In 1967, Thorpe analyzed chalcopyrite from the Mabel property. He determined that the gold:silver ratio was approximately 1:2 (Thorpe, 1967, page 57).

The Mabel was part of the Centre Star group (082FSW094) and some production was reported in 1906 when 22.7 tonnes of ore were shipped (Minister of Mines Annual Report 1906, page 153).

CAPSULE GEOLOGY

The area of interest is in the vicinity of Ivanhoe Ridge and Sophia Creek, some 6.4 kilometres southwest of Rossland. From incomplete information it appears that two chromite showings have been prospected, one located on Crown-grants at about 1341 metres elevation on Ivanhoe Ridge (Burlington, 082FSW264), and the other, about 1.6 kilometres to the south, at about 1250 metres elevation on the ridge between the two main forks of Sophia Creek and about 300 metres southeast of the natural gas pipeline. The Vandot group of 5 recorded claims, reported to be located on the Cascade highway at the first summit west of Rossland, were owned

CAPSULE GEOLOGY

in 1966 by V.M. Van, of Rossland. Old trenches were deepened and sampled.

Noranda Exploration Company Limited held the property in 1984 as the Ross, Ross 2-3, and Cal claims. Work included magnetometer surveys over 16 kilometres, induced polarization and electromagnetometric surveys over 1 kilometre, a geochemical soil survey comprising 177 samples, and trenching.

The Vandot showing is underlain by ultramafic rock, probable of Permian age and related to the Slide Mountain terrane, comprised of serpentinite that is brown weathering and stands out as outcrops with sparse vegetation. The serpentinite is in contact with altered Lower Jurassic Elise Formation volcanics of the Rossland Group. These rocks are intruded by a mass of the Middle Eocene Coryell Intrusions comprised of syenite with associated dykes.

There are three chromite showings on the property in black serpentinite. The serpentinite is highly fractured with light green talc developed in the fractures and minor veinlets of blue-green fibrous asbestos and yellow-green steatite. The highly fractured rocks host abundant nickeliferous magnetite and chromite.

Three shallow pits on the property expose fine-grained serpentinite with many fractures and abundant light green serpentine. Visible chromite associated with these fractures is fairly abundant in one pit. A vertical lense of massive chromite is 30 centimetres wide in a sheared zone striking 330 degrees. The walls host disseminated chromite within patchy bands up to 10 centimetres in width. Chromite stringers and disseminated chromite also occur in the serpentinite. One dump hosts massive chromite up to 15 centimetres in thickness. In 1979, a selected grab of massive chromite yielded 29.8 per cent CrO₃, 17.2 per cent Fe₂O₃, and 0.08 per cent TiO₂ (Assessment Report 7162). Two selected samples of chromite taken by Fyles from a trench assayed 3.24 and 12.0 per cent chromium and 0.10 and 0.20 per cent nickel (Bulletin 74). Samples from another trench near the northern edge of this same mass of serpentinite assayed 0.23 per cent chromium and 0.17 per cent nickel (Bulletin 74).

In 1974, the chromite showings were sampled and analyzed for platinum. Six samples showed trace silver, trace gold, 1.0 to 1.4 grams per tonne platinum, 0.16 to 0.23 per cent nickel, 0.8 to 16.5 per cent chromium and 0.006 to 0.016 per cent cobalt (Assessment Report 4927). Apparently other companies have not been able to duplicate the platinum results. Samples from the serpentinite mass along Little Sheep Creek were submitted to the Geological Survey of Canada and pyrite, millerite, and a mineral of the linnaeite group were identified. Ten samples taken by Fyles at various places throughout the two masses of serpentinite exposed in the area gave nickel assays of less than 0.24 per cent (Bulletin 74).

CAPSULE GEOLOGY

The Phoenix occurrence is considered Rossland-type mineralization, with sulphides infilling well-defined fractures and faults in the Lower Jurassic Rossland monzonite. The host rock is comprised of a biotite-hornblende-augite monzonite stock which is medium to fine-grained, grey to green in color. The monzonite hosts magnetite, apatite, some sphene with chlorite, epidote, pyrite and pyrrhotite.

The Phoenix vein strikes 080 degrees and dips near vertically, and ranges between 0.6 to 1.2 metres in width hosting 15 to 20 centimetres of gold and copper ore. Mineralization consists mainly of pyrite, pyrrhotite, and chalcopyrite with lenses of quartz and carbonate gangue.

The system was mined in 1912 to 1915 and from 1939 to 1942. A total of 279 tonnes of ore were mined from which was recovered 4,697 grams gold, 16,016 grams silver and 3,212 kilograms copper.

CAPSULE GEOLOGY

The old Abe Lincoln workings are hosted by the Lower Jurassic Rossland monzonite which is comprised of a biotite-hornblende-augite monzonite stock which is medium-grained, grey to green in color and hosts magnetite, apatite, some sphene with chlorite, epidote, pyrite, and pyrrhotite. The monzonite intrudes the Lower Jurassic Rossland Group (Elise Formation) sediments, volcanics and augite porphyry sill.

On the surface, the claim hosts an east-west striking vein which is comprised of auriferous pyrrhotite, chalcopyrite, and pyrite. Pyrite occurs as well formed crystals in the pyrrhotite and as disseminations in the host rock. A wide, porphyritic dyke cross-cuts the monzonite to the north and west of the workings. The Abe Lincoln mineralization is classed as typical Rossland-type.

CAPSULE GEOLOGY

Elmo claim (Lot 923) was Crown-granted in 1896 to F.C. Loring. Development work continued until 1901 and included about 701 metres of drifts and crosscuts in 2 adits. Further activity was reported in 1908 when a small amount of ore was shipped under the name J.P. Johnson.

No further activity was reported until 1941 when the St. Elmo workings were reopened by A. Grubsic and Ike Glover. Scheelite was discovered in the old workings in 1942 and the Consolidated Mining, Smelting and Power Company Limited examined the property under an option agreement.

Northwood Mining Limited optioned the Golden Queen, St. Elmo, and Surprise (Lot 693) claims from Messrs. Grubsic and Glover in August 1964 and the Gertrude claim (Lot 690) from William Keane. By an agreement of September 1964 Northwood assigned the above 4 Crown-granted claims to McKinney Gold Mines Limited. Geophysical and geochemical surveys were started late in 1964. The geochemical survey of the Golden Queen and St. Elmo claims was continued in 1965. Some bulldozer stripping was done and numerous showings sampled. In addition, 47 vertical diamond drill holes totalling 1471 metres were drilled in the northwestern part of the Golden Queen and western part of the St. Elmo claim. Surface stripping and diamond drilling between elevations of 1472 and 1515 metres on the northwest corner of the Golden Queen claim, and about 152 metres east of the "A" orebody on the Coxey claim, delimited a Y-shaped body of mineralization (designated the NGQ Zone) containing an indicated 68,000 tons averaging 0.24 per cent molybdenite. Near the western boundary of the St. Elmo claim a mineralized zone (designated the NSE Zone) as outlined, which to a depth of 23 metres contains about 73,000 tons averaging 0.33 per cent molybdenite.

Scurry-Rainbow Oil Limited optioned the property in December 1966, the option included the Novelty claim (Lot 958). Drilling by Scurry in 1967 tested the eastern part of the breccia complex on the Golden Queen and St. Elmo claims and the full width of the Novelty claim. Of the 14020 metres of diamond drilling in 174 holes, most was done on the adjacent Giant claim (082FSW109). Further diamond drilling was done by Scurry in 1968. Under the terms of the agreement Scurry earned a 50 per cent interest in the property. The company name (McKinney) was changed in March 1967 to Continental McKinney Mines Limited. Based on the drilling on this property, and on the adjacent Giant property, independent consultants in 1967 calculated the indicated-reserves available for open pit operations in 5 separate orebodies at 810,540 tons averaging 0.39 per cent molybdenite. In addition, some 88,000 tons of possible ore of various grades are indicated below open pit limits.

Continental McKinney in May 1973 amalgamated with Trinat Resources Ltd., Gundex Holdings Ltd., and Modoc Holdings Ltd., under the name Chandalar Resources Limited. A geochemical soil survey was carried out by Mine Finders, Inc., of Lakewood Colorado in 1973. Chandler Resources abandoned its interest in the property prior to 1975; Scutty-Rainbow sold its interest in 1975.

David Minerals Ltd. optioned the Golden Queen, St. Elmo, Surprise, and Novelty claims from J.D. Turcotte of Christina Lake, subject to a prior agreement between Turcotte and M. Delich of Rossland. From the exploration work done by Scurry Rainbow on the Golden Queen and St. Elmo (1971) there were outlined 237,000 tons grading 0.273 per cent MOS2 (Geol. Rept. for David Minerals in SMF 268/80, 24/12/80).

In 1981, David Minerals diamond drilled 22 holes here and in the Giant, California, Novelty, Gold King areas. (See 82 F/4, Mo 3).

Reserves were re-calculated by J.M. Stitt (1980) as follows:

Golden Queen - 19,500 tons at 0.30% MOS2
St. Elmo - 65,100 tons at 0.28% MOS2-

(Report by J.L. Deleen (1983) - in David Minerals Statement of Material Facts, 11/07/85).

The St. Elmo Crown Grant is underlain, on the west, by the Pennsylvanian and possibly Permian Mount Roberts Formation siltstone, hornfelsed siltstone, hornfels and a breccia complex. The siltstone is rusty, sooty and massive or thinly bedded with minor disseminated pyrrhotite and pyrite. The hornfels and hornfelsic siltstones are thinly laminated and massive cherty rocks which locally contain brown garnet and epidote. The Mount Roberts succession overlies augite porphyry of the Rossland sill, which underlies the eastern half of the Crown grant, and is thought to have been thrust over the sill. The Rossland sill intrudes the upper part of the Elise Formation (Rossland Group) and is considered part of that formation.

The principal host for the molybdenum mineralization on Red Mountain is the hornfelsed and brecciated siltstone. On Red Mountain, a large mass of quartz diorite, probably part of the Trail

CAPSULE GEOLOGY

pluton, was encountered 600 metres below the surface by deep drilling. It contains scattered molybdenite in quartz veinlets for as much as 300 metres below the upper surface of the quartz diorite. The siltstone is also intruded by lenticular masses of andesite and late steeply dipping dykes which trend northward. Small scale faults parallel to this trend step the older rocks down on the west.

According to the National Mineral Inventory (082F04 Mo2), adits explored weak shear zones dipping about 70 degrees north. They are mineralized with pyrrhotite, pyrite and chalcopyrite with calcite and some local silicification, but no true vein quartz. Scheelite occurs in these shear zones in shoots of which the longest is 21 metres. The maximum width is 1.5 metres with an average width of the ore shoots ranging between 0.45 to 0.76 metres. The scheelite occurs as fine disseminations and clusters of grains and locally as fine stringers in the rock.

Drysdale reports in 1915 that the main St. Elmo tunnel was near the east end of the claim (Geological Survey of Canada Memoir 77, page 134). The adit is driven along an east and west wall from which molybdenite, sphalerite and galena occur in a calcite-quartz gangue. A tunnel driven from the Consolidated St. Elmo Crown Grant (082FSW135), adjacent to the east of the St. Elmo claim, encountered a large body of fine-grained ore. In 1899, the end of this tunnel was about 43 metres east of the St. Elmo line. A 1964 sketch plan of the area shows over 200 metres of tunnels on the St. Elmo that are connected to the workings on the Consolidated St. Elmo. In 1908, 70 tonnes of ore was mined and produced 93 grams gold, 6874 grams silver, and 1446 kilograms copper.

Scattered mineralization occurs in a northeasterly trending zone, between elevations 1545 and 1560 metres near the western boundary of the claim. The zone, known in later days as the NSE zone, is about 122 metres long and 30 metres wide and hosts molybdenite as well as chalcopyrite, pyrite, sphalerite and galena in narrow east striking veinlets. The host rocks are apparently quartzites.

In 1980, a molybdenum indicated reserve calculated for the St. Elmo claim was 59,052 tonnes of 0.28 per cent MoS₂ (David Minerals, Statement of Material Facts, July 1985). This is a recalculation of the mineralized NSE zone to a depth of approximately 23 metres. The conversion used for MoS₂ to Mo is 1.6681.

CAPSULE GEOLOGY

porphyry is a uniform dark green rock with phenocrysts of augite up to 3 millimetres across. The upper contact is planar and dips about 20 degrees west, concordant with the bedding of the siltstone and hornfels of the Rosslund Group. Several narrow dykes or sills of augite porphyry occur within the hornfels which is rich in hornblende and disseminated magnetite. The augite porphyry appears to be intrusive into the siltstones and to have a narrow thermal contact metamorphic zone of hornblende-magnetite hornfels.

The Rosslund Group rocks are intruded to the south by the Lower Jurassic Rosslund monzonite and to the north by the Middle to Late Jurassic Trail Pluton which is comprised of a granodiorite stock.

The vein on the Consolidated St. Elmo claim dips between 60 to 70 degrees north and can be traced for almost the full length of the claim. The vein varies in width from 0.9 to 1.2 metres in width and hosts pyrite, pyrrhotite and scattered chalcopyrite. A 14-metre shaft and 18-metre adit were driven along the vein following a slip plane which hosted 1.5 metres of solid pyrite and pyrrhotite with minor chalcopyrite. The vein was mined in conjunction with the drifts and crosscuts along ore shoots on the Cliff claim (082FSW136).

Several other minerals were reported by Thorpe (1967). A ruby silver mineral, probably pyrargyrite, was observed in a single deposit of the Consolidated St. Elmo. The ore mineral appeared to be secondary. Sphalerite occurs in coarsely granular pyrite, appearing to have replaced the pyrite. Scheelite also occurs.

CAPSULE GEOLOGY

The Cliff claim is located on the lower east slope of Red Mountain, about 1.6 kilometres of Rossland. The Consolidated St. Elmo adjoins to the west.

The Cliff claim (Lot 921) was staked in September 1890 by Gay Ruder and the Consolidated St. Elmo (Lot 924) in October of that same year by Will Springer. Both claims were Crown-granted, in 1896 to J.R. Cook and associates of Spokane. The Cliff Gold and Copper Mining Company, Limited, was incorporated in 1899. Some further work was reported in 1904. The Granby Consolidated Mining, Smelting and Power Company Limited, acquired the property in 1910 and some development work was carried out. Exploration and development work to that date had been done in 15-metre shaft and 18-metre adit on the Consolidated St. Elmo claim and about 305 metres of drifts and crosscuts in 3 adits on the Cliff claim.

The claims were subsequently acquired by a Rossland syndicate headed by L.A. Campbell. Lessees shipped small tonnages of ore during the period 1933-1936.

Scheelite was discovered in the old workings in 1942 and The Consolidated Mining and Smelting Company of Canada (Limited) examined the property under an option agreement; diamond drilling totalling 67 metres was done on the Cliff claim.

The claims were held in 1968 by Continental McKinney Mines Limited under a lease agreement with an expiry date of July 1972.

The old workings are within the Lower Jurassic Rossland Group (Elise Formation) augite porphyry, known as the Rossland sill. The sill lies beneath siltstone and hornfels and is exposed on the eastern slopes of Red Mountain. The augite porphyry is a uniform dark green rock with phenocrysts of augite up to 3 millimetres across. The upper contact is planar and dips about 20 degrees west,

CAPSULE GEOLOGY

concordant with the bedding of the siltstone and hornfels of the Rosslund Group. Several narrow dykes or sills of augite porphyry occur within the hornfels which is rich in hornblende and disseminated magnetite. The augite porphyry appears to be intrusive into the siltstones and to have a narrow thermal contact metamorphic zone of hornblende-magnetite hornfels.

The Rosslund Group rocks are intruded to the south by the Early Jurassic Rosslund monzonite stock and to the north by the Middle to Late Jurassic Trail Pluton which is comprised of a granodiorite stock.

Mineralization on the claim consists of veins host pyrrhotite, pyrite, and chalcopyrite. These were explored and mined by over 310 metres of drifts and crosscuts in conjunction with adits on the Consolidated St. Elmo claim (082FSW135).

The ore consists of a series of shoots in which sulphides infill well defined fractures or faults. The ore shoots end abruptly against crosscutting dyke structures and the veins are disjointed by faulting. A vein in tunnel No. 2, dipping 40 to 50 degrees north consists primarily of pyrrhotite over a width of 7 metres. The auriferous pyrrhotite is also associated with pyrite and minor arsenopyrite. In tunnel No. 3 a vein dipping 43 degrees north is comprised of massive pyrrhotite with some chalcopyrite and pyrite. On the surface the vein ranges between 0.3 to 0.6 metre in width. In 1942, scheelite was discovered in some of the old workings. The scheelite occurs in many parts of the vein and for a few centimetres into the wallrock. It is mainly disseminated but in places forms streaks and patches 5 to 8 centimetres wide. The average WO₃ content across mineable widths is considered low.

Native bismuth is found in ore from the Cliff property. In 1967, a polished surface of ore from the property indicated 1.4 per cent of the area was occupied by bismuth which has veined and replaced arsenopyrite and also appeared to have extensively replaced pyrrhotite.

Between 1898 to 1911 and 1933 to 1936, 1915 tonnes of ore was mined and produced 14868 grams gold, 99530 grams silver, and 24,195 kilograms copper.

CAPSULE GEOLOGY

The Southern Belle claim lies within the Lower Jurassic Rossland Group (Elise Formation) augite porphyry, known as the Rossland sill. The sill lies beneath siltstone and hornfels and is exposed on the eastern slopes of Red Mountain. The augite porphyry is a uniform dark green rock with phenocrysts of augite up to 3 millimetres across. The upper contact is planar and dips about 20 degrees west, concordant with the bedding of the siltstone and hornfels of the Rossland Group. Several narrow dykes or sills of augite porphyry occur within the hornfels which is rich in hornblende and disseminated magnetite. The augite porphyry appears to be intrusive into the siltstones and to have a narrow thermal contact metamorphic zone of hornblende-magnetite hornfels.

The Rossland Group rocks are intruded to the south by the Early Jurassic Rossland monzonite stock and to the north by the Middle to Late Trail Pluton which is comprised of a granodiorite stock.

The Southern Belle adjoins the Cliff and Consolidated St. Elmo claims to the north (082FSW135 and 136). The country rock is augite porphyry. A vein, up to 30 centimetre wide, hosts auriferous pyrrhotite and pyrite and in 1915 was reported to assay about 33 grams per tonne gold (Geological Survey of Canada Memoir 77, page 134). By 1915, a prospect shaft had been sunk on a 0.6-metre wide pyrite vein

CAPSULE GEOLOGY

with strike of 077 degrees and dip of 80 degrees north. A lower tunnel discloses the same pyrite vein in the form of three bands of low grade pyrite 15, 30 and 5 centimetres in width, respectively.

Plutonic Rocks

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The Golden Chariot occurrence is hosted by the Early Jurassic Rossland monzonite which is comprised of a biotite-hornblende-augite monzonite stock that is medium-grained, grey to green in color and hosts magnetite, apatite, some sphene with epidote, chlorite, pyrite and pyrrhotite. The monzonite intrudes the Lower Jurassic Rossland Group (Elise Formation) sediments, volcanics and greenstone.

The Golden Chariot and Great Western Crown grants are traversed northeast and southwest by a wide, iron stained mineralized zone. The zone consists of sulphides infilling fractures and/or faults hosting auriferous pyrrhotite, chalcopyrite, and pyrite in a gangue of altered host rock and calcite. The pyrite occurs as crystals in the pyrrhotite or as disseminations in the host rock. Drilling in the west part of the claim exposed a 0.76 metre wide solid sulphide vein carrying low gold values. In the eastern part of the property, a shaft was sunk in 3.6 metres of massive ore in a quartz gangue. In both veins, the sulphides were coarse-grained pyrrhotite and pyrite with minor patches of intermixed chalcopyrite.

The ore is reported to assay about 5 to 7 grams per tonne gold (Geological Survey of Canada Memoir 77, page 127).

CAPSULE GEOLOGY

The John showing is underlain by sediments of the Lower Jurassic Elise Formation, Rossland Group. The host rocks consist of thin-bedded limestones and argillites lying above massive limestone. The bedding strikes 153 degrees and dips 40 degrees to the southwest. Workings, consisting of a pit and an 18-metre long adit, explore a fissure which varies from a crack to 0.45 metres in width. Pyrite is reported to be the main visible mineral. The fissure is vertical and strikes 100 degrees. In 1954, a shipment consisting of 7.2 tonnes of "development rock" was made to the Trail smelter. The ore produced 404 grams of silver, 79 kilograms of lead and 145 kilograms of zinc (Minister of Mines Annual Report 1954, page 153).

CAPSULE GEOLOGY

The Mountain View Crown Grant hosts open pits E and F of the Coxey Group. The area is underlain by the Pennsylvanian and possibly Permian Mount Roberts Formation siltstone, hornfelsed siltstone, hornfels and a breccia complex. The siltstone is rusty, sooty and massive or thinly bedded with minor disseminated pyrrhotite and pyrite. The hornfels and hornfelsic siltstones are thinly laminated and massive cherty rocks which locally contain brown garnet and epidote.

The succession is thought to have been thrust over augite porphyry of the underlying Rossland sill of the Elise Formation (Rossland Group) prior to the intrusion of the Middle to Late Jurassic Trail pluton (Nelson Intrusions). The siltstone is intruded by lenticular masses of andesite, irregular bodies of quartz diorite and quartz diorite breccia, and late steeply dipping dykes which trend northward. The quartz diorite is assumed to be part of the Trail pluton.

A green, magnetite-bearing hornfels occurs in and around E and F pits. This magnetite-hornfels is similar to the rock that occurs on

CAPSULE GEOLOGY

surface and just above the Rossland sill. Steeply dipping regional faults trending 160 degrees offset the orebodies A, B, and C of the Coxey Mine (082FSW110) with orebodies E and F on the Mountain View claim. One interpretation suggests that all the orebodies are within 100 metres of stratigraphic section; according to another they may be at two horizons covering a stratigraphic interval of 200 metres.

The molybdenum mineralization occurs essentially within the Rossland Group breccia complex and the quartz-diorite breccia. In the breccia complex, the rocks are angular with a matrix comprised of fine silicates, quartz, calcite, garnet or scheelite. Molybdenite, usually without other sulphides, occurs in randomly oriented fractures in all types of hornfels breccia and quartz-diorite breccia. Commonly it lies along the margins of breccia blocks and locally is concentrated at junctions between the blocks. Pyrrhotite, and locally pyrite, are disseminated in the hornfels and also occur in fractures and as massive lenses between the breccia fragments. Some silver values are reported as well as minor galena and arsenopyrite mineralization. In the southeast corner of the F pit a narrow chalcopyrite-pyrrhotite vein trending 120 degrees and dipping 75 degrees to the north cuts molybdenum-bearing hornfels. The vein is typical of Rossland-type mineralization in the main camp, and this exposure is taken as evidence that the copper-gold mineralization of the Rossland camp is later than the molybdenum mineralization.

Scheelite, occurring as medium to coarse grains, is scattered throughout the breccia complex; rarely, it forms spectacular clusters of grains between fragments. Its occurrence is erratic but company records indicate that the highest grades were found in the E and F orebodies, where the average grade was about 0.10 per cent WO₃ (tungsten trioxide).

The characteristics of the molybdenite and scheelite mineralization and its association with the Middle to Late Jurassic Trail pluton, especially its upper and western margins, point to its classification as a porphyry-type deposit (Bulletin 74).

It was reported in 1893 that on the Mountain View claim there was a vein 9 metres wide and 60 metres long, the ore of which was reported to average about 41 grams per tonne gold (Geological Survey of Canada Memoir 77, page 135).

The property is located on the west slope of Red Mountain about 17.6 kilometres northwest of Rossland. It consists of 10 claims, the Coxey, Nevada, Mountain View, Ontario, Good Friday, Peak, High Ore, Ophir, Jumbo, and Sam Hayes. Most of these claims were Crown-granted during the period 1895-97 and were well known in the early days of the Rossland camp.

Development work on the Coxey was begun in 1897 by Messrs. Cook & Johnson. In 1899 Montreal Goldfields Ltd prospected the property for gold and copper. Development work consisted of two tunnels, a shaft, and several open cuts. The Coxey claim was reportedly worked by lessees Williams and Ruffner during the first World War but it is not known what development work was done at that time.

Late in 1963 Torwest Resources acquired the group of 10 claim. During 1964, 59 diamond drill holes were put down on the Coxey claim, 53 on the A or east zone and 6 on the B or west zone. Stripping on the B zone traced the mineralization for over 213 metres.

Metal Mines Limited optioned the property in September 1964 and early in 1965 they assigned one half of their interest in the project to Canadian Nickel Company Limited, the exploration arm of The International Nickel Company of Canada Limited.

At the end of 1964 ore reserves were estimated at 400,000 tons grading 0.5 per cent molybdenite.

Thirty-four drill-holes put down by Metal Mines Limited late in 1964 reportedly confirmed the results of the Torwest drilling. Red Mountain Mines Limited was formed in April 1965 to operate the property. The new company was owned by Torwest Resources (60 per cent), Metal Mines (20 per cent), and Canadian Nickel (20 per cent). Mining was by open pit. A 400 ton per day mill began operating April 24, 1966. Reserves at that time were estimated at 800,000 tons averaging 0.45 per cent molybdenite.

The property was financed to production jointly by Canadian Nickel Company and Consolidated Canadian Faraday Limited.

Mining was done initially in the A zone. Mill capacity was increased to 600 tons per day by 1969 and 750 tons per day by 1970. The mine closed in December 1970 due to lack of ore. The discovery of the E zone late in 1970 permitted the resumption of milling in February 1971. The mine closed in January 1972. After closing, The International Nickel Company engaged Min Finders Inc., of Lakewood Colorado to carry out an extensive exploration program based on a porphyry model of mineralization. Geochemistry, geophysics and deep drilling were carried out in the mine area between 1972 and 1974.

In 1980-81 David Minerals Ltd acquired the property from AJM

CAPSULE GEOLOGY

Explorations Ltd. and AJM Mill Ltd. and also acquiring the interests of Hunstone Ventures Ltd. and those of Inco Limited, Consolidated Canadian Faraday and Teck Corporation. The 1980 agreement included purchase of the 600 tpd mill. In 1981 the company drilled 9 short holes just south of the mine area. Reserves were reported as drill indicated 270,000 tons at 0.37 per cent MOS2 on the Coxey and Nevada claims (David Minerals Ltd., FS 139/82, p. 3, 1982).

CAPSULE GEOLOGY

The Hattie occurrence is hosted by a sequence of the Lower Jurassic Elise Formation (Rossland Group) consisting of greenstone, volcanic breccia, conglomerate and sandstone. The Hattie mineralization is considered to be a Rossland-type ore which is hosted by Rossland Group rock and located 400 metres south of the southern edge of the Early Jurassic Rossland Monzonite. The monzonite has recently been dated at 190 million years (Andrew, K.P.E., Personal Communication, March, 1991). The showing lies within the zone of thermal metamorphism associated with the monzonite intrusion.

The Hattie vein system consist of fissure filled veins in the Rossland volcanics which host abundant arsenopyrite, chalcopyrite, and pyrite. Pyrite occurs as disseminations in the host rocks as well as in veinlets which crosscut the stratified host rock. The gangue consists mainly of altered host rock with minor lenses of quartz and calcite. The main vein strikes east-west and dips 85 degrees south to vertical. The vein averages 7.6 centimetres in width. A sample taken across 30 centimetres assayed 11.31 grams per tonne gold, 181.72 grams per tonne silver and 5.02 per cent copper (Minister of Mines Annual Report 1921, page 151). In 1980 a series of east-west stacking veins were exposed dipping 75 degrees south. In 1967, Thorpe reported that native gold, bismuth and associated

CAPSULE GEOLOGY

bismuthinite occurs in the ore.
Between 1934 to 1939, 21 tonnes of ore was mined from the Hattie vein system and 310 grams gold and 1090 grams silver were recovered.

CAPSULE GEOLOGY

The Blue Bird mine workings are hosted by the Lower Jurassic Rossland Group (Elise Formation) siltstone, argillite, hornfelsed siltstone and hornfels. The showings are located within the zone of thermal metamorphism associated with the Early Jurassic Rossland monzonite intrusion. The grey to black siltstone and argillite grades to hornfels. Ammonites of Early Jurassic age were reported to occur in siltstone on Ivanhoe Ridge.

The mine is hosted by the Bluebird-Mayflower shear zone which

CAPSULE GEOLOGY

strikes 120 to 130 degrees and dips from 50 to 65 degrees to the northeast, and is traceable for 600 metres. The Blue Bird zone consists of a series of lenses cut by numerous cross-faults and dykes. The ore bodies have a tendency to pinch and swell. As of 1988, underground development and drilling had tested the zone to a depth of 110 metres at which depth the structure and mineralization appear to be present. Limited drilling between the Blue Bird and Mayflower zone (082FSW146) to the east, to a depth of 45 metres has confirmed continuity of the mineralized structure but grades have been low. At the western extent of the shear zone, near the Hattie Brown shaft (082FSW359), the structure is cut by a 12.2 metre wide monzonite dyke of the Middle Eocene Coryell Intrusions. Surface work and drilling has suggested that the structure continues to the west of the dyke and is mineralized.

Mineralization at the Blue Bird consists of quartz veins hosting pyrite, sphalerite, galena, arsenopyrite, stibnite, chalcopyrite, pyrrhotite, and locally, boulangerite. The stibnite occurs as radiating, white metallic needle-like crystals. The vein system is considered as part of the South Belt-type of mineralization (Bulletin 74, page 39 to 40). The principal gangue mineral is quartz, however, carbonate veinlets also host pyrite, sphalerite, and galena mineralization. Tetrahedrite is generally very closely associated with the galena. The vein system strikes between 110 to 115 degrees, dipping steeply south. The veins are on strike with the main veins on the Mayflower claim and are considered as the westerly extension. Boulangerite appears to replace arsenopyrite, pyrite, and sphalerite in the ore from the Blue Bird mine. Small arsenopyrite crystals and plates of pyrrhotite are included in sphalerite and some have been inherited as inclusions in the boulangerite.

The main access to the vein is by adit No. 2 which was driven at an elevation of 844 metres just above and west of Gopher Creek. The vein is well mineralized 61 metres below this level and 244 metres west of the portal. The host rock is mainly hornfelsic siltstone which dips at moderate angles to the west and is cut by northerly trending dykes. Average grades based on production statistics are 3.87 grams per tonne gold, 653.8 grams per tonne silver, 3.5 per cent lead, 4.2 per cent zinc, and minor copper. Approximately 6503 tonnes of ore were mined from the Blue Bird zone between 1908 to 1914, 1935, 1951 to 1952, and 1972 to 1978. Recovery of commodities from this ore includes: 12,857 grams gold, 3,910,823 grams silver, 181,088 kilograms lead, 207,496 kilograms zinc, and 864 kilograms copper.

In 1990, drill hole 90-3 intersected 3.8 metres grading 11.31 grams per tonne gold (George Cross News Letter No.10, January 15, 1991).

Refer to the Le Roi deposit (082FSW093) for a summary of the Rossland mining camp.

CAPSULE GEOLOGY

The old Mayflower mine workings are hosted by the Lower Jurassic Rossland Group (Elise Formation) augite porphyry, known as the Rossland sill. The porphyry is dark green with phenocrysts of dark augite which are partly altered to hornblende. The rock is commonly brecciated with preferential epidote alteration. The sill is intruded by the Early Jurassic Rossland monzonite which is comprised of a biotite-hornblende-augite monzonite. The sill lies within the zone of thermal metamorphism. Diorite porphyry and lamprophyre dykes crosscut these older rocks striking 015 degrees and dipping 50 to 60 degrees eastward. A sample from a crosscutting lamprophyre dyke on the Mayflower claim gave a potassium-argon date from biotite as 49.4 plus or minus 1.4 million years (Bulletin 74, page 54).

The mine is hosted by the Bluebird-Mayflower shear zone which strikes 120 to 130 degrees and dips from 50 to 65 degrees to the northeast, and is traceable for 600 metres. The Mayflower zone, located about 200 metres east of the Blue Bird zone (082FSW145) on the same structure, is similar in most respects to the Blue Bird zone but differs in its higher gold to silver ratio. Exploration has been carried out to a depth of 60 metres at which level the mineralization is still present. Limited drilling between the Blue Bird and

CAPSULE GEOLOGY

Mayflower zones, to a depth of 45 metres, has confirmed continuity of the mineralized structure, but grades have been low. At the western extent of the shear zone, near the Hattie Brown shaft (082FSW359), the structure is cut by a 12.2 metre wide monzonite dyke of the Middle Eocene Coryell Intrusions. Surface work and drilling has suggested that the structure continues to the west of the dyke and is mineralized.

The main vein strikes 110 degrees and dips 70 to 80 degrees north. The earliest work was on the South vein; later development work proceeded on the North and Main veins which all strike east-west and dip steeply north. The main portal, at elevation 877 metres intersects 5 main ore shoots of 56 metres in length. Mineralization consists of sulphides replacing wallrock along well-defined fracture and faults and infilling fractures. The ore shoots end abruptly against dykes or cross structures.

The ore is composed of fine-grained, disseminated or rudely banded massive sulphides in a gangue consisting of thoroughly sericitized rock with minor carbonate and quartz. The mineralization is of the South Belt-type which contains pyrite, pyrrhotite, arsenopyrite, sphalerite, galena, and boulangerite (Bulletin 74, pages 39-40). Microscopic examination of the ore suggests that pyrrhotite was the earliest mineral to form, followed by and partly replaced by pyrite and arsenopyrite. Tetrahedrite is generally, closely associated with the galena. Silver assays of ore from the Mayflower property suggests that the tetrahedrite contains perhaps 10 per cent silver (Thorpe, 1967). Ruby silver, probably pyrargyrite is reported to occur in the ore as well as magnetite which is associated with the arsenopyrite.

A total of 876 tonnes of ore was mined from the workings between 1907 to 1910, 1929, 1935, 1937, 1948 and 1949. Recovered from this ore were 4,136 grams of gold, 376,780 grams of silver, 25,785 kilograms of lead, 49,390 kilograms of zinc and 139 kilograms of cadmium.

CAPSULE GEOLOGY

The Josie group, consisting of the Josi, Poorman, No. 1, Annie and Annie Fraction claims, lies west of and adjoining the Centre Star property on the northwestern edge of the City of Rossland. The Josie claim was apparently located by, R.E. Lemon in 1890 and Crown-granted to F.C. Loring in 1895. The British American Corporation Limited purchased the Josie and a number of adjoining claims in 1896 and development work was carried on for several years. The property was acquired in 1900 by Le Roi No. 2, Limited, an English company. Mining operations were carried out on 10 levels from a 396-metre deep shaft, and in several adits. Operations were continuous until January 1922 when the mine closed. The Consolidated Mining & Smelting Company of Canada Ltd., owner of the adjoining Centre Star group, purchased the property in 1923 and operations were carried on until 1928 when the mine was closed. Lessees worked the property from 1932 until June 1942. The Josie showing is part of the "Main vein" system which forms a continuous well-defined fracture system, on a regional scale, which strikes 070 degrees for a strike length in excess of 1 kilometre. The system dips steeply north; the Josie vein system dips 75 degrees north. Refer to the Le Roi deposit (082FSW093) for further details of the Rossland mining camp and the Main vein-type ore deposit. The Josie vein system is hosted by the Early Jurassic Rossland monzonite and augite porphyry of the Lower Jurassic Elise Formation (Rossland Group), known as the Rossland sill. The Rossland monzonite is an east-trending stock of biotite-hornblende-augite monzonite. Tertiary lamprophyre dykes,

CAPSULE GEOLOGY

trending northwards, crosscut the monzonite and sill. The Josie dyke averages more than 20 metres in thickness and appears to control the concentrations of copper and copper-gold ore. The ore shoots lie along portions of the main fissure and end abruptly against dykes or cross structures. The Josie vein system is comprised of three main veins, the Hamilton and the North Annie and South Annie (082FSW148) which strike westerly and dip steeply north. Sulphide mineralization consists of the replacement of wallrock along well-defined fractures and the infilling of fractures and faults with pyrrhotite and chalcopyrite. The gangue consists mainly of altered wallrock with minor lenses of quartz and calcite. Minor pyrite occurs as crystals in the pyrrhotite and as disseminations in the host rock. Massive fine-grained sphalerite of a deep brownish colour was observed in small irregular veinlets and blebs from the 275-metre level of the Josie mine.

Although development of the Josie started around 1896, production records start in 1900. Between 1900 to 1922, 554,482 tonnes of ore were mined from the Josie systems. From this, a total of 9,344,182 grams gold, 15,110,710 grams silver and 7,776,067 kilograms copper were recovered.

CAPSULE GEOLOGY

The Josie group, consisting of the Josie, Poorman, No. 1, Annie and Annie Fraction claims, lies west of and adjoining the Centre Star property on the northwestern edge of the City of Rossland.

The Josie claim was apparently located by, R.E. Lemon in 1890 and Crown-granted to F.C. Loring in 1895. The British American Corporation Limited purchased the Josie and a number of adjoining claims in 1896 and development work was carried on for several years. The property was acquired in 1900 by Le Roi No. 2, Limited, an English company. Mining operations were carried out on 10 levels from a 396-metre deep shaft, and in several adits. Operations were continuous until January 1922 when the mine closed.

The Consolidated Mining & Smelting Company of Canada Ltd., owner of the adjoining Centre Star group, purchased the property in 1923 and operations were carried on until 1928 when the mine was closed. Lessees worked the property from 1932 until June 1942.

The Annie Crown Grant (Lot 730) hosts two major veins which are part of the "Main vein" system that forms a continuous well-defined regional fracture system striking 070 degrees for a length in excess of 1.0 kilometre. The Annie occurrence consists of the North Annie

CAPSULE GEOLOGY

and the South Annie veins which strike west and dip steeply north. The veins were mined between 1898 and 1922 in conjunction with the Josie or LeRoi No. 2 mine (082FSW147).

The Annie claim is underlain by the Rossland sill, a mass of augite porphyry that intrudes siltstone, hornfels and hornfelsed siltstone of the Lower Jurassic Elise Formation, Rossland Group. The strata are intruded by the Early Jurassic Rossland monzonite, an east-trending biotite-hornblende-augite monzonite stock. The rocks are crosscut by late, lamprophyre and diorite dykes.

Mineralization in the main Annie veins consists of sulphide replacement of wallrock along well-defined fractures. The sulphides include pyrrhotite, chalcopyrite and pyrite in a gangue of altered country rock with lenses of quartz and calcite. The mineralization is described as the Rossland-type heavy sulphide ore, which is predominantly pyrite and pyrrhotite with a little chalcopyrite, and yields gold and copper.

For further details of the Rossland mining camp and the Main vein system refer to the Le Roi deposit (082FSW093).

CAPSULE GEOLOGY

The Georgia occurrence is underlain by Lower Jurassic Rossland Group (Elise Formation) siltstone, argillite and hornfelsed siltstone

CAPSULE GEOLOGY

which is intruded by the Rossland Monzonite. The grey to black siltstone and argillite grades into hornfels and forms distinct layers within the volcanic breccias and several horizons grade laterally into sandstone and breccia. Small ammonites of Early Jurassic age are reported to occur in the siltstone on Ivanhoe Ridge. The Rossland Group rocks are crosscut by north trending Early Tertiary lamprophyre and diorite dykes hosting disseminated pyrite.

The Georgia vein system consists of 12 individual veins and lies within the siltstone near the monzonite contact. Mineralization is part of the eastern extension of the Main vein system, and consists mainly of pyrrhotite, chalcopyrite with minor pyrite in quartz-calcite gangue. The best grades of mineralization were obtained along steeply dipping east-west veins where grades consistently ranged between 5.14 to 8.6 grams per tonne gold. Refer to the Le Roi deposit (82FSW093) for further details on the Rossland camp and the Main vein system.

In 4 years between 1933 and 1939, 49 tonnes of ore yielded 466 grams gold and 653 grams silver.

In 1980, 16 drill holes ranged between an average of 0.034 to 2.6 grams per tonne gold, less than 0.4 grams per tonne silver and 0.005 to 0.02 per cent copper (Assessment Report 7868). In 1982, a 1.2-metre chip sample taken across vein 11, where it was exposed in adit #3, assayed 1.23 grams per tonne gold; a second 1.2 metre sample across barren wallrock assayed: 0.75 grams per tonne gold (Assessment Report 11846).

The Georgia property presently has proven reserves of 48,983 tonnes grading 7.88 grams per tonne gold (George Cross News Letter No.139 (July 20), 1995).

CAPSULE GEOLOGY

The Shawn occurrence is hosted by argillaceous quartzites of the Lower Cambrian Reno Formation. The strata are intruded by granite to granodiorite of the Middle to Late Jurassic Nelson intrusions. Swarms of northeast-trending quartz veins with minor sulphides occur in the quartzites, including several which crosscut the stratigraphy at 320 degrees and at 040 to 050 degrees.

A quartz vein exposed in a trench near an old adit varied in width from 5 to 15 centimetres and contained pyrite, chalcopyrite and galena. A grab sample of the vein assayed 6.84 grams per tonne gold, 25.0 grams per tonne silver and 0.6 per cent lead (Assessment Report 17233, page 18). Within a few hundred metres, other old trenches exposed veins. A grab sample from one such quartz vein graded 28.6 grams per tonne gold, 56.0 grams per tonne silver, 0.5 per cent lead and 0.024 per cent zinc; a 60 centimetre chip sample across this vein yielded 8 grams per tonne gold, 6.4 grams per tonne silver and minor amounts of lead and zinc (Assessment Report 17233, page 16).

CAPSULE GEOLOGY

The Columbia-Kootenay vein system is part of the "Main vein" system which forms a continuous well-defined fracture system on a regional scale. The main vein system trends 070 degrees for a strike length in excess of 1.0 kilometres, consisting of mineralized fracture fillings dipping steeply north. Refer to the Le Roi deposit (082FSW093) for further details on the Rossland mining camp and the Main vein system.

The area of the Columbia-Kootenay vein system is underlain by the Lower Jurassic Rossland Group (Elise Formation) volcanic breccia, conglomerate and sandstone sequence which dips fairly uniformly at moderate angles to the west. Primary sedimentary structures indicate the beds face westwards and only small north trending faults cause minor offsets. The Rossland sill, of the Elise Formation, forms an irregular mass of augite porphyry in the thin-bedded sedimentary and massive volcanic breccias and conglomerates. The sill is difficult to distinguish from the thermally metamorphosed Rossland Group rocks.

CAPSULE GEOLOGY

The Rossland Group is intruded to the south by the Rossland monzonite, an east trending stock comprised of biotite-hornblende-augite monzonite. The contact is gradational and grades northwards into the volcanic conglomerate over a distance of 300 metres. A zone of thermal metamorphism has bleached the well-indurated hornfels of the Rossland Group which contains pyroxene and garnet. To the north, the strata are intruded by the Tail pluton of the Middle to Late Jurassic Nelson Intrusions. A swarm of Tertiary diorite dykes crosscut both the monzonite and Rossland Group rocks.

The mineralized zone trends northeast and dips between 45 to 75 degrees northwest passing through both the Columbia and Kootenay Crown grants. The mineralized zone follows a contact between biotite-bearing monzonite, which forms the hanging wall, and augite porphyry (Rossland sill), which forms the footwall and which the ore appears to have replaced. The ore consist of both massive and disseminated pyrrhotite in a hard, fine-grained gangue with minor chalcopryrite. Arsenopyrite occurs in places with the auriferous pyrrhotite. Much of the ore which is made up sulphides in calcite and altered rock gangue, appears to be laminated. The vein is fairly continuous and varies in width from a few centimetres up to 10 metres of nearly solid pyrrhotite. A nickel sulphur arsenide, gersdorffite, is reported to occur in small octahedral crystals in the sulphide ore and is associated with the massive pyrrhotite and chalcopryrite from the Columbia-Kootenay vein. Also, native bismuth and bismuthinite are associated with minor chalcopryrite. The ore shoots end abruptly against cross structures.

Between 1896 to 1904, 144 tonnes of ore were mined and 68,520 grams of gold recovered.

CAPSULE GEOLOGY

The old workings on the Crown Point and Hidden Treasure claims are located in an area recently mapped as basaltic tuffs of the Rossland Group, Elise Formation (Open File 1991-2). The Lower Jurassic Rossland Group rocks are intruded by the Early Jurassic Rossland monzonite comprised of a biotite-hornblende-augite monzonite stock. The old workings lie within the zone of thermal metamorphism associated with the monzonite intrusion.

The Crown Point ore shoot is reported to occur along the border of a "diorite porphyrite" tongue intrusive into "augite porphyrite" (Geological Survey of Canada Memoir 77, page 163). The diorite porphyrite, later called diorite porphyry, is considered to be an early dyke facies of the Rossland monzonite. The augite porphyrite is probably an augite phyrlic phase of the basaltic tuffs recently mapped in the area. The ore deposit was later crosscut by a north-trending Tertiary pulaskite (syenite) dyke which ranges from 9 to 12 metres in width and hosts disseminated pyrite.

Mineralization consists of massive pyrrhotite and chalcopyrite with pyrite which replaces altered wallrock along a well-defined fracture or fault system. The sulphides occur in a gangue of altered rock with quartz and calcite lenses. The deposit strikes 030 degrees and dips to the north. Mineralization is classed as Rossland-type which is heavy sulphide ore, predominantly pyrite and pyrrhotite with

CAPSULE GEOLOGY

minor chalcopyrite and yields gold and copper.
Between 1905 to 1906, 714 tonnes of ore were mined from which were recovered 9456 grams gold, 6065 grams silver and 3600 kilograms copper.

CAPSULE GEOLOGY

The Lily May mine is underlain by siltstone and hornfelsic siltstone of the Lower Jurassic Elise Formation, Rossland Group. The occurrence is located 400 metres south of the southern edge of the Early Jurassic Rossland Monzonite and lies within the zone of thermal metamorphism associated with the monzonite intrusive. The grey to black siltstone and argillite grades to hornfels. Ammonites of Early Jurassic age were reported to occur in the siltstone on Ivanhoe Ridge.

Mineralization consists of veins, crosscutting the siltstone, hosting pyrite, pyrrhotite, magnetite, chalcopyrite, sphalerite, galena and minor stibnite. The vein system is considered part of the South belt of mineralization in the Rossland Camp. The ore is composed of fine-grained, disseminated, or crudely banded, massive sulphides in a gangue consisting of thoroughly sericitized rock with carbonate and quartz. The gangue consists mainly of quartz with altered wallrock. The deposit strikes 135 degrees, dipping 85 degrees north. Minor magnetite skarns also occur.

In 1910 and 1935, a total of 37 tonnes of ore were mined from the vein system with the resulting recovery of 124 grams of gold, 18,506 grams of silver, 549 kilograms of copper, 407 kilograms of lead and 578 kilograms zinc.

At the Lily May mine, considerable galena occurs in massive form

CAPSULE GEOLOGY

showing cleavage cubes 0.6 centimetres in diameter. The galena is argentiferous and is associated with the sphalerite, chalcopyrite, pyrrhotite and minor stibnite. Boulangerite occurs in the ore. Also, a small amount of galena occurs as narrow bands and irregular masses interstitial to bladed and tabular crystals of boulangerite.

COMMENTS: These are the highest assays reported for silver and gold.

REFERENCE: Minister of Mines Annual Report 1896, page 31.

CAPSULE GEOLOGY

The Curlew workings are hosted by the Lower Jurassic Rossland Group (Elise Formation) augite porphyry, known as the Rossland sill. The porphyry is dark green with phenocrysts of dark augite which are partly altered to hornblende. The Early Jurassic Rossland monzonite stock intrudes the Rossland Group rocks and the Curlew Crown Grant lies within the zone of thermal metamorphism.

The underground workings were initially centred on an ore vein from 15 to 25 centimetres wide. The ore is reported to be similar to that of the Blue Bird (082FSW145) which consists of quartz veins containing pyrite, sphalerite, galena, arsenopyrite, stibnite, chalcopyrite, pyrrhotite and boulangerite. The ore is reported to have given assays from 10 to 17 grams per tonne gold and from 2400 to 2740

CAPSULE GEOLOGY

grams per tonne silver (Minister of Mines Annual Report 1896, page 31).

In 1908, 6 tonnes of ore were mined from a vein which produced 62 grams of gold and 3,608 grams of silver.

CAPSULE GEOLOGY

The Red Eagle workings are hosted by the Lower Jurassic Rossland Group (Elise Formation) augite porphyry, known as the Rossland sill. The porphyry is dark green with phenocrysts of dark augite which are partly altered to hornblende. The rock is commonly brecciated with preferential epidote alteration. The Early Jurassic Rossland monzonite stock intrudes the Rossland Group rocks and the Red Eagle claim lies within the zone of thermal metamorphism.

The mineralogy of the Red Eagle occurrence has not been reported but mineralization is considered a South Belt-type which typically contains pyrite, pyrrhotite, arsenopyrite, galena, sphalerite and locally, boulangerite in a gangue of sericitized wallrock, quartz and carbonate (Bulletin 74, page 39,40). In 1908 and 1927, 7 tonnes of ore were mined from which was recovered 4,603 grams of silver, 60 kilograms of copper, 381 kilograms of lead and 15 kilograms of zinc.

Refer to the Le Roi deposit (082FSW093) for a summary of the Rossland mining camp.

CAPSULE GEOLOGY

The area of the Nature Boy occurrence is apparently underlain by the Early Jurassic Rossland monzonite, a biotite-hornblende-augite monzonite stock which intrudes the Lower Jurassic Rossland Group, Elise Formation. The monzonite is medium-grained, grey to green in colour and hosts magnetite, apatite, some sphene with chlorite, epidote, and pyrite.

In 1949, 3.6 tonnes of ore were mined from surface stripping from which was recovered 1062.8 grams per tonne silver, 85.3 kilograms lead, and 40.8 kilograms zinc.

SAMPLE TYPE: Rock
COMMODITY: Gold
GRADE: 24.0000 Grams per tonne
COMMENTS: The sample was taken from a "small vein" on the Nobus claim.
REFERENCE: Assessment Report 12644.

CAPSULE GEOLOGY

The area of the Ural occurrence is underlain by monzonite of the Early Jurassic Rossland monzonite. The stock is intrusive into rocks of the Lower Jurassic Elise Formation, Rossland Group which occur just south of the showing. The monzonites have been altered, showing chloritization and epidotization. The rocks are traversed by numerous faults. The major regional fault, Violin Lake Fault, traverses the rocks paralleling Cambridge Creek.

Between 1935 and 1936, 8 tonnes of ore were shipped under the name Ural and 218 grams gold and 311 grams silver were recovered. The nature of the deposit and its ore was not reported.

In 1984, a small vein within an old shaft on the Nobus claim, just west of Cambridge Creek was sampled and assayed 24.0 grams per tonne gold (Assessment Report 12644). The sulphide vein infills a shear and is comprised of arsenopyrite, pyrite and minor pyrrhotite in a gangue of altered host rock. Minor lead and zinc mineralization

CAPSULE GEOLOGY

with some silver and gold was reported. The mineralization is compared to the South belt-type of mineralization in the Rossland Camp which contains pyrite, pyrrhotite, arsenopyrite, sphalerite and galena.

CAPSULE GEOLOGY

The area of the Casino Red Cap occurrence is underlain by Lower Jurassic Rossland Group, Elise Formation rocks comprised of altered volcanics and sediments. Intruding the strata are a mass of the Middle to Late Jurassic Nelson Intrusions comprised of granodiorite to quartz diorite and a granitic stock of the Middle Eocene Sheppard Intrusion.

Mineralization occurs in a series of narrow quartz veins along the north dipping contact of the Nelson granodioritic stock and the Rossland sediments to the southeast. The veins have a general north-east strike and dip steeply to the northwest, ranging in widths which average about 35.6 centimetres. Mineralization consists of galena, sphalerite, pyrite and arsenopyrite in a gangue of quartz. The arsenopyrite is auriferous and gold assays from the arsenopyrite range up to 102.9 grams per tonne gold. A total of 5,514 tonnes of ore were mined between 1951 to 1965, and produced: 81,334 grams gold, 23,949 grams silver, 6,009 kilograms lead and 5,982 kilograms zinc.

Mineralized quartz is for the most part confined to the Rossland Group rocks adjacent to the contact. However, some quartz was noted in fractures in the intrusive. Numerous north striking rhyolite dykes were mapped on the surface and underground.

This property is located on the west side of the Columbia River near Casino Creek, about 8 kilometres southeast of Trail.

In 1951 the Casino Red Cap claim was owned by T.P. Voiken & Associates of Trail. The showing was developed by an open cut 2 metres long and 2 metres deep. A crosscut adit, collared 12 metres below the outcrop, was being driven towards the vein.

Nothing more was done with the property until 1957 when Messrs.

CAPSULE GEOLOGY

Wells and Donnelly began development work on a part-time basis. Two drifts 61 metres long and 8 metres apart in elevation were driven on the near vertical vein. A stope 46 metres long and 2 metres wide was mined between the levels. A small amount of cross-cutting was done on the lower level.

In 1961 the W.D. Mining Co. Ltd., consisting of 5 men with equal shares, operated the mine on a part-time basis. During the year 108 metres of diamond drilling was completed.

Casino Gold Mines Ltd. held an option on the property from June to September 1962. A geological survey was made and some development work done on No. 1 level; diamond drilling in 5 holes was done from No. 1 level. The property was then bought by Messrs. Donnelly, Pompu and Ernewin and in October stoping was begun above No. 1 level. During the first half of 1963 about 30 metres of crosscut and 23 metres of raise was completed; stoping was done on No. 1 vein between No. 1 and No. 3 levels.

Columbia River Mines Ltd. was formed in November 1963 to acquire the property and assets of W.D. Mining Co. In 1964 a development program consisting of 625 metres of drifts, raises, and sub-levels was begun on Nos. 1, 2 and 3 veins.

CAPSULE GEOLOGY

The Columbia claim at Waneta "produced" 0.9 tonnes of material which yielded 31 grams of gold, and 93 grams of silver (Minister of Mines Annual Report 1937, page E49). The area is underlain by volcanic and/or sedimentary rocks of the Lower Jurassic Elise Formation, Rossland Group.

No further information is available.

CAPSULE GEOLOGY

The Sunset Crown grant is underlain by the Pennsylvanian to Permian Mount Roberts Formation comprised of interbedded siltstone, argillite, greywacke and limestone units which strike 038 degrees and dip 40 degrees north. These are overlain by rocks of the Lower Jurassic Elise Formation (Rossland Group) comprised of black siltstone, andesitic flows, tuffs, and breccia. The formations are intruded by a Middle Eocene Sheppard leucocratic granite intrusion.

The occurrence consists of discontinuous veins or lenses of quartz which host argentiferous galena, sphalerite, chalcopyrite and minor pyrite in the metasediments of the Mount Roberts Formation. The lenses occur in steeply dipping fractures which strike east-west and vary in width from several centimetres to a few metres. Mineralized intersections occur in shear zones near or within the margins of the granitic intrusive and limestone contact. Hematite in ore from the New Sunset is partially replaced by magnetite.

In 5 years between 1898 and 1964 the mine produced a total 43 tonnes from which 4,448 grams of silver, 373 grams of gold, 1,420 kilograms of lead, 1,940 kilograms of zinc and 99 kilograms of copper were recovered.

CAPSULE GEOLOGY

The Douglas Crown-granted claim is located on the west side of Mount Sophia adjacent to the International Boundary and about 1.6 kilometres south of the Velvet mine from which it is accessible by road.

The earliest development of the Mine was in 1900 and 1901 when some 240 metres of tunnelling was done. No further activity was reported until the period from 1948 to 1950 when the Present owners did some development work and made a small shipment of ore.

The workings consist of 3 adits at elevations of approximately 1204, 1237 and 1274 metres. In 1949, when the property was examined by Little, the middle adit was caved and the upper adit accessible for only a short distance.

The Douglas Crown grant is underlain by coarse conglomerate of the Upper Cretaceous Sophie Mountain Formation in which lenticular beds of coarse-grained faintly stratified sandstone and argillite strike 340 degrees and dip 70 degrees northeast. The conglomerate is cut by several dykes of the Middle Eocene Coryell Intrusions comprised of pink to greenish porphyritic syenite as well as sheared lamprophyre dykes exposed in the underground workings.

CAPSULE GEOLOGY

A shear zone, striking 120 degrees and dipping 70 degrees northeast, exists along the contact between the conglomerate and syenite. The shear zone is approximately 3.0 metres wide and hosts individual mineralized lenses and veins of quartz ranging up to 0.3 metre in width. They occur in irregular intervals along the lower tunnel of the 230-metre long underground workings. The quartz veins are locally fractured, and the fractures filled with altered wallrock. Pyrite is the most abundant mineral with occasional concentrations of galena, sphalerite and chalcopyrite.

In 1948 and 1950, a total of 9 tonnes of quartz-rich ore was shipped and produced 591 grams silver, 592 kilograms lead, and 479 kilograms zinc.

CAPSULE GEOLOGY

The Velvet occurrence is underlain by Paleozoic serpentinite which forms a huge roof pendant surrounded by syenite of the Middle Eocene Coryell Intrusions. Within the serpentinite are large xenoliths of Rossland Group volcanic rocks, particularly on the Portland claim. The rocks within the pendant are cut by dykes up to 6.0 metres wide, commonly of porphyritic syenite and of medium-grained granodiorite. These dykes are related to the Coryell and Middle to Late Jurassic Nelson intrusions respectively, and in general are parallel with the main shears.

The origin of the copper, gold, silver veins at the Velvet Mine is not well understood. They may be mesothermal structures related to middle Jurassic thrust faults marginal to ophiolitic lithologies; it may be a skarn; it may be that the veins are related to the Middle Eocene Coryell Intrusions (EMPR Bulletin 109, page 48).

The mineralization occurs in replacement veins that strike north and dip steeply to the west. Besides the main or Velvet vein, four other veins are known to exist in its footwall some 18, 40, 58 and 98 metres to the east, respectively. A few small, relatively short east-west striking veins cut the main vein. Ore shoots occur at intersections of the main vein with crosscutting dykes or faults. Mineralization includes specularite, pyrite, chalcopyrite and malachite in a gangue of quartz and calcite. Molybdenite also occurs

CAPSULE GEOLOGY

locally in a gangue of quartz and altered wallrock. Chalcopyrite mineralization is described as typically massive where it occurs along the walls of the ore shoots. Small amounts of scheelite have been seen in the dump and underground workings. As well, lead and zinc were recovered from minor occurrences of galena and sphalerite.

From 1901 to 1964, 88,833 tonnes of ore produced 620,785 grams gold, 664,359 grams silver, 1,154,104 kilograms copper, 37 kilograms lead, and 25 kilograms zinc. In 1982, it was reported that 907 tonnes of ore grading 5.4 grams per tonne gold with other commodities was shipped to the HB mill (082FSW004) of David Minerals Ltd.

The Velvet and Portland Crown-granted claims and several others held by record lie on the northwest slope of Mount Sophia at about 1097 metres elevation. The mine is about 13 kilometres directly southwest of Rossland and 2 kilometres north of the International Boundary.

In April 1896 J. Cromie located the Portland claim and in September of the same year O. Geldness located the Velvet. The two claims were developed separately until 1904. The Velvet claim was acquired in 1897 by Velvet Mines Ltd. and they carried on development work until Velvet-Portland Mines Ltd. was formed in 1904 to acquire both properties. The mine was operated intermittently by the company or by leasers until it was closed in 1916. Granby Consolidated Mining, Smelting & Producing Co. examined the workings in 1918 and subsequently relinquished their option.

Rossland-Velvet Mines Ltd. took over the property in 1920 and intermittent work was carried on by the company or by leasers until 1928 when the mine closed. Velvet Gold Mining Co. Ltd., formed in the fall of 1932 reopened the mine and operated it intermittently until the fall of 1937.

Velgo Mining Incorporated took over the property in 1938 and later in the year leased it to R. Bielli & Associates who subsequently formed the Velvet Leasing Syndicate; the syndicate name was changed in 1941 to Velvet Gold Leasers. The leasers operated until 1942 when the mine was closed. The mine remained closed until 1952 except for a brief period in 1946 when Velvet Gold-Copper Mines Incorporated acquired the property and leased it to J. Coryell, Jr. A diamond drilling program was carried out at this time consisting of 7 holes totalling 438 metres from No. 8 level and 4 holes totalling 172 metres from the surface.

In 1952 the property was acquired by Messrs. Kenward and Sweet. Leasers began mining operations and in 1953 built a small mill. Mid-West Copper & Uranium Mines Ltd. acquired the property in 1955 and intermittent operations were carried on by the company or by leasers. A new mill was built and put into operation in 1956. In October 1964 the company was reorganized under the name Mid-West Mines Ltd. The property is developed by a vertical shaft serving 6 levels, of which No. 4 and No. 6 are accessible from the surface by adits. A 527-metre long adit on No. 8 level is connected to No. 6 level by a raise. Around 1978, Velvet Exploration Co. Ltd. (formerly Kendal Mining and Exploration Company Limited) acquired the mine. In 1980, they carried out 914.4 metres of drilling of which 244 metres was diamond drilling, the rest was percussion. In August 1982 it was reported that 1,000 tons grading 5.48 grams per tonne gold and other commodities were shipped to the H.B. mill of David Minerals Ltd. in Salmo.

ROY

STATUS: Prospect
REGIONS: British Columbia
NTS MAP: 082F04W
BC MAP:

MINING DIVISION: Trail Creek
UTM ZONE: 11 (NAD 83)

LATITUDE: 49 12 20 N
LONGITUDE: 117 46 44 W
ELEVATION: 1630 Metres

NORTHING: 5450599
EASTING: 443265

LOCATION ACCURACY: Within 500M

COMMENTS: Located about 13.0 kilometres north of Trail on the rounded summit of the divide between Murphy and Sullivan creeks. (Not to be confused with the Lord Roberts (L. 12606) of the Union mine 082FSW164).

COMMODITIES: Magnetite Iron Copper Silver Bismuth

MINERALS

SIGNIFICANT: Magnetite Pyrrhotite Pyrite Chalcopyrite
COMMENTS: Possible bismuthinite.
ASSOCIATED: Hornblende Feldspar Quartz
ALTERATION: Garnet Epidote Feldspar
ALTERATION TYPE: Skarn
MINERALIZATION AGE: Unknown

DEPOSIT

CHARACTER: Massive Disseminated
CLASSIFICATION: Igneous-contact Skarn Industrial Min.
TYPE: K03 Fe skarn K01 Cu skarn
DIMENSION: 10 Metres STRIKE/DIP: TREND/PLUNGE:
COMMENTS: Massive magnetite is up to 10 metres wide.

INVENTORY

ORE ZONE: SAMPLE REPORT ON: N
CATEGORY: Assay/analysis YEAR: 1920
SAMPLE TYPE: Rock
COMMODITY GRADE
Iron 54.0000 Per cent

COMMENTS: A sample of the best grade of magnetite assayed 54 per cent iron and 2.69 per cent sulphur.

REFERENCE: Minister of Mines Annual Report 1920.

CAPSULE GEOLOGY

On the Lord Roberts prospect a number of shallow open cuts have exposed a body of magnetite which varies in grade and apparently follows the somewhat irregular contact between rocks of the Middle to Late Jurassic Nelson Intrusions and sediments of the Pennsylvanian to Permian Mount Roberts Formation. The Mount Roberts Formation rocks consist of interbedded siltstone, quartzite, greywacke, slate, pebble conglomerate and limestone. They are intruded by a stock comprised of granodiorite to quartz diorite.

The massive blue-grey magnetite (occurring on the Lord Roberts

CAPSULE GEOLOGY

claim) ranges up to about 10 metres in width and hosts disseminated pyrite, pyrrhotite and chalcopyrite. In 1920, a sample of the best grade of magnetite assayed: iron, 54 per cent; phosphorus, nil; and sulphur, 2.69 per cent (Minister of Mines Annual Report 1920, page 137). A sample of the magnetite with disseminated chalcopyrite and pyrrhotite was assayed for copper, and gave negative results. Hornblende, epidote, garnet, feldspar and quartz were detected in the bluish magnetite. Magnetite and pyrite are abundant near the footwall and pyrrhotite and chalcopyrite near the hanging wall. In the lowest shaft, exposed magnetite hosts pyrrhotite, pyrite, bismuthinite(?) and chalcopyrite in a quartz-hornblende-feldspar gangue.

In 1924, 7 tonnes of ore were shipped which produced 187 grams of silver and 22 kilograms of copper.

CAPSULE GEOLOGY

shear zone. Small tonnages were shipped in 1937, 1946, and 1952 for a total of 31.74 tonnes containing approximately 187 grams gold, 37.9 kilograms silver, 4.8 kilograms lead, and 2558 kilograms zinc.

In 1967, Thorpe examined the mineralogy of the outer zone deposits in the Rossland area. The Union mine is considered part of the outer zone of mineralization and hosts arsenopyrite, pyrite, sphalerite and galena. Additional minerals in this deposit include boulangerite, ruby silver and native bismuth.

In 1983, samples were collected from the old Union workings. A sample of quartzite hosting disseminated galena was taken from pyritic mineralization along a north trending carbonaceous shear that contains epidote and rich quartz veining. The sample assayed 3.22 grams per tonne gold, 1310.0 grams per tonne silver, 6.0 per cent lead, 13.2 per cent zinc, and 0.11 per cent copper (Assessment Report 11618).

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The Nest Egg showing is considered to be Rossland-type mineralization, with sulphides infilling well-defined fractures and faults in the Early Jurassic Rossland monzonite. The host rock is comprised of a biotite-hornblende-augite monzonite stock which is medium-grained, grey to green in colour and hosts magnetite, apatite, some sphene with chlorite, epidote, pyrite and pyrrhotite.

The showing is a vein which strikes east-west and hosts pyrite, pyrrhotite and chalcopyrite with quartz-carbonate gangue. Over 72 tonnes of ore containing values in copper and gold were shipped from the Nest Egg in 1907, 1908 and 1934. Values in silver are also reported.

Samples taken as part of Ph.D. thesis were reported to contain only arsenopyrite, hematite, pyrite and appreciable magnetite (Thorpe, 1967, pages 18 and 32).

CAPSULE GEOLOGY

The Venus and Juno mines are located 4.4 kilometres southwest of Nelson. The two mines combined produced 5411 tonnes in the early 1900's and again in the 1930's. All workings, except the Juno adit, are caved in.

The area is underlain by augite basalt flows, flow breccias and subvolcanic intrusions of the Lower Jurassic Elise Formation (unit Je4), Rossland Group. These have been intruded by granodiorite of the Middle to Late Jurassic Nelson Intrusions. Veins, and stringers up to 1 metre wide, occupy shear zones in schistose volcanics and granodiorite.

The Venus vein strikes 320 to 335 degrees, dips 20 to 50 degrees north and is hosted in both volcanic rocks and granodiorite. The vein, associated with a basic dyke in the lowest adit, has not been traced beyond a fault or downdip from the lowest workings. The vein closely follows the granite-schistose volcanics contact.

The Juno vein, hosted in schistose volcanics, strikes 060 degrees and dips 55 to 60 degrees north, almost at right angles to the Venus vein. The vein was not explored for more than 200 metres on strike or 100 metres downdip.

The veins comprise quartz mineralized with pyrite and minor galena and sphalerite. The veins vary from a few centimetres to over 1 metre in width and locally occur as a number of quartz stringers in sheared host rock. The records indicate the veins tend to be less definite away from the granite contact and the schists become more faulted and brecciated. The two veins should intersect but the junction has not been located in any of the workings.

CAPSULE GEOLOGY

Production records indicate an average grade of 19.8 grams per tonne gold and 17.7 grams per tonne silver, with minor copper and lead reported.

METAMORPHIC TYPE: Contact RELATIONSHIP: GRADE: Hornfels

CAPSULE GEOLOGY

The SDR showings are located just south of the contact between the Lower Jurassic Rossland Group (Elise Formation) volcanics and the Early Jurassic Rossland monzonite stock. The Elise Formation in this area has recently been mapped as argillaceous siltstone (Unit Je10a, Open File 1991-2).

A zone about 150 metres by 150 metres contains rocks that have been contact metamorphosed and host abundant magnetite and epidote. A sample taken in 1947 across 46 centimetres of "magnetite vein" assayed 1.37 grams per tonne gold, 0.27 per cent zinc and trace silver and lead (Assessment Report 24, Sheet 2). In 1981, a grab sample taken from the highly altered rock assayed 1.03 grams per tonne gold, 1.03 grams per tonne silver, 0.16 per cent copper, 0.01 per cent lead and less than 0.01 per cent zinc (Assessment Report 9827). Associated with the contact zone is a highly siliceous zone which hosts quartz veinlets with chalcopyrite and arsenopyrite.

In 1988, the zone was trenched in an east direction for about 75 metres. Within the trenched area, the mineralization consists of a central core of massive arsenopyrite, flanked by a much broader zone of massive magnetite, pyrite, pyrrhotite and minor chalcopyrite. Alteration minerals observed here were epidote, calcite, hornblende, garnet, muscovite, and graphite. One trench sample site exhibiting strong silicification assayed 17.62 grams per tonne gold across 2 metres.

CAPSULE GEOLOGY

kilometres southwest of Nelson. The vein was initially discovered in 1896.

The area is underlain by schistose augite basalt flows and flow breccias of the Lower Jurassic Elise Formation (unit Je4) of the Rossland Group, these are in contact with a granodiorite stock of the Middle to Late Jurassic Nelson Intrusions and have been intruded by feldspar porphyry of the Jurassic Silver King Intrusions.

The Athabasca vein strikes at 045 degrees with a 30 to 50 degree northwest dip. The vein is hosted within granodiorite and tends to flatten as it traverses the schistose volcanics to the south. The vein comprises quartz gangue mineralized with pyrite, some galena, sphalerite and free gold. The gold occurs as 80 per cent free gold and 20 per cent is associated with sphalerite. The vein is a few centimetres to about 1.5 metres wide, averaging about 0.3 metres.

The workings were developed where the vein crosses the granodiorite-volcanic fault contact. Pervasive shearing and faulting have offset and displaced portions of the vein. Scheelite occurs near the lithologic contact.

An enrichment of metal values occurs within the schistose volcanics at the granodiorite contact. The flatter sections of the vein, in the schist, were productive but here the vein is highly faulted and folded with dykes common on the planes of the normal faults.

A weighted average of 27 samples taken in 1988 was 22.29 grams per tonne gold (Assessment Report 17184). Up to 18,144 tonnes of material grading 8.579 grams per tonne gold may exist at the old mill site (Assessment Report 17184).

INVENTORY

ORE ZONE: VEIN REPORT ON: N
CATEGORY: Assay/analysis YEAR: 1987
SAMPLE TYPE: Channel
COMMODITY Gold GRADE 73.0500 Grams per tonne
COMMENTS: Sample (CAFS-2) of California veins from No. 2 level.
REFERENCE: Property File - Christina Explorations Ltd., Prospectus, May 12, 1988.

ORE ZONE: CALIFORNIA REPORT ON: Y
CATEGORY: Inferred YEAR: 1982
QUANTITY: 36000 Tonnes
COMMODITY Gold GRADE 29.1400 Grams per tonne
COMMENTS: At the west end of the No. 3 level. A potential tonnage of an ore
block 91 metres long over 1 metre width.
REFERENCE: Assessment Report 11027.

CAPSULE GEOLOGY

The California deposit is located 4 kilometres south of Nelson. The vein has been developed on 3 levels by 650 metres of drifts, producing 1,462 tonnes from 1910 to 1949.

The area is underlain by schistose volcanics comprising augite basalt flows and flow breccias of the Lower Jurassic Elise Formation, Rossland Group. These have been intruded by plagioclase porphyry of the Jurassic Silver King Intrusions and granodiorite and quartz monzonite of the Middle to Late Jurassic Nelson Intrusions.

The California occurrence comprises the California vein, the Deadwood vein, the Union vein, the Creek showing, the Cabin vein and the Exchequer vein.

The California vein is hosted in andesite near the granodiorite contact in a shear zone which strikes east and dips 45 to 50 degrees south. The shear zone is up to 30 metres wide and hosts two parallel quartz veins with graphitic andesite between them. The vein on the hanging wall, 0.5 to 1.0 metre wide, contains the best sulphide mineralization and the footwall vein, rarely more than 0.3 metre wide, hosts higher gold values. The veins touch or can be separated by up to 2 metres of altered rock. Mineralization consists of quartz gangue containing significant pyrite with some galena, sphalerite, and free gold. The quartz veins are strongly sheared with graphitic material on fracture and shear planes. The contacts with the country rocks are heavily slickensided. Some enrichment of metal values was observed where normal faults crosscut the vein-shear zone. Faulting, with movement of up to 1.2 metres, has been observed in the workings. A channel sample taken (CAFS-2) from level No. 2, in 1987, across parallel well mineralized quartz veins, 5 to 15 centimetres wide, and hosting sphalerite, chalcopyrite and possibly tetrahedrite in narrow bands and as patches or disseminated grains assayed 73.05 grams per tonne gold (Property File - Christina Explorations Ltd., Prospectus, May 12, 1988). An ore block, 91 metres long grading 29.14 grams per tonne gold over a 1 metre width, is believed to exist at the west end of the No. 3 level. A potential tonnage of 36,000 tonnes has been calculated for this zone (Assessment Report 11027).

The parallel Deadwood vein, which outcrops to the southeast of the California vein, comprises a zone of numerous quartz stringers and veinlets hosted in a shear zone. The zone is approximately 75 metres wide in pyritized and carbonate altered tuffaceous volcanics. Reports indicate significant but erratic gold values were present.

The Union vein, several hundred metres north of California vein, is hosted in granodiorite. The vein dips at 15 degrees toward the volcanic contact and appears to be a tension feature. The vein, 0.3 to 0.8 metre wide, consists of white quartz hosting sparsely disseminated pyrite and sphalerite, similar to the California vein. Samples from the stope area have assayed up to 13 grams per tonne gold and 222.82 grams per tonne silver over a 0.3 metre width (Property File - Christina Explorations Ltd., Prospectus, May 12, 1988). Samples taken in 1987 assayed between 0.41 to 4.5 grams per tonne gold with minor silver values (Property File - Christina Explorations Ltd., Prospectus, May 12, 1988).

The Cabin vein, Exchequer vein and Creek showing occur roughly along strike of the California vein. Sampling of the Cabin vein, 300 metres east of the California vein, assayed 8.98 to 26.43 grams per tonne gold across 1 metre (Property File - Christina Explorations Ltd., Prospectus, May 12, 1988). Sampling of the Exchequer vein, 50 metres west of workings, assayed up to 53.58 grams per tonne gold (1988). The Creek showing, 400 metres east of the California vein, assayed 2.88 grams per tonne gold and 375.02 grams per tonne silver across 1.3 metres (Assessment Report 11027).

CAPSULE GEOLOGY

The Shamrock occurrence is located approximately 5 kilometres southwest of Nelson. Minor production has been reported for this claim.

The area is underlain by augite basalt flows, breccia flows and subvolcanic intrusions of the Lower Jurassic Elise Formation, Rossland Group. These have been intruded by plagioclase porphyry of the Late (?) to Middle Jurassic Silver King Porphyry.

No geological description is available but a total of 7.7 tonnes of ore grade material was shipped in 1937 and 1948, which yielded some silver, lead, zinc, and minor gold. This occurrence is likely similar in setting to the Silver King deposit (082FSW176).

CAPSULE GEOLOGY

The Irene occurrence is located 5.5 kilometres south of Nelson. Minor production is recorded from this claim. The claim is now part of the Great Western group claims (082FSW333).

The area is underlain by augite basalt flows, breccia flows and subvolcanic intrusions of the Lower Jurassic Elise Formation, Rossland Group. These have been intruded by plagioclase porphyry of the Late (?) to Middle Jurassic Silver King Porphyry. Shearing and metamorphism is common in the area. Regionally, schists are host to northwest trending shears, parallel to foliation, which host quartz veins with sulphides.

No geological description of the occurrence is available, though it is likely similar to the Silver King occurrence (082FSW176).

It is recorded that 15 tonnes of ore material was shipped in 1939 which produced 274 grams of gold and 377 grams of silver. In 1945, trenching and surface stripping was done on "mineralized shears". No other work is recorded.

CAPSULE GEOLOGY

The Victoria-Jessie occurrence is located on Toad Mountain, 12.8 kilometres south of Nelson. Production is recorded from this property, Crown granted in 1894-95, in 1907 and again in the 1940's.

The area is underlain by sheared, schistose augite basalt flows, breccia flows and subvolcanic intrusions of the Lower Jurassic Elise Formation, Rossland Group. These have been intruded by plagioclase porphyry of the Late (?) to Middle Jurassic Silver King Porphyry. Shearing (Silver King shear) and metamorphism is prevalent in the area. Regionally, schists are host to northwest trending shears, parallel to foliation, which host quartz veins with sulphides.

A drift exposes a wide zone of alternating schist with quartz stringers and lenses in northwest trending shears or east-west cross fractures. Mineralization comprises iron sulphides, in this area commonly pyrite, chalcopyrite, and galena, which also occur in the host rock. The mineralized zones follow zones of shearing and are conformable with the host rock which strikes 115 degrees and dips 50 degrees south.

Production totalled 3255 tonnes of material which yielded 3.79 kilograms of gold, 94.12 kilograms of silver and 83,577 kilograms of copper.

No other information is available.

CAPSULE GEOLOGY

The Starlight occurrence is located on Toad Mountain, about 12 kilometres south of Nelson. Minor production is recorded for this claim in 1937 (the 1981 figures are questionable). The claim adjoins the Victoria-Jessie property (082FSW173) to the south.

The area is underlain by sheared schistose augite basalt flows, breccia flows and subvolcanic intrusions of the Lower Jurassic Elise Formation (unit Jel and Je4, Open File 1989-11), Rossland Group. These are intruded by plagioclase porphyry of the Late (?) to Middle Jurassic Silver King Porphyry. Shearing (Silver King shear) and metamorphism is prevalent in the area. Regionally, schists are host to northwest trending shears, parallel to foliation, which host quartz veins with sulphides.

A quartz vein up to 1.53 metres wide, within schists and volcanics contains disseminated and massive pyrite. Locally the zone is characterized by numerous quartz stringers and lenses.

The Starlight vein produced 10.8 tonnes which yielded 583 grams of gold, 2936 grams of silver and 200 kilograms of copper. Free gold is contained in the vein material.

CAPSULE GEOLOGY

The Daylight-Berlin showing is located 14.4 kilometres south of Nelson, just northeast of the Silver King mine (082FSW176). The claims were explored by shafts, adits and several pits or trenches at the turn of century. Production commenced in 1937, when the old workings were rehabilitated, and continued intermittently until 1949.

The area is underlain by sheared and highly schistose augite basalt flows, breccia flows and subvolcanic intrusions of the Lower Jurassic Elise Formation (unit Je1 and Je4), Rossland Group (Open File 1989-11). These have been intruded by plagioclase porphyry of the Late (?) to Middle Jurassic Silver King Porphyry. Shearing (Silver King shear) and metamorphism is prevalent in the area. Regionally, schists are host to northwest trending shears, parallel to foliation, which host quartz veins with sulphides.

Sericite schist and foliated greenstone host a number of quartz-carbonate veins and lenses which contain chlorite, sericite, epidote and a few needles of tourmaline. These generally follow the foliation which is roughly parallel to the orientation of the schists, striking 305 degrees and dipping 45 to 55 degrees south. Small masses of chalcopyrite, pyrite, and/or tetrahedrite are commonly found in quartz or intensely silicified schists. Shearing, in zones up to 0.91 metre wide, strikes 340 degrees, dips 45 degrees west and hosts small lenses of rusty quartz carbonate material. Veins are 0.10 to 0.25 metre wide.

Ore material consisted of either quartz vein material or highly silicified schists with finely disseminated pyrite and chalcopyrite.

CAPSULE GEOLOGY

Traces of tetrahedrite and pyrrhotite are recorded. Microscopic studies showed that some of the pyrite contains minute inclusions of pyrrhotite and the gold was observed in the form of grains and stringers in gangue near pyrite and at the contact of pyrite with gangue.

Production is recorded as totalling 327 tonnes with a grade of 27 grams per tonne gold and 15 grams per tonne silver. Also recovered were, 70 kilograms of lead and 68 kilograms of zinc.

CAPSULE GEOLOGY

silver, 0.5 gram per tonne gold and 3.2 per cent copper.

First discovered by the Hall brothers in 1886, the Silver King mine produced incredibly rich silver-copper ore and gained fame in Canada, U.S.A. and Britain. In 1893 the Halls sold out to British interests who formed Hall Mines Co. The company constructed a smelter in Nelson and built a tramline to the Silver King. In 1900 the mine closed in response to lower silver prices, the new American import tariffs on metals, and the inability to locate more high grade ore with the existing exploration technology. Cominco acquired the property but their attempt to explore and re-open the mine was thwarted by World War I. Production from 1889 to 1958 totalled 202,049 tonnes yielding 138,214,612 grams of silver, 8,896 grams of gold, 6,789,739 kilograms of copper, 15,234 kilograms of lead and 4,071 kilograms of zinc.

The mine was dormant until 1965 when a Vancouver company began an exploration program. Surface drilling and underground sampling discovered a modest tonnage of proven and probable ore. The property was examined in 1973 with geophysics and geochemistry. Three anomalies were discovered, some indicating buried mineralization with similar orientation to the original orebodies. Exploration occurred in 1983 and resource calculations were reported.

Amulet Resources Ltd. was incorporated in 1998, optioned the property and plan drilling.

The property is located at about 1676 metres elevation on Toad Mountains 6.4 kilometres south of Nelson.

The showings were discovered by the Hall Brothers in the fall of 1886 while prospecting for placer gold. Three claims were staked, the Kootenay Bonanza, Silver Kings and American Flag (Lots 140-142, respectively), and these were Crown-granted in 1890. Development work was carried out under the name "Kootenay Bonanza Co.". The first high-grade ore was shipped in 1889.

The Hall Mines Limited, of London, England, purchased the property in 1893. A mine development program was begun and a 7.2 kilometre tramway was built to Nelson, where the company opened a 100 ton-per-day smelter in January 1896. Smelter capacity was increased to 300 tons-per-day in 1897. The company was reorganized in 1900 under the name Hall Mining and Smelting Company, Limited. The company shut down the mining operation in 1902 and subsequently leased the mine to a former company superintendent) M.S. Davys, who resumed mining operations. In 1904 the company resumed work under a partnership arrangement with Mr. Davys; the partnership terminated in 1906. Both mine and smelter closed in September 1907.

The property was leased in 1908 to the Kootenay Development Syndicate, Limited, of London, England, with M.S. Davys as Managing Director. The mine closed in June 1910. To that date the mine had been developed by opencuts, four adits (Nos. 1, 3, 4, and 5), with a main shaft from the level of No. 5 to the 10th level, giving a total vertical depth on the lode of 283 metres. From No. 8 level to the surface the several levels are connected by stopes and raises. The main lode had been stoped from the surface to the sill of No. 5 level, and the south lode from No. 5 to the level of No. 8.

The Dandy claim, adjoining the Silver King group on the northwest, was staked in about 1887 and Crown-granted to Messrs. Fox, Kelly, and Cook in 1891; the Crown-grant was listed, apparently in error, as Lot 141, same as the Silver King. Development work to 1893 included a 12-metre shaft see and a 5-metre long adit. Owner A.H. Kelly reportedly shipped 600 tons of ore in 1899. The Dandy and Ollie Consolidated Mines) Limited, was incorporated in 1903 but no work was reported.

In the Fall of 1910 (Pacific coast interests) through R.S. Lennie, merged some 40 claims on Toad Mountain, formerly held by Hall Mining, The Dandy and Ollie Consolidated Mines, Starlight Mines, Limited Kootenay Development Syndicate, Limited, and by several individuals. Kootenay Bonanza Mines, Limited, was incorporated in January 1912 to hold the property.

The Consolidated Mining and Smelting Company of Canada (Limited) purchased a controlling interest in the property and Silver King Mines Limited was incorporated in December 1912 as the operating company. The Dandy adit was extended some 732 metres to intersect the Silver King shaft 12 metres above No. 8 level; other development work and about 1524 metres of diamond drilling was carried out. Development work was suspended in the Fall of 1914 but resumed in 1916 under contract. Small scale development work and diamond drilling continued until October 1919 when the mine closed. The Silver King Mines, Limited charter was surrendered in 1927.

Lessees carried out small scale intermittent mining operations in 1936, 1946 to 1949, 1956, and 1958.

Now Cronin Babine Mines Limited, by an agreement of February 1965 with The Consolidated Mining and Smelting Company of Canada

CAPSULE GEOLOGY

Limited (changed to Cominco Ltd. in 1966), acquired an option to earn a 75 per cent interest in the property through an exploration expenditure of 9200,000. A private company, Silver King Mines Ltd., was incorporated in 1967 to hold the 24 Crown-grant and 6 recorded claims.

Work by Now Cronin during 1965-1967 included surface diamond drilling totalling 3715 metres in more than 54 holes. This work indicated proven reserves of 82,400 tons averaging 291.4 grams per tonne silver, 2.1 per cent copper, and 1.0 per cent lead.

The company name (New Cronin) was changed in 1973 to Sproatt Silver Mines Ltd. The option was exercised in 1973 and the claims transferred to Silver King Mines Ltd. Work during the year included a time domain induced potential survey over 11 line-miles and a geochemical soil survey comprising 200 samples. In past work diamond drilling has established a proven 82,700 tons averaging 294.8 grams per tonne silver, 0.9 per cent lead, and 2.0 per cent copper (Sproatt Silver Mines Ltd. Statement of Material Facts, Nov. 7, 1975).

The company name (Sproatt) was changed in 1977 to Hecate Gold Corp. In June 1982 the company was amalgamated with Host Ventures Ltd. under the latter name. Work in 1983, including trenching, diamond drilling 566 metres in 10 holes and dump sampling was financed by the company, thereby increasing its interest in Silver King Mines Ltd to 90 per cent (Cominco Ltd.). The company name (Host Ventures) was changed in 1984 to Hot Resources Ltd, and in 1985 to Inter-Globe Resources Ltd.

CAPSULE GEOLOGY

The Referendum workings are located approximately 11 kilometres southwest of Nelson. The claim was located in 1900 and minor gold production came from a shallow shaft. The Tec Gold showing (082FSW324) is just to the southeast. The veins are hosted by andesites of the Lower Jurassic Rossland

CAPSULE GEOLOGY

Group Elise Formation. In the Referendum mine area, zones of alternating sedimentary, metamorphic and volcanic rocks are present. The rocks include agglomerates, conglomerates with boudinage texture, tuffs and crystal tuffs with metamorphic rocks comprised of sericite schist and chlorite schist. The volcanic rocks in the mine area are andesites and basalts intruded by lamprophyre dykes which host tension veins with tourmaline and ilmenite. Some tension veins are quartz-calcite filled, others only host quartz. To the southeast of the mine area, an Eocene Coryell syenite intrudes the Rossland Group rocks. Just to the west, a stock of the Middle to Late Jurassic Nelson Intrusions is present.

The showing consists of a quartz vein about 0.35 to 0.60 metre wide, striking 305 degrees with a steep to vertical dip. No sulphides are documented but a gouge-like, black material forms a thin veneer on shear partings and often fills fractures. The main vein has abundant massive, fine-grained tourmaline. As well, the small tension veins which join the main vein also host tourmaline. A chip sample taken across 0.35 metre of the quartz vein in 1981 assayed 0.07 gram per tonne gold (Assessment Report 10239).

Gold was reportedly recovered in the early 1900's and gold and silver values were recovered from about 181.4 tonnes mined in 1984-85. Between 1983 and 1985, 159 tonnes of ore were milled and produced 573 grams gold, 1839 grams silver, 190 kilograms lead, and 229 kilograms zinc.

CAPSULE GEOLOGY

The Northern Light showing is located near a small tributary of Fortynine Creek, 10.5 kilometres southwest of Nelson. Minor production is recorded for the claim in 1907.

The area is underlain by schistose volcanics comprising tuffs, lapilli tuff (unit Je8l, Open File 1989-11), basalt flows and flow breccias (unit Je4) of the Lower Jurassic Elise Formation (Rossland Group). These have been intruded by granodiorite and quartz monzonite of the Middle to Late Jurassic Nelson Intrusions.

The occurrence has been described, along with the Gold Hill (082FSW092) and Gold King (082FSW181), as "fissure filled lodes containing gangue minerals, mainly quartz and maybe some carbonates with little or no disseminated sulphides in wallrock... where host rocks are massive andesite and augite porphyry or brittle argillaceous quartzite" (Geological Survey of Canada Memoir 308).

The workings, consisting of a tunnel, a shallow shaft and open cuts, are between 1525 and 1600 metres elevation. The upper workings expose a quartz vein 0.6 to 1.2 metres wide hosted in schist and mineralized with "iron oxides" and "copper carbonate stains".

A sample from the shaft dump assayed 30.51 grams per tonne gold, 34.28 grams per tonne silver and 0.16 per cent copper (Minister of Mines Annual Report 1928, page 323).

Insufficient work has been done to evaluate the potential of the vein. Production totalling 31 tonnes is reported for 1907, yielding

CAPSULE GEOLOGY

62 grams of gold, 1835 grams of silver and 124 kilograms of copper.

CAPSULE GEOLOGY

Formation and volcanic rocks of the Elise Formation, both of the Lower Jurassic Rossland Group. These have been intruded by Middle to Late Jurassic Nelson Intrusions. The Red Mountain fault crosscuts the area. Lithologies consist of argillite, siltstone, andesite tuff, lapilli tuff, granodiorite and quartz monzonite.

North striking quartz veins, up to 1 metre wide, crosscut granodiorite and tuff. Mineralization consists of pods and disseminations of pyrite, galena, sphalerite, chalcopyrite and, locally in the main vein, visible gold. Veins in the vicinity of the main workings are often associated with a limonite cap which is reported to contain visible gold. Gold values are apparently related to pyrite content. Quartz filled fractures in aplite dykes also carry small amounts of sulphides. The pockets, or lenses, of sulphides in the vein are typically highly oxidized in the exposures near surface. Breccia occurs in the footwall of the ore shoot that was mined. The Red Mountain fault occurs immediately to the west of, or in, the workings.

Production totals 104 tonnes of hand selected ore yielding 3951 grams of gold, 4385 grams of silver, 2028 kilograms lead and 1082 kilograms zinc. Chip sampling indicates values of up to 6 grams per tonne gold, locally, and samples taken in the area have assayed up to 2.16 per cent copper (Assessment Report 18188).

CAPSULE GEOLOGY

The section of the Celtic Queen and Trilby claims where the showings are located are underlain by green volcanic conglomerate, breccia and sandstone of the Lower Jurassic Elise Formation (Rossland Group) (Assessment Report 16751, Map 2). Within about 50 metres to the north is the contact with the Early Jurassic Rossland monzonite, an east trending stock with a wide thermal aureole and, locally, a gradational contact with the country rocks.

An east trending fissure carrying mixed sulphides is exposed in a shaft and a number of cuts for a length of up to 60 metres. At the surface the vein is from 0.3 to 0.6 metres wide but widens to 1.2

CAPSULE GEOLOGY

The Gold King occurrence is located on the south side of Hall Creek, 11 kilometres south-southwest of Nelson. The occurrence is exposed in an old tunnel. Similar mineralization occurs to the north at the Independence showing (082FSW372).

The area is underlain by volcanic rocks of the Lower Jurassic Elise Formation (unit Je1, Open File 1989-11), Rossland Group which have been intruded by granite of the Middle to Late Jurassic Nelson Intrusions. The volcanics consists of dark green augite porphyry, porphyry flow breccias, agglomerates, minor crystalline tuffs and porphyry dykes.

Sheared quartz veins and stringers, from 0.01 to 1.5 metres wide and 2 to 50 metres long, strike 030 degrees and dip 80 degrees northwest. Vein emplacement appears to be controlled by two major trends (northwest and northeast) of joints, faults and shears. Pyrite is the major ore mineral with lesser amounts of pyrrhotite, chalcopyrite, bornite, tetrahedrite and free gold. Gangue minerals are usually quartz with minor carbonate, epidote and chlorite. Locally, the wall rocks may carry disseminated pyrite which also contain gold values. Pyrite is more abundant than pyrrhotite.

CAPSULE GEOLOGY

Select grab samples taken in 1984 from trench HTS14 containing up to 5 per cent by volume pyrite and chalcopyrite assayed up to 6.86 grams per tonne gold, 41.14 grams per tonne silver and 1.36 per cent copper (Assessment Report 12992).

A total of 7 tonnes of ore has been mined from the workings from 1931 to 1940 producing 341 grams of gold, 621 grams of silver and 51 kilograms of copper.

CAPSULE GEOLOGY

The Bear occurrence is located on the south side of Hall Creek, 12 kilometres due south of Nelson. The deposit was worked from 1937 to 1942. The Fern mine (082FSW183) adjoins the claims to the east. The area is underlain by augite basalt flows and flow breccias of the Lower Jurassic Elise Formation (Unit Je1, Open File 1989-11), Rossland Group intruded by granodiorite and quartz monzonite of the Middle to Late Jurassic Nelson Intrusions and a dark, fine-grained dyke with light feldspar phenocrysts. The dyke is host to numerous east trending joints and fractures. Fractures and zones of crushed wallrock are host to quartz with pyrite. Minor malachite and abundant pyrite stringers and blebs occur in quartzose crushed rocks. The wallrock adjacent to quartz stringers is oxidized and argillically altered. The Bear workings are developed at the contact between augite

CAPSULE GEOLOGY

porphyry and a porphyritic granite dyke (?). The vein in the adit is up to 25 centimetres wide, pinches out to 10 centimetres and contains free gold. At surface the ore is rusty and decomposed but also hosts free gold.

The highest assay from a sampling program in 1987 was from a rusty fracture in an open cut, 10 metres east of the adit entrance. The oxidized, argillically altered and crushed quartzose material assayed 35 grams per tonne gold (Assessment Report 16847).

The deposit produced 114 tonnes of material which yielded 4,167 grams of gold and 1,897 grams of silver.

CAPSULE GEOLOGY

This property is located at 1524 metres elevation on the south side of Hall Creek, 11.2 kilometres south of Nelson.

The ground was staked by a Captain Duncan in about 1894. Five claims, the Fern (Lot 374), Eureka, Hidden Treasure, Chiccoia, and Foothill, were bonded to Frank Fletcher in about 1895; the Fern claim was Crown-granted in 1896.

The Fern Gold Mining and Milling Company Limited Liability was formed in 1897 to explore and develop the property. A 10 stamp mill was erected that same year and the mine and mill operated until the latter part of 1900. Lessee E. Rammelmeyer worked the mine

CAPSULE GEOLOGY

intermittently from 1902 until about 1908. Other small scale, intermittent, leasee operations were carried on until 1927.

The Gold Fern Syndicate was formed by Buffalo and Toronto interests in 1933 to lease and operate the mine. Development work began in 1934. The syndicate formed Gold Fern Mines Limited in 1935 and the company continued exploration and development work into 1937 when all activity ceased. The property was acquired by C.E. and L.R. Hawley, of Spokane, in about 1939 and lessees worked in the mine until 1943.

Work on the property was resumed in 1945 by Harold Lakes and Associates, who obtained an option on the mine. A diamond drilling program was begun and succeeded in finding the extension of the vein south of the fault which bounded the area stoped in the first mining operation. A new company, Fern Mine, Limited, was formed in March 1946 to develop and operate the property. The company was financed by Premier Border Gold Mining Company, Limited and Quatsino Copper-Gold Mines Limited. A crosscut adit was collared 30 metres below the outcrop of the vein extension and the vein was drifted on for 142 metres. Values of interest were found in the first 16 metres from the fault and again at 86 to 119 metres from it but the widths represented were too narrow for company operation.

The original mining operation was carried on in 4 adits between elevations of 1536 and 1478 metres, and includes some 427 metres of drifts and 78 metres of crosscuts. In 1934 a crosscut adit was started 244 metres below No. 4 level and driven 49 metres before work was suspended. No. 5 level is a crosscut, driven 15 metres of the estimated 30 metres required to reach the "B" vein. The 7th adit, began in 1946, was driven a total of 167 metres.

Weland Mining Ltd. acquired the property in 1965 and began a program of surface exploration and underground diamond drilling.

The Fern mine is located on Hall Creek, 14.4 kilometres south of Nelson. The deposit was located in 1896. The majority of the production was from 1897 to 1904 and from 1904 to 1942 production was intermittent.

The area is underlain by sheared volcanics, comprising augite basalt flows, flow breccias and subvolcanic intrusions (Unit J_{el}, Open File 1989-11) of the Lower Jurassic Elise Formation, Rossland Group. These have been intruded by granitic Middle To Late Jurassic Nelson Intrusions.

The Fern vein, hosted in augite porphyry is well defined, sinuous and strikes 305 to 075 degrees with a 60 degree west dip. This orientation is generally conformable with the Silver King shear zone. Locally, it follows a granite porphyry dyke and varies from a few centimetres up to 2 metres in width. The mined portions of the vein were up to 1 metre wide and high grade streaks were up to 0.30 metre wide. Quartz with crushed rock and minor siderite is the gangue for pyrite, chalcopyrite, bornite, pyrrhotite and free gold. Pyrite, by far, is the dominant sulphide. Arsenopyrite is a minor constituent of some quartz veins. The vein is cut off by a fault containing a lamprophyre dyke which strikes northwest and dips 75 degrees north. The ore contained substantial oxidized material.

The records indicate that better grades of precious metals were obtained from areas of the vein which were within or associated with the older, granite porphyry dyke. The vein is later than the dyke. An extension to the vein was found 1945 and 1946 but results were disappointing.

Numerous other veins occur in the area, but vein B and vein P 1 are the only ones with good values, up to 9.6 grams per tonne gold (Geological Survey of Canada Memoir 191, page 52).

The mine produced 11,277 tonnes yielding 196,448 grams of gold and 16,515 grams of silver.

CAPSULE GEOLOGY

The Canadian Belle occurrence is located 1.2 kilometres south of Hall Creek, on the east side of Keno Creek, 13 kilometres south of Nelson. The claims were Crown granted in 1901 and minor production is recorded for 1939 and 1940.

The area is underlain by siltstone, sandstone, conglomerate and argillite of the Lower Jurassic Hall Formation (Rossland Group). These are intruded by diorite porphyry and granite of the Middle to Late Jurassic Nelson Intrusions.

Black argillites are host to numerous faults and fractures of variable orientation. Granite intrudes the stratigraphy south of the showing and locally the sediments are cut by "tongues" of diorite porphyry. Faults and fractures vary from 1 centimetre to 1.8 metres in width with locally developed gouge zones. Quartz and sulphides have been emplaced at a late stage and locally heal some of the fracture zones. Most prospecting has been done on fractures/shears with a general northeast trend and some mineralized east-west trending structures. Old workings appear concentrated on a number of closely spaced parallel breaks. The mineralization occurs near the southern limit of the Silver King shear.

Quartz veining in the structural breaks is host to massive (locally, up to 0.20 metres wide) and disseminated arsenopyrite, pyrite, pyrrhotite, and chalcopyrite. Arsenopyrite is dominant and has microfractures which are healed by pyrite and chalcopyrite. Pyrrhotite occurs as minute inclusions in the arsenopyrite and grains of free gold less than 1.5 microns in diameter are hosted by

CAPSULE GEOLOGY

arsenopyrite without any obvious relationship to grain boundaries or fractures.

Production totals 24 tonnes, yielding 840 grams of gold, 280 grams of silver and 23 kilograms of copper.

CAPSULE GEOLOGY

The property is located on the west side of the Salmo River 11.2 kilometres south of Nelson. The Euphrates property lies the east side of the river directly across from the Golden Age.

The discovery of gold-quartz float on the lower slope of the mountain led to intensive prospecting of the area by E. and S.

CAPSULE GEOLOGY

Terzian, and the staking of 9 claims in 1922. Trenching and several short adits led to the discovery of the vein in place. The owners incorporated The Golden Age Mining Company, Limited, in August 1923. The company installed a 20-stamp mill, which was used very little as there was no ore available. In 1927-28 the mill operated occasionally on ore from the Euphrates property. The mill was destroyed by fire in 1929. Some development work was done in 1924 by Carl Anderson, of Spokane, under a lease agreement. Small shipments were reported by the owners in 1931 and 1940.

Trimetals Mining, Inc., of Spokane, Washington, acquired the property in 1941 and during 1941-42 carried out underground development work and diamond drilling. Some ore is milled at the Euphrates mill before work ceased in April 1942. Further development work was done by the company in 1945-46 and a small amount of ore was shipped at that time; work ceased in October 1946.

The workings at that time included 3 adits. The lower, 15 metres below the road, consisted of a 40-metre drift and a 6-metre crosscut; the main (middle) adit, at road level, consisted of 440 metres of drift, and 3 short crosscuts to the west; the upper adit, 27 metres above the main adit, consisted of a 53-metre long drift.

Foremost Construction Ltd. shipped 62 tons of crude ore from the property in 1963.

Nelway Mines Ltd. held the property in 1966 as the T.P.M. and J groups of 26 recorded claims. During 1966-67 the company carried out stripping, sampling, and 61 metres of diamond drilling in 3 holes.

Robert Mines Ltd., incorporated May 1969, acquired the T.P.M. I and 2 claims. These claims, and adjacent ground, were restaked as the PIA 1-10 claims. The company also acquired the Euphrates property. During 1971 the main adit, on PIA 7 claim, was reopened and extended 11 metres, and geochemical, magnetic, electromagnetic, and self potential surveys were carried out. During 1972-73 diamond drilling in 2 holes totalling 34 metres on the PIA 7 claim, and trenching and stripping on PIA 3 claim were carried out.

The Golden Age deposit is located 13 kilometres south of Nelson on the Salmo River. The vein system was discovered in 1922 and it has been developed by 3 adit levels with the center or #2 adit still accessible. There was more than 500 metres of drifting and limited stoping.

The area is underlain by highly schistose volcanics of the Lower Jurassic Elise Formation, Rossland Group. The volcanics comprise andesite, andesite lapilli tuff (unit Je81), augite porphyry basalt and flow breccias (unit Je4), tuffaceous siltstone and sandstone (unit Je10), mafic tuff (unit Je7f) and tuffaceous conglomerate (unit Je11b) (Open File 1989-11). The volcanics have been intruded by lamprophyre dykes.

The workings followed a fault/vein structure striking between 310 and 325 degrees and dipping 60 to 80 degrees south. Mineralization occurs in bulbous quartz sulphide lenses along a fault trace. Shearing is common in both the hanging wall and footwall. Shearing and silicification are discontinuous and apparently en echelon. Sheared and mineralized sections are often bounded by dykes and/or faults. Fault gouge is common and the attitude of the faults is variable. Some of the faulting is post-mineralization. The mineralized shear is closely associated with mafic dykes and is similar to the Euphrates (082FSW186) showing to the southeast. The quartz stringers often exhibit boudinage and drag fold structures.

Mineralization consists of one or more poorly defined shear zones with discontinuous stringers, veinlets and knots of quartz. These quartzose zones are up to 1 metre wide by 1 to 30 metres long and appear to be better developed in the arcuate or curvilinear sections of the shears. The quartz zones host pyrite, chalcopyrite, arsenopyrite, minor galena and sphalerite, scheelite, tetrahedrite and malachite associated with chalcopyrite. Gangue consists of calcite, ankerite and sericite. Minor tourmaline is observed associated with the quartz. Metallurgical studies have determined that 40 per cent of the gold and silver occur as locked particles with pyrite (Assessment Report 17464).

A suite of 20 channel samples along a strike length of 107 metres indicated grades in the order of 7.2 grams gold, 28 grams silver and 0.29 per cent copper (Assessment Report 3304). A grab sample of quartz material yielded 0.35 per cent tungsten (Assessment Report 13682). In 1988, a channel sample across 1 metre of highly sheared, sericitized and siliceous andesite from the main adit (AGE-88-010) assayed 2.6 grams per tonne gold (Assessment Report 17464). The 155 tonnes produced was primarily for testing purposes.

CAPSULE GEOLOGY

Lillian, Pasadena, and Minto were staked. An additional 16 claims staked in 1927 included the old Lost Cabin showings. The owners incorporated The Euphrates Mining Company, Limited, in April 1928. Portland, Oregon, interests acquired an option on a controlling interest in the company and development work was carried out in several adits. Small amounts of ore were put through the 10-stamp mill on the Golden Age property in 1927 and 1929; the mill was destroyed by fire later in 1929. An aerial tram to the Ell-Tee adit at 1203 metres elevation was installed in 1930 and a small amount of ore was shipped in 1931. The Portland interests gave up their option in the fall of 1931.

Work resumed in August 1933 when an option on a controlling interest in Euphrates Mining was acquired by the Spokane-Idaho Copper Company, of Spokane, Washington. The company extended the lower Ell-Tee adit and carried out some diamond drilling. Work was suspended in the summer of 1934.

The Euphrates Mining Company resumed work on the property and in 1936 some 381 metres of drifting and 228.6 metres of cross cutting was carried out. The workings at that time included, on the Ell-Tee vein, an upper adit 53 metres long, and a lower adit about 610 metres long. From the lower adit crosscuts were driven 73 metres to the northeast towards the Minto vein, and for 91 metres in search of the Lost Cabin vein. A crosscut was also driven 229 metres to the Nickel Plate vein, which was drifted on for 427 metres. The Minto workings included 2 adits, an upper driven 37 metres, and a lower about 175 metres in length. On the Nickel Plate vein, which was a new discovery, trenching was done in 1935 and 1936.

General Lee Mining & Milling Co., Inc., of Seattle, carried out 610 metres of underground diamond drilling on the property in 1938. In 1940 the Gold-Silver-Tungsten Mining & Milling Co., of Seattle, hold the property. A 100 ton-per-day mill, from the Ottawa mine in the Slocan, was installed, and the tramline rebuilt. The mill operated for a short period in 1941, milling a small amount of ore from the Nickel Plate and Minto veins.

A small amount of crude ore was shipped in 1960 by L. Soukeroff and B. Logan.

Robert Mines Ltd., incorporated May 1969, acquired the A 1-8 claims covering the Euphrates property; the Golden Age property was also acquired. In 1970 a geochemical soil survey (197 samples) was carried out on the A group. Geochemical, magnetic, electromagnetic, and self potential surveys were carried out in 1971. During 1972-73 geological mapping, stripping, and 93 metres of diamond drilling in 4 holes was done on the A 2-A 4 claims.

The Euphrates deposit is located 12 kilometres south of Nelson. The area was initially explored in the late 1800's. Highly schistose, augite porphyry volcanics of the Lower Jurassic Elise Formation (Units Jel0 and Jel1b, Open File 1989-11), Rossland Group contain a number of vein deposits either conformable to or crosscutting the regional foliation trend of 320 degrees with dips of 70 to 80 degrees southwest. The deposit is at the southern end of the Silver King shear zone, a wide regional zone of intense deformation. The occurrence consists of the El Tee, Minto and Nickel Plate adits at about 1161 metres elevation and the Lost Cabin adit at about 1464 metres. The El Tee vein roughly parallels the regional foliation trend at surface but dips 70 degrees northeast. The vein is narrow, maximum width about 0.15 metre, and has sharp, unsheared contacts with the host rocks. Near surface it is oxidized to shallow depths and carries significant free gold. The Lost Cabin and Minto veins, northeast of the El Tee, are controlled by poorly defined shears. These shears are about 8 and 4 metres wide respectively and roughly parallel the regional schistosity. They contain narrow stringers and lenses of quartz within sheared, chloritized volcanics with minor sulphides in the wallrocks. The Nickel Plate "vein" is a shear controlled, felsic dyke about 4 metres thick which carries less than 1 gram gold on average and generally parallels the orientation of the Minto and Lost Cabin veins. The vein systems in general host a gangue of quartz plus or minus carbonate and chlorite with galena, sphalerite, pyrite, arsenopyrite, chalcopyrite, native gold and native silver in decreasing order of abundance. Between 1928 to 1941 about 272 tonnes were mined, mainly from the El Tee vein, which contained approximately 48 grams per tonne gold, 251.6 grams per tonne silver, 2.77 per cent lead and 1.7 per cent zinc. The system is similar to, and may be a strike extension of, the Golden Age deposit (082FSW185) to the northwest, across the Salmo River. Minor scheelite was reported and a tongue (sill?) of granite of the Middle to Late Jurassic Nelson Intrusions outcrops about 250 metres southwest of the showing.

CAPSULE GEOLOGY

The Second Relief mine is located in a mountain valley 20 kilometres northwest of Salmo. The deposit was brought into production in 1902, was mined until 1919, resumed in 1928 and produced until 1941. This is the third largest gold-enriched skarn producer in the province. The main vein has been opened on 11 levels.

The area is underlain by lapilli tuff (Unit Je81, Open File 1989-11) and augite porphyry volcanics of the Elise Formation and siltstone, sandstone, argillite and quartzite of the Archibald Formation both of the Lower Jurassic Rossland Group. These occur as a roof pendant within granodiorite of the Bonnington pluton of the Middle to Late Jurassic Nelson Intrusions. The deposit occurs on the west limb of the Erie Creek anticline along the Red Mountain fault.

The Second Relief mine comprises at least eight subparallel veins striking northeast and dipping steeply northwest in greenstone or argillaceous quartzite. These are the Second Relief or No.1, the No.'s 2 to 5, the Ida D and the Inez and Rand veins (082FSW216). The

CAPSULE GEOLOGY

veins are sheared, quartz poor structures irregularly mineralized with pyrite and/or pyrrhotite plus one or more of magnetite, chalcopyrite, and sphalerite. Some of the veins locally host fine-grained visible gold. Gold and silver bearing veins consist of quartz, pyrite, epidote, garnet and magnetite. Lesser auriferous veins contain massive pyrrhotite and chalcopyrite.

The Second Relief is the main economic vein but the No.'s 2 to 5 parallel veins occur immediately to the southeast within about 100 metres. The Second Relief vein follows the hanging wall contact of an 8 to 12 metre wide diorite porphyry dyke and crosscuts projections of that dyke into the country rock. Where the dyke and vein go from volcanics to sediments the vein tends to follow the general bedding of the sediments but at the same time the precious metal values decrease greatly. The Second Relief or No.1 vein is 0.2 to 3.5 metres wide, has a strike length of 300 metres and has been mined to a depth of 400 metres. The vein strikes 050 degrees and dips 80 to 85 degrees north. The gangue comprises quartz and locally disseminated magnetite, garnet and epidote, indicating the likely presence of skarn alteration associated with the Nelson batholith immediately to the northeast of the occurrence. The vein carries pyrite, pyrrhotite and chalcopyrite with traces of molybdenite reported. The parallel veins were disappointing in their precious metal values.

The No. 2 vein, about 10 to 16 metres southeast of the No. 1 vein, is over 300 metres long and has been exposed by trenching for more than 228 metres. The exposed mineralized portion of the vein is up to 2.4 metres wide. Gold assayed between 0.137 to 34.2 grams per tonne gold across 1 metre or more. This vein is similar to the Second Relief vein and closely parallels it in strike and dip. The vein, hosted by fragmental volcanic rocks, is mineralized with pyrite, pyrrhotite, magnetite, sphalerite, chalcopyrite and, locally, visible fine-grained gold particles. Vein quartz is sparse and the vein is surrounded by a silicification envelope.

The No. 3 vein is a narrow stringer with no obvious mineralization.

The No. 4 vein, 96 metres southeast of the No. 1 vein, has been exposed by open cuts over a length of 15 metres. The quartz vein hosts pyrrhotite with chalcopyrite and a sample across 0.5 metre assayed 12.3 grams per tonne gold (Assessment Report 19839). The hanging wall is greenstone and the footwall is diorite.

The No. 5 vein, 106 metres east of the workings, is mineralized with pyrite and chalcopyrite. In the adit, the vein is 1.5 metres wide. In 1988, 2 samples assayed 0.07 and 26.53 grams per tonne gold respectively (Assessment Report 19839).

The Ida D vein occurs in the central portion of the property, about 150 metres west of the Second Relief vein. Samples from the portal area in 1988 assayed 0.10 to 35.65 grams per tonne gold (Assessment Report 19839). Production from this vein is reported as 34,280 grams of gold.

Sampling of pyritic alteration zones in the central portion of the property assayed 6.2 grams per tonne gold over more than 7 metres (Vancouver Stockwatch, Sept. 12, 1989).

The deposit is classed as a gold-enriched skarn. Production totals 207,023 tonnes which yielded 866,433 grams of silver, 3,117,637 grams of gold, 20,210 kilograms of copper, 1057 kilograms of lead and 147 kilograms of zinc.

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The Porto Rico (L.2385) occurrence is located on Barrett Creek, 15.5 Kilometres north-northwest of Salmo. Underground development began in 1896 and production is recorded for 1897.

The area is underlain by basaltic to andesitic lapilli tuff and pyroclastics (Unit Je3) of the Lower Jurassic Elise Formation, Rosslund Group (Open File 1989-11). These are intruded by the Late to Middle (?) Jurassic Mammoth Intrusions comprising plagioclase augite porphyritic diorite (?).

The occurrence consists of a quartz-filled fissure that strikes northeast and dips about 45 degrees to the northwest. The host rock is comprised of an augite porphyry sill which intrudes andesitic volcanics. The quartz vein averages about 0.8 metre in width and hosts pyrite, gold, arsenopyrite and very minor galena, sphalerite and chalcopyrite.

In 1899, 3719 tonnes of ore was mined producing 108,083 grams of gold and 31,103 grams of silver. Production from the Porto Rico vein over 13 years, in the period 1897 to 1969, totalled 5740 tonnes which produced 178,470 grams gold, 46,405 grams silver, 138 kilograms lead, 51 kilograms zinc and 322 kilograms copper.

In 1979, mineralization was observed on the Sunshine (Lot 2389) claim. It occurs in an old shaft and consists of a 1.3-metre wide shear zone which strikes east-west and dips 55 degrees north. Pyrite

CAPSULE GEOLOGY

and arsenopyrite occur in a breccia zone that is 0.5 metre wide. The sulphides cement irregular fragments of quartz and altered andesitic wallrock. The shear cuts porphyritic augite andesite which is stratigraphically below the augite porphyry sill in which the main vein on the Porto Rico claim is exposed. The andesitic volcanics show extensive propylitic alteration. Samples assayed 11.65 to 24.34 grams per tonne gold and 3.42 to 3.77 grams per tonne silver (Assessment Report 7702).

Northeast of the main vein, on the Lizzie B (Lot 2386) claim, malachite staining was found in mafic dyke material.

CAPSULE GEOLOGY

The Spotted Horse deposit is located on the headwaters of a west flowing tributary of Barrett Creek about 17 kilometres north-northeast of Salmo. Workings comprise an open cut, a short adit and trenches. The workings are just northeast of the Porto Rico mine (082FSW189).

The area is underlain by basaltic lapilli tuff (Je2) and basalt flows and flow breccias (Je4) of the Lower Jurassic Elise Formation, Rossland Group (Open File 1989-11).

The adit exposes quartz and calcite veinlets and stringers in a shear zone, 0.91 to 1.2 metres wide, which generally strikes 110 degrees and dips 55 to 60 degrees north. The 0.15-metre wide quartz vein at the portal pinches out within a short distance. Native gold has been reported from the stringers and tungsten has also been reported from this occurrence. The vein hosts pyrite and gold. The vein is probably a continuation of the Porto Rico (082FSW189) main vein. The host rock is an augite porphyry sill which intrudes the volcanics.

Production from 1901, 1903 and 1937 totalled 47 tonnes which produced 1649 grams of gold and 2083 grams of silver.

CAPSULE GEOLOGY

The Commodore occurrence is located on the south side of Wildhorse Creek, 9.6 kilometres east of Ymir. Workings comprise tunnels, trenching, drifting and drilling.

The area is underlain by porphyritic granite of the Late to Middle Jurassic Nelson Intrusions (Nelson batholith). The Nelson batholith hosts pendants of Lower Jurassic Ymir Group sediments comprising siltstone, sandstone, argillite and conglomerate.

A discontinuous quartz vein and/or veinlets trend generally north and parallel the trend of the schists dipping steeply west. The vein varies from massive quartz up to 2 metres wide to two small, barren quartz veinlets hosted by schists and in part by the granitic intrusive. Locally, massive sulphides are reported but gold and silver values are not economically significant. Ruby silver (pyrrargyrite) has been reported as well as traces of tetrahedrite.

CAPSULE GEOLOGY

The Elise occurrence is located 8 kilometres northeast of Ymir on the Elise claim Lot 1310. The vein has been investigated by about 150 metres of underground workings.

Argillites and phyllites of the Lower Jurassic Ymir Group are host to northeast trending quartz veins carrying minor amounts of base and precious metals. The sediments strike 330 degrees and dip 70 to 85 degrees north. Granitic dykes of the Middle to Late Jurassic Nelson Intrusions have been noted in the area.

The Elise vein, about 1 metre wide, is hosted in sheared sediments. Mineralization consists of pyrite, minor native silver and lesser amounts of pyrrhotite, galena, sphalerite and trace chalcopyrite. Minor malachite is present as a secondary sulphide. Some silicification of the country rock in the vicinity of the vein-shear zone is reported. The vein strikes 054 degrees and dips steeply northwest.

Surface workings, an adit and a shaft were located in 1896 and 5 tonnes of material were shipped producing 9331 grams of silver.

CAPSULE GEOLOGY

mine. The vein, exposed in old workings, pinches and swells from 10 to 25 centimetres in width and strikes at about 260 degrees and dips 70 to 90 degrees north. The vein consists of massive bull quartz containing up to 30 per cent sulphides composed of pyrite and pyrrhotite with minor sphalerite, galena and arsenopyrite.

The vein contains highly variable values in gold ranging from less than 5 grams to over 45 grams per tonne. The records do not indicate the amount of hand cobbing carried out on the mined material to arrive at those final grades. The property, apparently, also produced minor amounts of copper but there is no indication of copper minerals present on the property nor in similar occurrences on adjoining and related properties. The Arizona vein produced about 296 tonnes of ore in total.

A 1985 chip sample of smoky, drusy quartz with dense, limonitic boxworks (J-04) taken from the vein assayed 60 grams per tonne gold (Assessment Report 14555). A geochemistry program in 1985 failed to outline the continuation of the Arizona vein.

COMMODITY GRADE
Silver 1.7000 Grams per tonne
Gold 8.9000 Grams per tonne
COMMENTS: Across 0.3 metres of the Ymir Belle vein taken from a small pit 15
metres west of shaft.
REFERENCE: Assessment Report 17985.

CAPSULE GEOLOGY

The Ymir Belle showing is located 10 kilometres northeast of Ymir, in between the Foghorn (082FSW078) and Wilcox (082FSW077) mines. Workings consist of small open cuts and pits and a shaft 44 metres deep.

The area is underlain by granodiorite of the Late to Middle Jurassic Nelson Intrusions (Nelson batholith) which contains roof pendants of mica schist and quartzite of the Lower Jurassic Ymir Group. Quartz veins occur in shear zones and as fissure fillings which trend east to northeast and are crosscut by lamprophyre dykes.

The showing consists of three veins, two of which may be strike extensions of a single vein.

These two veins strike about east and dip 60 to 70 degrees north. The veins are parallel and have an average width of 0.60 to 0.90 metre, but may be up to 1.5 metres in width. The gangue is

CAPSULE GEOLOGY

quartz and decomposed granite with pyrite, galena and sphalerite. Sampling indicates local grades of 8 to 10 grams gold. A chip sample across 1 metre of the New Victor vein, including 0.20 metre of quartz-pyrite vein material, assayed 5.0 grams per tonne gold and 5.2 grams per tonne silver (Assessment Report 17985)

The third vein strikes north, is about 0.40 to 0.45 metre wide and is reported to contain up to 30 grams per tonne gold locally. This vein, the Ymir Belle vein, is exposed in a shaft immediately north of the New Victor Crown Grant. The best assay from a sampling program in 1988 was from a chip sample across 0.3 metres of a small pit 15 metres west of the shaft. This chip sample assayed 8.9 grams per tonne gold and 1.7 grams per tonne silver (Assessment Report 17985).

CAPSULE GEOLOGY

metamorphism has bleached the well-indurated hornfels of the Rossland Group which contains pyroxene and garnet. A swarm of Tertiary diorite dykes crosscut both the monzonite and Rossland Group rocks. Also, the Middle Eocene Coryell syenite intrudes the Rossland Group rocks at the eastern part of the claim.

There are three tunnels and several prospect shafts on the claim. Tunnel #1 discloses about 0.5 metres of solid ore comprised mainly of massive magnetite and chalcopyrite. In tunnel #2, mineralization occurs along a fissure or fault contact between the hornfelsed Rossland volcanics and a dioritic dyke. Massive pyrrhotite shows pronounced spheroid weathering. The vein is 0.5 metres wide hosting solid sulphides in quartz gangue. The host rock is crosscut by several Tertiary syenite dykes associated with the Coryell Intrusion. The dykes host minor disseminated chalcopyrite and exhibit porcelaineous-chilled margins. In tunnel #3 the Rossland rocks dip 60 degrees west.

COMMENTS: Sample across zone of oxidized vein material from a trench on the Good Hope vein.
REFERENCE: Assessment Report 16464.

CAPSULE GEOLOGY

The Pilot-Good Hope occurrence is located 10 kilometres northeast of Ymir. The workings date to the turn of the century and consist of an adit on Lot 4382 and 13 open cuts and trenches near the adit and on the Baldy #2 claim. The occurrence comprises three

CAPSULE GEOLOGY

veins; the Good Hope, the Pilot and the Swiss Cheese.

The area is underlain by porphyritic and gneissic granodiorite (Nelson batholith) of the Middle to Late Jurassic Nelson Intrusions which host north-northeast trending veins. The veins comprise Lower Jurassic Ymir Group sediments striking 10 to 82 degrees southeast. The sediments have been metamorphosed to quartz-biotite schist and biotite schist.

Several parallel, sheared, quartz veins occur within granodiorite. The veins are highly brecciated and locally contain white kaolinite gouge. The veins are highly variable in width along strike and contain quartz in the wider sections. Lamprophyre dykes crosscut the veins and granitic country rock but are post-mineralization.

The Good Hope adit cuts a quartz vein about 0.30 metre wide. The vein is 0.45 metre wide over a length of 16.8 metres and then it thins. The orientation of the vein, northeast striking and 50 to 55 degrees north dipping, is approximately parallel to the abundant fractures noted in the granodiorite. The vein occupies a fault zone along its entire exposed length as evidenced by gouge or crushed granite in the quartz. The best assay results from sampling in 1987 came from a chip sample taken across a zone of oxidized quartz vein material in a trench. This assay was greater than 100 grams per tonne silver, 123 grams per tonne gold, 0.05 per cent lead and 0.12 per cent zinc (Assessment Report 16464).

The Swiss Cheese workings comprise several short adits and trenches. These expose a 0.20 to 0.40 metre wide quartz vein striking 080 degrees. The vein occurs within a 0.50 metre wide gouge zone near the contact with quartz-biotite schist. The vein hosts pyrite and is intensely oxidized. The highest assay from sampling in 1987 was from a dump sample of quartz with abundant free fine gold, pyrite, zinc staining and intense limonitic staining (Assessment Report 16464).

The Pilot vein lies about 100 metres southeast of the Good Hope veins and is parallel to the Good Hope. The greatest exposed width is about 45 centimetres of quartz with 15 centimetres of fault gouge. Best assays were in the order of 128 grams of gold and 102 grams of silver per tonne but metal values are highly erratic and no significant zone of mineralization has been outlined.

CAPSULE GEOLOGY

The Myrtle occurrence is located within the Ymir townsite. Workings comprise an adit and a shaft.

The area is underlain by basalt flows, flow breccias and subvolcanic intrusions of the Lower Jurassic Elise Formation (Units Je1 and Je4) and sediments of the Lower Jurassic Ymir Group (Open File 1989-11). These are cut by the Mt. Elise shear zone.

A quartz vein, striking 025 degrees and dipping 50 degrees north, occurs in a fault or crush zone. The vein varies from 0.30 to 0.60 metre in width and is locally represented by shattered or brecciated country rock with quartz and mineralized sulphide streaks. Along strike, the zone is filled with well mineralized quartz gangue. Mineralization consists of pyrite, some galena and traces of sphalerite. The sulphides occur as masses and streaks in the vein and in the country rock. The vein is intersected by a lamprophyre dyke and is conformable with schistosity.

It is reported that 25 tonnes of hand sorted material was mined producing 528 grams of gold, 2053 grams of silver, 122 kilograms of lead and 183 kilograms of zinc. Higher assays were reported from grab samples in the adit and shaft.

CAPSULE GEOLOGY

The Dewey occurrences are located on the south slope of Jubilee Mountain, about 3 kilometres southeast of Ymir. The property was first explored in 1926.

The area is underlain by granite of the Late to Middle Jurassic Nelson Intrusions and sediments of the Lower Jurassic Ymir Group, comprising argillite, siltstone and limestone.

Northeast trending quartz veins host disseminated pyrite and minor galena and sphalerite. Northeast trending fault zones have been worked in the past but carry only traces of precious metals. Disseminated pyrite, galena and dark sphalerite with occasional chalcopyrite are reported from a 90 to 122 centimetre wide zone of silicified limestone near a granitic contact.

The vein on the Jubilee claim is exposed by 3 open cuts, has been traced for 15 metres and is 0.91 to 2.44 metres wide. The vein strikes 040 degrees and dips 80 degrees north.

In 1949 and 1952, a total of 40 tonnes was produced yielding 156 grams of gold, 4915 grams of silver, 1700 kilograms of lead and 1786 kilograms of zinc.

CAPSULE GEOLOGY

Quartzites and argillites of the Middle Ordovician Active Formation are intruded by granodiorite of the Middle to Late Jurassic Nelson Intrusions. The intrusive-quartzite contact is highly irregular, strikes generally northwest and dips gently in a south direction under the sediments. Lamprophyre dykes typically occur near faults.

Heavy mineralization, consisting of pyrrhotite, pyrite, sphalerite, galena, chalcopyrite and quartz occurs in a fissure vein called the Peck zone which strikes south across the intrusive-quartzite contact and has a west dip. Some visible gold has been observed. There are also two Queen vein (082FSW048) types of sulphide-bearing quartz veins which crosscut the fissure ore. The Queen A type are steeply dipping quartz veins that are from 1.5 to 1.8 metres wide and have associated minor parallel quartz stringers that occur up to a metre away from the vein. There are at least 3 of these large Queen A type veins in the mine area. The Queen B types is more of a fault than a quartz vein but irregular masses of quartz that do occur contain minor sulphides and some precious metal values. These veins branch and dip rapidly while the Queen A types do not.

The Queen vein strikes east-west with a steep south dip. Within the granite it is narrow and hosts some quartz and tourmaline and the granite is silicified. To the west the Queen vein becomes mineralized locally and intersects the Peck zone. Where the Peck zone intersects the granite to the north, mineralization consisting

CAPSULE GEOLOGY

of pyrite, pyrrhotite, sphalerite, and galena dies out and the granite-quartzite contact area is intensely silicified. To the south, the ore becomes massive and is up to 1.25 metres wide with some disseminated sulphides in the wallrocks. The ore zone is cut off to the south by the Queen fissure which exhibits sinistral movement in drag folds in the sulphide ores.

The total Howard mine production indicates grades of 17.15 grams per tonne gold, 85.7 grams per tonne silver and 12 per cent combined lead and zinc. The ore was confined to the zone between the granite-quartzite contact and the fault zone of the Queen fissure. In 10 years between 1937 and 1970 the Howard mine produced 20,091 tonnes of ore, of which 19,216 tonnes were mined in 1938. Recovery of elements from all ore mined, totalled 212,121 grams of gold, 1,613,871 grams of silver, 1,059,009 kilograms of lead, 343,307 kilograms of zinc and 68 kilograms of cadmium.

CAPSULE GEOLOGY

Augite-porphyry of the Elise Formation and argillites of the Hall Formation, both of the Lower Jurassic Rossland Group, contain general northwest trending shear controlled quartz veining and lamprophyre dykes. The veins and dykes are associated with granites of the Middle to Late Jurassic Nelson Intrusions. The quartz veins carry high gold and variable silver values.

The Clubine-Comstock has workings on two major shears striking about 340 degrees and dipping about 35 degrees northeast. The No. 1 level workings are within argillites of the Hall Formation about 60 metres west of the main workings. The quartz vein is sheared and fractured and is more lead-zinc rich with lower gold values than the main workings. The main workings are on a shear zone associated with a lamprophyre dyke. Although both hanging and footwall sides of the dyke are sheared, quartz veining and mineralization appears confined predominantly to the footwall side. Lenses of quartz in the order of 0.5 metres wide with variable amounts and ratios of pyrite, chalcopyrite, galena and minor sphalerite and pyrrhotite are present. It is reported that the best grade and tonnage came from a zone of intersection of the vein with the Main Fault which strikes more to the west and has a steeper dip than the quartz vein.

The age of the veins is not known, they may be associated with the Nelson Intrusives, with the Hidden Creek Stock or with Tertiary deformation which elsewhere shows similar orientations (EMPR Bulletin 109, page 42).

Mine production totalled 3,616 tonnes of ore for the 13 years between 1926 and 1942. About 83 per cent (2,990 tonnes) of the total was mined in 4 years from 1936 to 1939. Recovery of economic minerals included 123,293 grams of gold, 239,463 grams of silver and

CAPSULE GEOLOGY

818 kilograms of zinc.

CAPSULE GEOLOGY

Argillites and argillaceous quartzites of the Lower Jurassic Hall Formation (Rossland Group) contain a quartz vein with pyrite and galena which strikes 350 degrees and dips about 15 degrees south-west. It was reported that in 1930 the lower tunnel, already 27 metres long, was extended considerably. Shipments of ore from the Second Chance, totalling 10 tonnes, were made in 1932, 1933 and 1934. A total of 280 grams of gold and 155 grams of silver were recovered.

CAPSULE GEOLOGY

The Keystone-Delaware is a fault controlled, quartz vein deposit within argillites and argillitic quartzites of the Lower Jurassic Hall Formation of the Rossland Group. Granodiorite of the Middle to Late Jurassic Nelson Intrusions intrudes to the northeast of the occurrence. Typical of such vein deposits in the area there are also lamprophyre dykes and possible localized silicification. It is presumed that the Keystone-Delaware is the up-dip extension of the Arlington ore zone (082FSW205).

The vein has an average strike of about 035 degrees and dips about 20 degrees northwest while the host stratigraphy strikes about 015 degrees and dips about 65 degrees west. The vein varies from about 5 centimetres to about 1.5 metres in width but averages about 0.6 metres, it is partly filled with quartz plus pyrite and some galena, sphalerite, tetrahedrite and rare pyrrhotite. Locally some mineralized cross fracturing is developed.

Gold values vary from 2 to 100 grams and intermittent production from 1901 to 1942 of 1669 tonnes indicates an average grade of about 50 grams per tonne gold and 100 grams per tonne silver. Additional production took place from 1979-1981.

CAPSULE GEOLOGY

Argillites of the Lower Jurassic Hall Formation of the Rossland Group contain quartz veining with pyrite, galena and sphalerite. The Canadian King occurrence is immediately north of the old Arlington mine (082FSW205) and is within the same folded sequence of argillites and quartzitic argillites.

This mine was operated intermittently from 1900 to 1912 producing 440 tonnes of ore. It was operated after 1906 on a lease basis as part of the Arlington mine. Total recovery is reported to be 37,976 grams of gold, 80,526 grams of silver, and 1,224 kilograms of lead.

CAPSULE GEOLOGY

Argillites and arenaceous sediments of the Lower Jurassic Hall Formation (Rossland Group) are host to a number of closely spaced, quartz veinlets which follow the trend of the bedding. The stratigraphy is gently folded and the amount of quartz increases where small, flat rolls developed in the sediments. Arsenopyrite and minor chalcopyrite were identified in quartz veinlets. Quartz composed about 0.4 metres of the adit face. No reliable precious metal assays are recorded.

A total of 19 tonnes of ore were mined in 1932, 1934 and 1942 from which was recovered 560 grams of gold and 1,027 grams of silver.

CAPSULE GEOLOGY

This property, consisting of 9 Crown-granted claims and fractions, is located between Rest and Hooch Creeks about 4.8 kilometres northwest of Salmo.

The Arlington claim (Lot 3648) was Crown-granted to the Hastings (British Columbia) Exploration Syndicate Ltd. in 1899. The mine was in continuous operation from 1900 until June 1912; leasers kept the mine operating until November 1913. No further work was done until 1927 when the Arlington Mining Company reopened the mine and installed a 15 stamp mill; the company operated intermittently through 1928.

In 1929 the property was acquired by Relief-Arlington Mines Ltd.; the company was subsequently controlled by the W.N. O'Neil Company Ltd. and in the 1940's by Premier Cold Mining Company. The mine was operated under lease by R. Oscarson from 1932 to 1942.

Messrs. Schrieves and R. & K. Golac optioned the property in 1943 and acquired title to it in 1945. Intermittent operations were carried on by the owners or by leasers until October 1948 when F.C. Buckland optioned the property. Subsequent operations were carried on under an agreement by Kenville Gold Mines Limited until May 31, 1950, when the property reverted to the former owners.

CAPSULE GEOLOGY

New Arlington Mines Limited was formed in December 1951 to work the property. The mill capacity was increased from 50 to 125 tons per day and milling operations, mainly of dump material, continued into 1954. Subsequent operations were carried on intermittently by leasers. In about 1961 the property was acquired by J. Russell of Borregga Springs, California.

Development work totals over 5182 metres of drift, crosscuts and raises. The vein has been explored and largely mined out for 457 metres along the strike.

Lower to Middle Jurassic argillites and argillaceous quartzites of the Hall Formation (Rosslund Group) are gently folded and intruded by a granite-porphry sill of the Middle to Late Jurassic Nelson Intrusions.

Pyrite, galena, and sphalerite mineralization is hosted by quartz in a 0.6 metre thick vein which closely follows the granite-sediment contact but which locally occurs as a footwall or hanging wall to the intrusive sill. The vein lies in strata which exhibits gentle "rolls" or folds down-dip and these structures may have had some controlling influence on mineralization. The vein has been explored and largely mined out for 460 metres along strike.

The mine was in production from 1900 to 1913 and again from 1932 to 1970. The total amount of ore mined for these years was 69,823 tonnes. Recovered from the ore was 1,700,339 grams of gold, 4,334,578 grams of silver, 520,420 kilograms of lead and 456,920 kilograms of zinc.

In 1969, G.D. Fox and Associates of Trail, hauled material from the old dumps to the Trail smelter. These operations ceased in 1970. It is possible that Shalman Resources Limited held the property in 1975.

In 1982, the property was owned by Chutine Resources Ltd. They estimate that there are about 113,000 tonnes of dump material from which samples assayed between 3 and 53.5 grams of gold per tonne (Northern Miner, October 28, 1982, page 6).

In 1983, a soil geochemistry survey was carried out. About 3084 tonnes were mined producing about 7400 grams of gold. In 1985, Ryan Exploration Company Ltd. acquired the Chutine's interest. Chutine dropped its option in 1988.

CAPSULE GEOLOGY

The Commander claim is underlain by the Early Jurassic Rossland monzonite, an east-trending stock comprised of a biotite-hornblende-augite monzonite. Syenite of the Middle Eocene Coryell Intrusions invades the Rossland monzonite at the eastern part of the property and the monzonite is crosscut by a variety of Tertiary dioritic and lamprophyre dykes.

Mineralization on the claim consists of disseminated coarse and fine-grained pyrite, pyrrhotite and chalcopyrite. A black copper oxide, melanterite (?) was found on the dumps on the property. In 1915, disseminated sulphides from the monzonite host assayed 5 to 7 grams per tonne gold (Geological Survey of Canada Memoir 77, page 131). In 1942, scheelite was detected in the shaft dump.

REFERENCE: Assessment Report 18786.

CAPSULE GEOLOGY

The Silver Dollar and Lucky Boy occurrences are underlain by greywackes, argillites and interbedded tuffs and flows of the Lower Jurassic Hall Formation, Rossland Group. Feldspar-quartz porphyry dykes and/or sills occur and are somewhat conformable to bedding. The strata, striking north and dipping 40 to 90 degrees east, has been folded and appears to have been overturned. A granitic stock of the Middle to Late Jurassic Nelson Intrusions occurs within several hundred metres of the workings.

CAPSULE GEOLOGY

The Silver Dollar occurrence occurs in argillite and consists of a crosscutting vein, up to 1.5 metres wide, striking 290 degrees and dipping steeply north. Sphalerite, galena with only minor chalcopyrite and pyrite occur erratically along the strike length of the vein with calcite and ankerite.

The Lucky Boy vein is hosted in a shear zone, striking about 020 degrees north and dipping 10 to 30 degrees east. Pyrite is found as euhedral crystals in all rocks types. Quartz within the shear zone occurs as veins, veinlets and stringers that are generally well fractured and broken. In and along the margins of the quartz are pyrite, chalcopyrite, galena, rare sphalerite and bornite and tetrahedrite. Alteration consists carbonatization and silicification. Samples taken from the underground working assayed up to 57.81 grams per tonne gold and 3790 grams per tonne silver and base metal values range up to 5.5 per cent lead, 3.7 per cent zinc and 0.82 per cent copper (Assessment Report 18786).

Production figures from both the Silver Dollar and the Lucky Boy workings are combined. Production was reportedly intermittent from 1899 to 1970 but records indicate that from 1947 to 1970, 5,425 tonnes of ore were mined which produced 50,916 grams of gold, 1,818,469 grams of silver, 52,597 kilograms of lead and 60,230 kilograms of zinc.

CAPSULE GEOLOGY

The Perrier mine is located 3 kilometres south of Nelson. The
 area has been intermittently explored since the early 1900's.

The area is underlain by altered augite (plus or minus
 plagioclase) basalt flows, flow breccia and subvolcanic intrusions of

CAPSULE GEOLOGY

the Lower Jurassic Elise Formation (Unit Jel), Rossland Group (Open File 1989-11). A tongue of granite to granodiorite of the Middle to Late Jurassic Nelson batholith occurs to the east.

There are three types of mineralization in the area: (1) gold-bearing quartz veins; (2) stratiform lead-zinc deposits; and (3) widespread disseminated sulphide mineralization. The veins appear to be fault controlled.

A flat lying quartz vein which crosscuts the regional foliation is hosted in chloritic schists. The vein strikes about 005 to 020 degrees and dips 35 to 60 degrees east. The vein, 0.25 to 0.55 metres wide, has been traced along strike for over 500 metres. The vein has quartz gangue with sphalerite, galena, pyrite, chalcopyrite and occasionally, free gold. Concentrations of sulphides are reported in zones where the vein has a flatter dip. A crosscutting vein which may be a branch of the main vein outcrops about 61 metres southeast of the shaft, strikes 330 degrees and has a vertical dip. This second vein hosts minute amounts of ruby silver and native silver with some carbonate (calcite).

The Julius Ceasar vein, about 450 metres due west of the Perrier mine, is hosted in quartz-feldspar porphyry. Chip samples assayed only low gold and silver values.

At the Lucky Boy adit, 150 metres south of the Perrier shaft, a mineralized zone, 0.45 metre wide, hosts galena, sphalerite, chalcopyrite and minor magnetite in schistose biotite tuffite. A grab sample taken in 1982 from the adit across the 0.45 metre assayed 0.190 per cent copper, 3.66 per cent lead, 5.75 per cent zinc, 114.5 grams per tonne silver, 2.71 grams per tonne gold (Assessment Report 10605). This deposit has been determined to be a Kuroko-type volcanogenic massive sulphide deposit.

Limited information and production records between 1913 and 1937 indicate the mine produced in excess of 2000 tonnes recovering over 34,681 grams of gold, 94,803 grams of silver, 14,384 kilograms of lead and 21,144 kilograms of zinc. Geochemical and geophysical survey results in 1988 were interesting (Assessment Report 17686).

CAPSULE GEOLOGY

The Catherine occurrence is located 6.5 kilometres south-southwest of Nelson. The Catherine Crown Grant was originally staked in 1902. Workings consist of a trench and three short adits.

The area is underlain by augite basalt flows, flow breccias and subvolcanic intrusions of the Lower Jurassic Elise Formation (Unit Jel), Rossland Group (Open File 1991-16). These are intruded by biotite granodiorite of the Late to Middle Jurassic Nelson Intrusions. The granodiorite forms a small stock with associated sills and late stage quartz veins.

The Catherine showing consists of one or more relatively flat lying quartz veins hosted in the granitic intrusive. Mineralization consists of galena, sphalerite, pyrite, chalcopyrite and pyrrhotite. The setting is similar to that of the Perrier mine (082FSW208), 800 metres to the west. The veins are 0.10 to 0.40 metre wide with local pinching and swelling. Vein material, often fractured and limonitic is composite with lenses or rafts of granite separating the quartz. Granitic wallrock alteration comprises weak to moderate sericitization locally accompanied by minor pyritization.

The original showing or Catherine vein was reported as being 1.2 to 1.8 metres wide, exposed by stripping for about 30 metres, northwest striking and about 30 to 35 degrees northeast dipping. Mineralization consists of pyrite, galena and free gold.

In 1983, the highest assay from the old workings was from a sample taken at the portal of adit #2 across 0.15 metres of quartz with galena, pyrite and sphalerite. This sample assayed 41.48 grams per tonne gold and 93.24 grams per tonne silver (Assessment Report 11720).

CAPSULE GEOLOGY

Recorded production, over the period 1928 to 1941, totalled 135 tonnes, yielding 5599 grams of gold, 15240 grams of silver, 3717 kilograms of lead and 1969 kilograms of zinc.

CAPSULE GEOLOGY

The Hummingbird occurrence is located 9 kilometres southeast of Nelson. The vein (veins ?) was being worked as early as 1922. Minor production is recorded for the years 1933, 1941 and 1960. Numerous open cuts, pits and trenches are scattered over the property. The setting is similar to the Wisconsin property (082FSE036) to the east.

The area is underlain by granite and granodiorite of the Late to Middle Jurassic Nelson Intrusions (Nelson batholith) near the contact with Lower Jurassic Ymir Group sediments. Sediments comprise argillite, quartzite, siltstone and limestone. Plutonic rocks outcrop north, south and east of the main showings and numerous granitic sills intrude the sediments. Post-ore faulting is observed.

Erratic and discontinuous breccia and quartz veins, containing sphalerite, galena, pyrite, some pyrrhotite, arsenopyrite and chalcopyrite, cut grey black argillaceous quartzite. The veins trend east which is roughly bedding-parallel. The veins occur in a 2 metre wide fault zone in brecciated and silicified country rock. The country rock is locally replaced by sphalerite, galena and pyrite. Mineralization occurs in crosscutting fractures/veinlets in open space filling textures, in bedding parallel veinlets, in veins and in discontinuous blebs and lenses.

The main vein averages about 15 centimetres wide, but may be up to 45 centimetres, strikes about 080 degrees and dips 45 to 50 degrees south. A minimum length of 35 metres is suggested from the character of the mineralization.

A 0.35-metre chip sample across a 0.25-metre wide quartz vein exposed in an open cut above the portal of the main vein assayed 1.15 grams per tonne gold, 4.8 grams per tonne silver, 0.26 per cent lead and 0.005 per cent zinc (Assessment Report 14867).

MINFILE NUMBER: **082FSW210**

CAPSULE GEOLOGY

In the years 1933 and 1941 minor production, totalling 77 tonnes, is recorded. The recovery was 1959 grams of gold, 4696 grams of silver, 1335 kilograms of lead and 5153 kilograms of zinc. Clean-up in 1960 produced 1711 grams of silver, 357 kilograms of lead and 973 kilograms of zinc from 20 tonnes of ore.

CAPSULE GEOLOGY

The Mammoth occurrence is located 15 kilometres south-southwest of Nelson. The area has been explored since 1917.

The area is underlain by sediments of the Hall Formation and

CAPSULE GEOLOGY

volcanic rocks of the Elise Formation both of the Lower Jurassic Rossland Group. These have been intruded by the Middle to Late Jurassic Nelson Intrusions.

Erratic but widespread molybdenum-copper, with minor lead-zinc-silver mineralization and traces of gold, occur within and around skarn and contact zones. The skarn zones, containing scattered mineralization, are hosted in volcanic and sedimentary rocks. Mineralization primarily occurs as disseminated pyrite, molybdenite, and chalcopyrite in skarn zones within augite porphyry and agglomerate of the Elise Formation adjacent to the Bonnington pluton. Locally, minor veins carry sulphides but further to the north (Keno 082FSW349) significant mineralization similar to the Fern mine (082FSW183) occurs. Tungsten was reported by Little in 1959 but this has not been verified except geochemically.

Silicification, potassic alteration and skarnification are most common in the volcanic rocks. Most of the sulphide-rich areas are at or near contact zones of volcanics with intrusive rocks. Although the hornfelsed argillites of the Hall Formation host significant disseminated pyrite and some pyrrhotite locally, no economic mineralization in these rocks is reported.

Recent samples taken from surface trenches assayed up to 0.066 per cent molybdenum, 1.66 per cent copper, 15.8 grams per tonne silver, 0.08 per cent lead, 0.143 per cent zinc and 0.1260 per cent nickel (Assessment Report 10416). Old drill core samples returned higher molybdenum values but the mineralization is very erratic. Only traces of gold have been reported.

CAPSULE GEOLOGY

The property is located on China Creek on the west side of the Columbia River 11.2 kilometres north of Trail, close to the main Highway.

Prospector Murray Swetz, of Vancouver, is reported to have obtained high scintillometer counts in the area in December 1967. He staked claims which were optioned to Calix Mines Ltd. in 1968. Norex Uranium Ltd. in 1968 acquired options on 66 claims in 3 groups in the same general area. Norex purchased a 50 per cent interest in 24 claims, the Atom 17-22 inclusive and Mota 1-18 inclusive, for \$48,500 from Prospector Matthew Pritchard, of Edmonton, by an agreement dated May 1969. The company carried out prospecting, trenching, and diamond drilling at a cost of \$9,162. Hogan Mines Ltd. in 1968 optioned 20 claims in the area from Prospector M. MacDougall of Nelson, who had conducted an airborne scintillometer survey over the area.

Silver Arrow Explorations Ltd. held a 20 claim uranium prospect in the area in 1968. The company in 1970 amalgamated with Buttle Lake Mining Company Limited under the name Stampede International Resources Ltd.

Subsequent events are lacking. Five companies: Golden Granite

CAPSULE GEOLOGY

Mines Limited, Groundstar Resources Limited, Nevex Mines Ltd., Nomad Mines Ltd. and Tandem Resources Ltd. in January 1977 formed China Creek Uranium Consortium Inc, to consolidate 78 units covering 4,800 acres in the area. Stampede International Resources Ltd. and Northwest Ventures Ltd. agreed to provide joint financing in return for share interests in China Creek Uranium. Work in 1977 included Preliminary scintillometer, geochemical, and radon gas detection surveys, trenching, and percussion drilling in 51 holes to depths of 15.2 to 30 metres. The drilling was done in two areas, the Oko Poko Hill on the northeast side of China Creek, and on the southwest side of China Creek opposite Oko Poko Hill.

Coarse-grained feldspar and quartz are the dominant minerals in layered, shallow-dipping pegmatoid horizons of the Late Cretaceous Castlegar Gneiss Complex (possibly the metamorphic equivalent of the Pennsylvanian to Permian Mount Roberts Formation). Euhedral and subhedral grains of pitchblende, up to 1 millimetre across, occur in the pegmatites. The best assay result was about 0.02 per cent uranium across a thickness of 45 centimetres (Skerl, 1968).

Several radioactive occurrences lie to the west of this showing.

CAPSULE GEOLOGY

The property is located at a 1067 metres elevation on the west side of Erie Creek, extending south from Grassy Creek, some 24 kilometres south-southwest of Nelson.

The Dora claim (Lot 5152) was Crown-granted to H. Porter in

CAPSULE GEOLOGY

1901. The following year the adjacent Drum Lummon (Lot 5481) was Crown-granted to P. Bums and the Homestake (Lot 3433) to The Copper Farm Gold Mining and Development Company, Limited. No work was reported but Map 52-13 A shows two adits in this vicinity.

The Consolidated Mining and Smelting Company Limited held an option on this ground in 1928 and diamond drilling was carried out.

Canzac Mines Ltd. in 1967 held Mineral Lease M 129 comprising the above claims and the adjoining Copper King (5153), Goodenough (5466), Monte Carlo (1066) and Nelson (12177), located on and extending south from Grassy Creek. The company also held Mineral Lease M 125 comprising the Rosa (2460), Belle (2461), Florence (3237) and Bully Boy (3238) reverted Crown-grants located about 1.6 kilometres to the south between Skillet and McKay creeks. The Hattie 1-32 claims were staked over the adjacent area, extending east of Erie creek to Young Grouse Creek, a tributary of Burnt Creek. Map 52-13 A shows an adit in the vicinity of the Rosa claim. Trenching was reported in 1967.

McIntyre Porcupine Mines Limited optioned the claims from Canzac by an agreement dated March 1968. Work by McIntyre in 1968-70 included geological mapping, a geochemical soil survey and 1703 metres of diamond drilling in 12 holes. Wollaston Lake Mines Ltd. acquired all the assets of Canzac Mines in 1969. The company name (Wollaston) was changed in 1971 to Comaplex Resources International Ltd. Under the option agreement McIntyre had to form a new company to acquire the property and accordingly Dalhat Mines Limited was incorporated March 1971 with Comaplex holding a 30 per cent share interest. Additional claims (Dal 1-17) were apparently staked at that time. Work in 1974 included geological mapping and an induced potential survey over 11.2 kilometres.

Canamax Resources Inc. apparently acquired the property.

The Copper King showings are located on the west side of Erie Creek, about 13.5 kilometres southwest of Ymir. The area was first explored in the 1890's. The workings, comprising numerous pits, adits and trenches, on the Drum Lummon, Copper King, Homestake and Dora claims are all now included in the Erie Creek property. There is only sparse information on these individual claims. The Arnold (082FSW301), Ben Hassen (082FSW300) and Hattie (082FSW226) occurrences are also part of this property.

The area is underlain by the Lower Jurassic Rossland Group Elise Formation volcanics and Archibald Formation sediments. The Rossland Group rocks are intruded by the Middle to Late Jurassic Nelson Intrusions, locally known as the Erie stock. The Erie stock is comprised of a light grey quartz monzonite with associated aplitic and feldspar porphyry dykes. Biotite hornfels is apparently a contact metamorphic effect related to both the Nelson batholith and the Erie Creek dyke swarm. It is mainly developed in argillite and siltstone. Chlorite occurs mainly on fractures and in shear veins in augite andesite and hornfels.

Mineralization on the property occurs roughly in four concentric zones. An inner quartz-molybdenum plus scheelite zone followed by a chalcopyrite zone, a pyrite-pyrrhotite zone and an outer sphalerite-galena zone. The inner zone is approximately 600 metres in diameter and is centered on the east side of Erie Creek. The host rocks are quartz monzonite dykes, stocks and white rhyolite. The chalcopyrite zone occurs over an area of 1.5 to 2 kilometres and occurs in quartz and sulphide veinlets as fracture coatings and in shear veins with pyrite, pyrrhotite and minor amounts of scheelite. Best copper values obtained, up to 1.3 per cent, were from vein and dump samples mainly from old workings on the west side of Erie Creek (Drum Lummon, Cooper King, Dora, Homestake). Pyrite and pyrrhotite, in an area about 1.5 by 2.5 kilometres, occurs finely disseminated and as fracture coatings. Sphalerite and galena with some gold occurs in shear veins beyond the inner zone, such as the Arnold (082FSW301) and Ben Hassen (082FSW300) showings.

On the Copper King claim stripping in 1934 exposed an irregular quartz vein over 11 metres. The vein, hosted in greenstone intruded by aplite dykes, strikes 345 degrees and dips 35 degrees east. Up to 1 metre of vuggy quartz contains greenstone inclusions, pyrite and arsenopyrite.

On the Dora claim, an open cut exposes an aplite dyke which has been fractured and filled with quartz, pyrite, galena and arsenopyrite. The Dora adit near the eastern boundary was driven on a mineralized stockwork in white rhyolite and may be within the inner quartz-molybdenum plus or minus scheelite zone although there is no documented evidence. In 1987, a sample of hornfels with chalcopyrite, taken from the northeastern boundary of the Dora claim, assayed 20.2 grams per tonne silver and 0.445 grams per tonne gold (Assessment Report 15510).

The Drum Lummon workings comprise four adits in argillaceous

CAPSULE GEOLOGY

rocks described as hosting chalcopyrite mineralization in fractures.

Sampling done in the vicinity of the Drum Lummon, Copper King and Homestake workings in 1987 had low assay results (Assessment Report 18478).

The mineralization is believed to be part of a zoned porphyry type deposit which has a central quartz vein stockwork zone containing molybdenum-copper-tungsten mineralization and a peripheral zone with veins containing copper, lead, zinc and silver mineralization. These showings are interpreted as occurring in the peripheral zone, since there is no documented evidence of molybdenum or tungsten mineralization.

CAPSULE GEOLOGY

A brown weathering serpentinite body, of probable Permian age, outcrops in the valley of Little Sheep Creek and is thought to be part the ultramafic intrusions of the Slide Mountain terrane. The serpentinite is in contact with altered volcanics of the Lower Jurassic Rossland Group, Elise Formation. These rocks are intruded by a syenite mass of the Middle Eocene Coryell Intrusions. Two masses of serpentinite lie within the Rossland map area and have relatively straight and transgressive margins. These lenticular masses form part of a linear belt extending 10 kilometres southwest from Rossland where it is truncated by the Coryell Batholith. The serpentinite is thought to have been emplaced along the Rossland break, which was the locus of dislocation and intrusion before the emplacement of the Coryell syenite. The northerly trending eastern

CAPSULE GEOLOGY

and western margins of the small serpentinite mass in Little Sheep Creek are known to be faults. The northern contact exposed in the workings of the Midnight (082FSW119) and I.X.L. (082FSW116) mines is highly sheared and associated with a zone of intense fracturing.

The typical massive serpentinite is a very dense black rock and hosts abundant serpentine and magnetite. Cross-fibre asbestos has infilled many joints as 0.2 to 0.6 centimetre veinlets and light green talc has developed in the immediate vicinity of the faults.

The serpentinite has been explored for deposits of nickel and chromium. Chromite occurs on the west side of Ivanhoe Ridge between the two main forks of Sophia Creek (Vandot - 082FSW130). Here visible chromite is exposed in trenches. In 1969, near the northern mass of serpentinite on the Midnight property (082FSW119) along the west side of Little Sheep Creek, companies sampled the underground workings and reported several thousand tonnes of serpentinite averaging 0.25 per cent nickel. Selected samples assayed as high as 0.45 per cent nickel (Bulletin 74, page 23). Chromite is associated with the fine-grained serpentinite. Samples were submitted to the Geological Survey of Canada and pyrite, millerite and a mineral of the linnaeite group were identified. Ten samples taken by Fyles (Bulletin 74) at various places throughout the two masses of serpentinite exposed in the area gave nickel assays of less than 0.24 per cent.

COMMENTS: Taken across 18.9 metres. Grade given for calcium oxide. Grade is in per cent.

REFERENCE: Minister of Mines Annual Report 1962, page 154.

CAPSULE GEOLOGY

A band of limestone of the Lower Cambrian Reeves Member of the Laib Formation outcrops on Swift creek, 500 metres northwest of its confluence with the Salmo River, and continues northeastward for 450 metres. The band contacts metamorphosed sedimentary rocks to the northwest and is intruded to the southeast by granite of the Middle to Late Jurassic Nelson Intrusions. Bedding strikes 049 degrees and dips 40 degrees northwest.

The deposit is comprised of interlayered 2.5 to 5 centimetre thick beds of blue grey and white, medium grained limestone with a few 0.6 to 0.9 metre thick zones of coarse grained white limestone (marble). A sample of chips taken at 0.30 metre intervals across 18.9 metres near the top of a quarry contained 50.89 per cent CaO, 1.7 per cent MgO, 6.32 per cent insolubles, 0.46 per cent R2O3, 0.46 per cent Fe2O3, 0.012 per cent MnO, 0.011 per cent P2O5, 0.014 per cent sulphur and 41.16 per cent ignition loss (Minister of Mines Annual Report 1962, p. 154).

CAPSULE GEOLOGY

International Marble & Stone Company initially quarried some limestone in 1962 about 90 metres north of Swift Creek on Lot 1594. Quarrying operations recommenced in 1969 and continued up to 1983, when the company encountered access problems to the site. Between 1972 and 1983, 70,469 tonnes of limestone were quarried.

COMMENTS: Highest assay from sampling of seven zones across intervals up to 2.37 metres in width and lengths up to 35 metres, on the Inez structure.

REFERENCE: Vancouver Stockwatch, Sept. 12, 1989.

CAPSULE GEOLOGY

The Rand and Inez veins are located in a mountain valley 20 kilometres northwest of Salmo. These are part of the Second Relief mine (082FSW187) which was the third largest gold-enriched skarn producer in the province.

The area is underlain by lapilli tuff and augite porphyry volcanics of the Elise Formation and siltstone, sandstone, argillite and quartzite of the Archibald Formation, both of the Lower Jurassic Rossland Group. These occur as a roof pendant within granodiorite of the Bonnington pluton of the Middle to Late Jurassic Nelson Intrusions. The veins occur on the west limb of a small anticline, whose axis runs down the Erie Creek valley, near the Red Mountain

CAPSULE GEOLOGY

fault.

The Rand and Inez vein systems crosscut the sediment-volcanic stratigraphy, striking generally northeast with steep northwest dips, converging towards the No. 2 adit. Vein mineralization is generally erratic comprising mineralized lenses of massive sulphides in the order of 0.4 by 9 metres along strike. Mineralization consists of pyrite, pyrrhotite and chalcopyrite. Gold also occurs as very fine flakes and minute particles.

The Inez vein structure, located west of Erie Creek, extends 320 metres from northeast to southwest. On this structure, 7 zones of possible significant mineralization have been identified. At the portal, the Inez vein is on the hanging wall of a banded, light buff coloured, 1-metre thick rhyolite dyke which is strongly faulted at the footwall contact. The vein is hosted in fragmental volcanic rocks with bands of siliceous hornfelsed sedimentary rocks. Sampling of these seven zones across intervals up to 2.37 metres in width and lengths of up to 35 metres assayed up to 21.73 grams per tonne gold (Vancouver Stockwatch, Sept. 12, 1989).

The Rand vein has been traced on surface for over 420 metres. The vein is cut off at the No. 2 portal crosscut by a strong fault containing up to 12 centimetres of gouge of crushed wallrock. A grab sample of weathered material, from the Rand vein, containing pyrrhotite and quartz assayed 238.9 grams per tonne gold and 38.05 grams per tonne silver (Vancouver Stockwatch, July 11, 1989). An unknown amount of ore was extracted from this vein.

CAPSULE GEOLOGY

The Eureka Crown grant is underlain by the Rainy Day pluton of the Middle to Late Jurassic Nelson Intrusions comprised of quartz-monzonite to quartz-diorite. The monzonite is medium-grained and hosts epidote, apatite, sphene, with minor sericite and penninite.

On the property there is a quartz vein, outcropping on the east side of Little Sheep Creek, which hosts pyrite, molybdenite and chalcopyrite. The vein is within the monzonitic stock and hosts pyrite cubes. Pyritized fracture planes trend north to south.

COMMENTS: The ore reserve is reported as 68,141 tonnes grading 0.62% WO₃.

REFERENCE: Boronowski, 2001 (Property File).

CAPSULE GEOLOGY

The Invincible orebody is adjacent to the western margin of the Dodger stock of the Middle to Late Jurassic Nelson Intrusions where it transects flat-lying beds of the Reeves Member limestone of the Lower Cambrian Laib Formation. The tungsten ore zone lies northward and along strike, but on the east side of the Granite fault, from the Feeney (082FSW247) and Emerald (82FSW010) deposits.

The orebody occurs on the overturned limb of the Jersey anticline and is bounded above and below by skarn and argillite of the Truman and Emerald members of the Laib Formation respectively. Most of the scheelite occurs in lenticular zones that extend at a

CAPSULE GEOLOGY

high angle from the granitic stock, more or less conformable with layering of the marble. The scheelite occurs as fine, disseminated grains within garnet-diopside skarn and is accompanied by pyrite, pyrrhotite, minor powellite and traces of molybdenite and wolframite. Quartz is common in zones of mineralized granite.

The ore zone extends up to 24 metres from the stock, and may be more than 3 metres thick in places. The zone lies about 260 metres below surface and produced 256,480 tonnes of 0.65 per cent WO₃ from 1970 to 1973 (Geology, Exploration and Mining in British Columbia 1973, pages 54-57). Production is included with the Emerald Tungsten mine (082FSW010) and recorded with the production statistics of the Jersey mine (082FSW009).

Ore Reserves calculated by Canadian Exploration Ltd. (Canex) in August 1973 estimated that the Invincible Tungsten Mine contains a combined probable, possible and marginal ore reserve of 68,141 tonnes grading 0.62% WO₃ (Boronowski, 2001). This represents approximately 335,089 kilograms (738,748 pounds) of tungsten.

The majority of the reserves are reported to be accessible from the underground workings. As of 2001, the northern extension of the Invincible mine remained untested.

CAPSULE GEOLOGY

Development of the 240 K zone, which lies east of the Annex, was in progress in 1973. Probable reserves in this zone were estimated at about 300,000 tons. (Reeves 1973 Annual Report). The mine closed in April 1975.

The Annex mine is on the south side of the Pend d'Oreille River and is located within dolomitized Reeves Member limestone of the Lower Cambrian Laib Group. The orebody appears to be a downfaulted section of the Reeves MacDonald ore zone (082FSW026) but reportedly contains higher metal grades than the Reeves. The sulphides within the dolomite included galena, sphalerite and pyrite with minor chalcopyrite. The mine produced a lead and zinc concentrate from which lead, zinc, silver, copper and cadmium metals were recovered.

Production from the Annex mine from 1970 to 1975, inclusive, totalled 763,314 tonnes of ore. From this ore 34,052,093 grams of silver, 7,136,975 kilograms of lead, 42,679,634 kilograms of zinc, 482,244 kilograms of cadmium and 16,492 kilograms of copper were recovered. The above production includes a small amount of salvage ore from the Reeves MacDonald mine.

Drilling from 1986 to 1988 by Golden Eye Minerals Ltd. intersected the Annex zone. Hole 87-1 yielded 167 metres averaging 8 per cent zinc, 0.88 per cent lead, 0.09 per cent cadmium and 54.9 grams per tonne silver, including 8 metres of 10 per cent zinc, 1.64 per cent lead, 0.12 per cent cadmium and 75.8 grams per tonne silver. Hole 88-1 yielded 9 metres averaging 7.53 per cent zinc, 0.39 per cent lead, 0.08 per cent cadmium and 106.6 grams per tonne silver (Northern Miner, May 25, 1998). In 1998 Redhawk Resources Inc. drilled the Annex zone from the Caviar 5 claim west of the Annex Mine (Assessment Report 25675). The Annex system was extended another 200 metres to a total of 365 metres of downplunge continuity. Hole 98-1 (extension hole) assayed 13 metres of 3.35 per cent zinc, 0.1 per cent lead and 4.46 grams per tonne silver (GCNL #163 (Aug.25), 1998).

The Annex property was included in the April 2000 option agreement between Redhawk and Reeves MacDonald Mines Limited where Redhawk has a 4-year option to purchase the Reeves property. Redhawk and joint venture partner Zinc Ox Resources plan to explore the Redbird (082FSW024) and the Reeves MacDonald option collectively under the Remac project name. See the Redbird & Reeves MacDonald for further information.

CAPSULE GEOLOGY

A small inlier of metamorphic rocks, possibly of the Lower Jurassic aged Rossland Group, Elise Formation outcrop directly east of Salmo in contact with granite of the Middle to Late Jurassic Nelson Intrusions. The metamorphic rocks carry disseminated grains of pyrite and molybdenite and the mineralization has a northerly trend coincident with the gneissosity.

CAPSULE GEOLOGY

The claim is underlain by Lower Jurassic Rossland Group, Elise Formation consisting of greenstone, volcanic breccia, volcanic conglomerate and sandstone. These are intruded to the north by the Rossland monzonite, an east trending stock of biotite-hornblende-augite monzonite. A small syenitic mass of the Middle Eocene Coryell intrusions intrudes the strata to the east.

Mineralization occurs in quartz-carbonate veinlets which host minor arsenopyrite and pyrite in the altered Rossland Group rocks. Associated with the veinlets are minor amounts of disseminated scheelite and pyrite with the wallrock.

CAPSULE GEOLOGY

Rossland Group. Lamprophyre dykes intrude the volcanic rocks. Biotite and pyrite alteration and isolated lenses of hornfelsed volcanics containing epidote-chlorite-garnet alteration are present near the contact.

Mineralized quartz veins, mainly in granitic rocks, contain pyrite, minor galena, sphalerite and molybdenite. Significant gold values are associated with pyrite. Molybdenite also occurs as isolated blebs in pegmatite veins. The veins are generally less than 0.5 metre wide. It is suspected that some of the quartz veins are localized by shears.

The discontinuous Whitewater vein is up to about 1.8 metres wide at the contact and is hosted in fractured country rock. The quartz is mineralized with pyrite but the gold values are erratic. The vein strikes 40 degrees and dips 60 degrees south. A drill hole sample in 1970 assayed 8.9 grams per tonne gold over 0.67 metre (Property File - Snowwater Resources Ltd., Prospectus, July 1988).

To the east of the Whitewater workings, drilling has been undertaken on the Breccia zone. The best intersection was across 1 metre and assayed 1.54 grams per tonne gold and 1.0 gram per tonne silver (Assessment Report 1990).

High grade float boulders of quartz mineralized with pyrite, occasional free gold and sporadic, minor sphalerite and galena have been traced along Whitewater Creek through the Columbia and Snowwater Crown Grants. The boulders appear to be related in part to schistose volcanics from south of the known vein exposures.

CAPSULE GEOLOGY

The Zilora occurrence is hosted by siltstone and hornfelsic siltstone of the Lower Jurassic Elise Formation, Rossland Group. The showing occurs within the contact aureole of the Early Jurassic Rossland monzonite. The Rossland monzonite has recently been age dated at 190 million years and consists of a biotite-hornblende-augite monzonite stock. The grey to black siltstone and argillite grades to hornfels and forms distinct layers within the Rossland Group volcanic breccias. Ammonites of Early Jurassic age were reported to occur in the siltstone on Ivanhoe Ridge. The showing is considered as part of the south belt of mineralization in the Rossland camp.

CAPSULE GEOLOGY

The Zilor vein trends east, with a strike between 090 and 145 degrees, dipping 75 degrees north. Vein mineralization consists of galena, sphalerite, pyrrhotite, arsenopyrite and chalcopyrite. The veins are hosted by the grey, hornfelsic siltstone which also contains disseminated pyrite. One sample assayed 1 gram per tonne gold, 306 grams per tonne silver, 0.08 per cent copper and greater than 1 per cent each of lead and zinc (Assessment Report 18310). Two old shafts are reported to exist on the Zilor property.

CAPSULE GEOLOGY

The Rainy Day claim is underlain by a small mass of quartz diorite of the Middle Eocene Rainy Day pluton. It is named after the Crown-granted claim which covers the central part of the pluton. The pluton is in contact with Lower Jurassic Elise Formation (Rossland Group) hornfels, banded hornfels and siltstone and is intruded on the west by syenite and monzonite of the Middle Eocene Coryell Intrusions. In 1983, a sample of the Rainy Day quartz diorite gave a potassium-argon age of 49.6 plus or minus 1.5 million years (Bulletin 74). The intrusive margins of the stock are sharp and irregular and underground mapping from the Le Roi mine (082FSW093) workings suggest the pluton may be tabular with a low to moderate dip.

Surface exposures are of light grey porphyritic and non-porphyritic quartz diorite. The non-porphyritic facies forms the central core and the porphyritic facies the marginal zone; both are truncated to the west by the Coryell syenite. The porphyritic, and to a lesser extent, the non-porphyritic quartz diorite are highly fractured with a network of intersecting veinlets containing fine-grained pyroxene, quartz, hornblende, biotite, chlorite, carbonates and sulphides comprised mainly of pyrite and molybdenite. Accessory minerals are apatite, sphene, magnetite and

CAPSULE GEOLOGY

The St Louis Crown grant is underlain by siltstone, argillite and hornfels of the Pennsylvanian and possibly Permian Mount Roberts Formation. To the north, the Mount Roberts rocks are intruded by the granodiorite of the Middle to Late Jurassic Trail pluton and to the south by rocks of the Early Jurassic Rossland monzonite. Augite porphyry (Rossland sill) of the Elise Formation, Rossland Group is also reported in the area. The country rock is highly metamorphosed with some skarn alteration as a result of the intrusions.

Weak sulphide mineralization consisting of disseminated pyrite, pyrrhotite and minor chalcopyrite occurs in the area. Lenses of mainly pyrrhotite also occur. Chalcopyrite is found in the skarn and other metamorphic rocks in the area of the St. Louis shaft.

CAPSULE GEOLOGY

The property is located at a 1067 metres elevation on the west side of Erie Creek, extending south from Grassy Creek, some 24 kilometres south-southwest of Nelson.
The Dora claim (Lot 5152) was Crown-granted to H. Porter in 1901. The following year the adjacent Drum Lummon (Lot 5481) was Crown-granted to P. Bums and the Homestake (Lot 3433) to The Copper Farm Gold Mining and Development Company, Limited. No work was reported but Map 52-13 A shows two adits in this vicinity.
The Consolidated Mining and Smelting Company Limited held an option on this ground in 1928 and diamond drilling was carried out.
Canzac Mines Ltd in 1967 held Mineral Lease M 129 comprising the above claims and the adjoining Copper King (5153), Goodenough (5466),

CAPSULE GEOLOGY

Monte Carlo (1066) and Nelson (12177), located on and extending south from Grassy Creek. The company also held Mineral Lease M 125 comprising the Rosa (2460), Belle (2461), Florence (3237) and Bully Boy (3238) reverted Crown-grants located about 1.6 kilometres to the south between Skillet and McKay creeks. The Hattie 1-32 claims were staked over the adjacent area, extending east of Erie creek to Young Grouse Creek, a tributary of Burnt Creek. Map 52-13 A shows an adit in the vicinity of the Rosa claim. Trenching was reported in 1967.

McIntyre Porcupine Mines Limited optioned the claims from Canzac by an agreement dated March 1968. Work by McIntyre in 1968-70 included geological mapping, a geochemical soil survey and 1703 metres of diamond drilling in 12 holes. Wollaston Lake Mines Ltd acquired all the assets of Canzac Mines in 1969. The company name (Wollaston) was changed in 1971 to Comaplex Resources International Ltd. Under the option agreement McIntyre had to form a new company to acquire the property and accordingly Dalhat Mines Limited was incorporated March 1971 with Comaplex holding a 30 per cent share interest. Additional claims (Dal 1-17) were apparently staked at that time. Work in 1974 included geological mapping and an induced potential survey over 11.2 kilometres.

Canamax Resources Inc. apparently acquired the property.

The Hattie showing is located on the east side of Erie Creek, about 12 kilometres southwest of Ymir. This showing, along with the Copper King (082FSW213), the Arnold (082FSW301) and the Ben Hassen (082FSW300) showings, occur on the Erie Creek property.

The area is underlain by Lower Jurassic Archibald Formation, Rossland Group sediments. The Rossland Group rocks are intruded by the Middle to Late Jurassic Nelson Intrusions, locally known as the Erie stock. The Erie stock is comprised of a light grey quartz monzonite with associated aplitic and feldspar porphyry dykes. Biotite hornfels is apparently a contact metamorphic effect related to both the Nelson batholith and the Erie Creek dyke swarm. Hornfels is mainly developed in argillite and siltstone. Chlorite occurs mainly on fractures and in shear veins in augite andesite and hornfels.

Drilling and prospecting have identified molybdenite mineralization on fracture surfaces and in quartz veinlets within quartz monzonite. Molybdenite with pyrite, pyrrhotite, minor chalcopyrite, and rare scheelite is disseminated in quartz veinlets associated with a quartz stockwork texture and as selvages on fracture surfaces. The mineralization, associated with the Erie Creek dyke swarm of felsic and mafic dykes, is not confined to the intrusive suite. Weak quartz-sericite-pyrite alteration occurs in envelopes along and adjacent to fractures and molybdenite-quartz veins.

Mineralization on the property occurs roughly in four concentric zones. An inner quartz-molybdenum plus scheelite zone followed by a chalcopyrite zone, a pyrite-pyrrhotite zone and an outer sphalerite-galena zone. The inner zone is approximately 600 metres in diameter and is centered on the east side of Erie Creek. The host rocks are quartz monzonite dykes, stocks and white rhyolite. The chalcopyrite zone occurs over an area of 1.5 to 2 kilometres and occurs in quartz and sulphide veinlets as fracture coatings and in shear veins with pyrite, pyrrhotite and minor amounts of scheelite. The best copper values obtained, up to 1.3 per cent, were from vein and dump samples mainly from old workings on the west side of Erie Creek (Drum Lummon, Cooper King, Dora, Homestake). Pyrite and pyrrhotite, in an area about 1.5 by 2.5 kilometres, occur finely disseminated and as fracture coatings. Sphalerite and galena with some gold occur in shear veins beyond the inner zone, such as the Arnold (082FSW301) and Ben Hassen (082FSW300) showings.

The inner quartz-molybdenite plus or minus scheelite zone is approximately centered on the Hattie or June 2 claim. Host rocks are quartz monzonite dykes and stock, and white rhyolite. Grades in the zone range from 0.01 to 0.059 per cent molybdenum; 0.0166 to 0.196 per cent copper and 0.005 to 0.14 per cent tungsten (Assessment Report 15510). Best results reported by McIntyre Porcupine Mines were 85 metres of 0.115 per cent MoS₂ and 0.05 per cent copper, including 30 metres of 41.14 grams per tonne silver (Assessment Report 15510).

The mineralization is believed to be part of a zoned porphyry-type deposit which has a central quartz vein stockwork zone containing molybdenum-copper-tungsten mineralization and a peripheral zone with veins containing copper, lead, zinc and silver mineralization. This showing is interpreted as occurring in the central stockwork zone.

CAPSULE GEOLOGY

The Rex showing is located near Blewett, at 610 metres elevation 9.6 kilometres west of Nelson. The location is uncertain. The area is underlain by Jurassic pseudodiorite and pyroxenite of unknown affinity and granitic rock of the Late to Middle Jurassic Nelson Intrusions. Chalcopyrite occurs in an aplite dyke within granitic rocks. No other information is available.

CAPSULE GEOLOGY

The Loto 3 showing is located along Blueberry Creek, in a roadcut about 1.3 kilometres northwest of the Nancy Green Lake cut-off.

The area is underlain by Paleozoic (?) argillaceous quartzites and argillites which may be part of the Lower Jurassic Rossland Group. These metamorphosed sediments have been intruded by the Middle to Late Jurassic Nelson Intrusions, comprised mainly of granite and granodiorite, and then later by Middle Eocene Coryell Intrusion syenite and associated dykes.

Scheelite mineralization is exposed along a highway roadcut within a 9-metre wide quartz vein. Disseminated scheelite occurs in

CAPSULE GEOLOGY

quartz veins just northwest of this main showing and in several places west of the highway. The host rock is skarn which is crosscut by numerous dykes and dioritic intrusives.

West of the mineralized roadcut, a brecciated dyke, possibly related to the Coryell Intrusion, hosts specular hematite and malachite.

A selected grab sample taken in 1980 from a quartz vein with scheelite assayed 10.97 per cent W_3O_8 (Assessment Report 8187).

CAPSULE GEOLOGY

The property is located at approximately 1524 metres elevation on the south side of Stewart Creek 3.2 kilometres west-northwest of

CAPSULE GEOLOGY

Ymir.

Early work on the showings, for which there is no record, included a 8-metre adit. Drysdale, 1917 (GSC Memoir 94) reported molybdenum on a claim towards the headwaters of Stewart Creek.

The Stewart group of 8 claims and the Stewart No. 2 group of 13 claims were staked in 1942 by E.P. Harkedahl, O.P. Anderson, and E. Emilson of Ymir. Premier Gold Mining Company, Limited optioned the property in July of that year. Work by the company included prospecting, stripping, trenching, reopening the old adit, and sampling. The option was given up in November of that year.

The Consolidated Mining and Smelting Company of Canada Limited optioned the property in 1943 and sampled the showings. A bulk sample was taken for a mill test. The option was dropped in July of that year.

The showings were restaked by Harkedahl and associates in about 1948 as the Scheelite and Scheelite 2-6 claims and the adjacent N.H. group of 8 claims. The 14 claims were optioned to K.J. Springer and associates who incorporated Arrow Tungsten Mines Limited in March 1951 to acquire the property. Mineralization in trenched zones A, B and C was estimated at 330 tons per vertical foot averaging 0.50% WO₃. If this continued down dip for 61 metres the probable reserve would be 66,000 tons (DM Cannon 5/04/51 in Arrow Tungsten Mines Limited Prospectus 30/04/51). The company drove an adit southerly for 140 metres. At 58 metres from the portal a raise was driven 27 metres to old surface workings. Diamond drilling at right angles to the adit was done in 3 holes to the east and 7 to the west. Only spotty scheelite and powellite was found in the narrow skarn band which the adit followed for 62 metres when it became indistinguishable. No mineralization was reported encountered by the diamond drilling. Work ceased in March 1952.

The property was held in 1978 as the Stewart 1-4 claims (66 units) by Eric and Jack Denny, of Nelson. A geochemical soil and silt survey was carried out over Stewart 1-3.

The Stewart 2 showing is located 4 kilometres west of Ymir and 28 kilometres south of Nelson. The property was staked in 1978. The Stewart 2 and Bobbi (082FSW250) occurrences are the most significant porphyry showings in the Nelson-Ymir area.

The area is underlain by the Lower Jurassic Elise and Hall formations of the Rossland Group which hosts a multi-stage intrusive complex. The complex comprises Middle to Late Jurassic Nelson quartz monzonite porphyries, Middle Eocene biotite augite monzonite Coryell Intrusions with related aplite, diabase and lamprophyre dykes. The intrusive complex and surrounding sediments and volcanics locally host, sometimes overlapping, silica flooding, potassium metasomatism, quartz-stockwork development, argillic, sericitic, and propylitic alteration. The volcanic rocks comprise intermediate to mafic flows, fine pyroclastic units, augite porphyry, agglomerate and volcanic breccias.

Tungsten-bearing skarns and pyrite-pyrrhotite veins with lead-zinc-silver values have been documented around the margins of the complex. Gold has been identified only in trace amounts within the intrusives but occurs as free gold and with pyrite within quartz veins peripheral to the intrusive complex.

Molybdenite has been identified as sparse disseminations and selvages on fracture surfaces within quartz-stockwork zones and in the Phase I Breccia unit. It is most extensive within the Phase II Breccia on the northwest margin of the complex where it occurs in a pipelike breccia body as fine disseminations within the matrix, as selvages on fractures and within quartz veinlets. Molybdenite is also disseminated within the quartz monzonite porphyry breccia fragments and more rarely forms quartz-molybdenite fragments within the molybdenum rich matrix of the Phase II Breccia.

Powellite is a common alteration mineral on surface of the Phase II Breccia and the breccia is associated with strong pyrite-sericite alteration.

Drill testing has identified reserves of 204,000 tonnes grading 0.22 per cent molybdenite within the Phase II Breccia zone. Actual grade is 0.37 per cent MoS₂ (Assessment Report 10072). Conversion used for MoS₂ to Mo is 1.6681.

Extensive geological mapping, rock geochemistry, ground and airborne geophysics and diamond drilling have been carried out over the intrusive complex and the surrounding country rocks.

CAPSULE GEOLOGY

The Silver 1 showing is located on the east side of Cottonwood Creek about 5 kilometres south of Nelson.
The area is underlain by intermediate volcanics and volcaniclastics of the Lower Jurassic Elise Formation (units Je1 and Je10), Rossland Group (Open File 1989-11). The stratigraphy is intruded by granite sills related to Middle to Late Jurassic granites and granodiorites of the Nelson Intrusions. A southerly extension of the Nelson batholith occurs to the east.
The showing consists of galena, sphalerite, pyrite and sparse chalcopyrite occurring along planes of schistosity. The mineralized zone has been exposed for a strike length of about 65 metres with a variable width of 1 to 3 metres. The zone is hosted in biotite schist. Reports indicate that some sulphide mineralization is also associated with the contact alteration zone of a 1-metre thick

CAPSULE GEOLOGY

granitic dyke.

Assays are erratic and tonnage potential is estimated to be very low. Values of 0.5 to 5.65 per cent lead, 4 to 13.45 per cent zinc and 13 to 497.2 grams per tonne of silver have been reported. A grab sample, taken in 1979 across 3 metres, from a trench 9 metres south of the main shaft, assayed 57.93 grams per tonne silver, 1.85 per cent lead and 7.36 per cent zinc (Assessment Report 7377).

COMMENTS: The sample width is 16.8 metres.
REFERENCE: Assessment Report 7377.

CAPSULE GEOLOGY

The Silver 5 showing is located along Selous Creek about 5 kilometres south of Nelson.

The area is underlain by intermediate volcanics and volcaniclastics of the Lower Jurassic Elise Formation (Units Je1 and Je10), Rossland Group (Open File 1989-11). The stratigraphy is intruded by porphyritic granite dykes related to Middle to Late Jurassic granites and granodiorites of the Nelson Intrusions.

The Silver 5 showing consists of schistose limestone containing bands of galena, sphalerite, pyrite and chalcopyrite. The zone is exposed for about 122 metres along strike with an apparent width of about 17 metres. The zone strikes directly north with a variable dip between 85 degrees west to 45 degrees east. This is possibly a replacement deposit.

Assay values are erratic and a sample 16.8 metres wide assayed 124.4 grams per tonne silver, 13.46 per cent lead and 1.3 per cent zinc (Assessment Report 7377).

CAPSULE GEOLOGY

The Hilltop showing consists of an extension of the quartz vein system at the Spokane (082FSE032) and Harris (082FSE078) occurrences), to the northeast, and several small associated veins at variable orientations. The showing is hosted by Hadrynian Monk Formation sediments of the Windermere Supergroup (correlative with pelitic rocks of the lower Horsethief Creek Group). These sediments have been intruded by granodiorite of the Middle to Late Jurassic Nelson Intrusions.

The general trends of the veins are east-west with steep north dips. The veins, which average 1 to 2 centimetres in width, host small lenses, stringers, and disseminations of pyrite, pyrrhotite, galena, sphalerite and some minor chalcopyrite. Gold and silver contents are apparently low.

CAPSULE GEOLOGY

Granites of the Middle to Late Jurassic Nelson Intrusions intrude phyllites, argillites, limestones and quartzites of the Lower Cambrian, upper Laib Formation. The intrusive contacts are irregular and rafts of sediments are contained within granitic intrusives. The Ness showing consists of quartz veining (in an area 45 by 60 metres), which contains some disseminated pyrite and chalcopyrite. Geochemistry indicates trace to very low amounts of copper with trace amounts of various other metals. No significant economic mineralization is documented.

CAPSULE GEOLOGY

The Blue Eyes showing is underlain by a non-porphyrific granodiorite of the Middle to Late Jurassic Trail pluton (Nelson Intrusions) that contains small shears and joints along which quartz veins are exposed in an adit driven westward at an elevation of 1371 metres. In trenches, five or more quartz veins, ranging up to 10 centimetres in width, host crystals of scheelite which range up to 2.0 centimetres in length. In general, these large crystals are in clusters and give a high tungsten content over a few square centimetres. However, the average grade of the veins is low.

An adit followed a series of small joints and shears that contain quartz veins bearing pyrite. Scheelite is present almost the whole length. Some of the veins are up to 30 centimetres in width and host scheelite along the margins. The smaller veins occupy joints in the granodiorite with scheelite disseminated in the veins and penetrating several centimetres into the wallrock. In 1942, a channel sample taken across 30 centimetres of vein and wallrock about 121 metres from the portal, assayed 0.33 per cent WO₃ and 0.17 per

COMMODITY: Gold 4.4200 Grams per tonne
COMMENTS: Sample #10133 from exposure along Connor Creek, across 1 metre. Also
2.4 grams per tonne silver.
REFERENCE: Assessment Report 18518.

CAPSULE GEOLOGY

The Hungary Man showing is located 20 kilometres southwest of Nelson. The claim was Crown granted in 1900 and two shafts and a crosscut were developed.

A pendant of feldspar porphyry andesite of the Lower Jurassic Elise Formation, Rossland Group occurs in diorite of the Middle to Late Jurassic Nelson Intrusions. The area has been mapped as being underlain by sediments of the Lower Jurassic Ymir Group.

Mineralization consists of massive to semi-massive sulphides in a schistose volcano-sedimentary sequence. Sulphides comprise pyrrhotite, pyrite and minor chalcopyrite in quartz gangue. There are indications that the mineralization continues for at least 300 metres. The mineralization appears to be concentrated along the andesite-diorite contact in mineralized shear and breccia zones. This is possibly a Besshi-type deposit.

The Hungary Man showing consists of sulphides in lenses up to 7 metres across and up to over 30 metres in length. These zones trend north-south parallel to the local structure striking 340 degrees and dipping 08 degrees north. Similar mineralization occurs on the

CAPSULE GEOLOGY

adjacent Connor and Anne-Marie claims.

A channel sample (#10133) from an exposure along Connor Creek assayed 4.42 grams per tonne gold and 2.4 grams per tonne silver over 1 metre (Assessment Report 18518). Results from a soil sampling program on the Anne-Marie claim to the north in 1989 were interesting.

SAMPLE TYPE: Rock
COMMODITY GRADE
Silver 1.1200 Grams per tonne
Gold 1.0200 Grams per tonne
COMMENTS: A sample taken from the Bluestar adit.
REFERENCE: Assessment Report 13489.

CAPSULE GEOLOGY

Underlying the Bluestar occurrence are black argillites, phyllites, quartzites and limestones of what Little (1985) calls the "Pend d'Oreille Sequence" of Yates. These have a Silurian(?), Lower and Middle Devonian, and Carboniferous(?) age (Geological Survey of Canada Open File 1195, page 9). These rocks are exposed west of Tillicum Creek and south of the Waneta fault which brings them in fault contact with the sediments and volcanics of the Jurassic Rossland Group.

The Bluestar showing consists of quartz veining along a north trending shear zone. The quartz carries minor disseminated pyrite and occasional flecks of chalcopyrite, galena and sphalerite. The zone is in the order of 1 to 2.5 metres wide and traceable along strike about 500 metres. No significant metal values were obtained by assaying samples. Mineralization appears sporadic although one sample at the Bluestar adit contained 1 part per million gold with a trace of silver (Assessment Report 13489).

CAPSULE GEOLOGY

The Kena Gold showings are located about 7 kilometres south of Nelson and are part of the larger Kena property of Sultan Minerals Inc. The Kena property hosts a number of porphyry style, gold and gold-copper occurrences. The property lies on the eastern limb of the Hall Creek Syncline, a south-plunging fold associated with intense shearing that dominates the structure of the Nelson map area. The syncline incorporates volcanic and lesser sedimentary rocks of the Lower Jurassic Elise Formation (Rossland Group) which are intruded by a synvolcanic monzodiorite complex and by the younger? Middle Jurassic Silver King Intrusions comprising a coarse grained plagioclase porphyry stock with related dikes and sills.

The Kena Gold showings (Main and Neil) were explored in the late 1800s and the old Cottonwood mine adit, located near a granitic stock, was used to prospect a quartz vein for gold, with little success. Elise Formation volcanics in the area comprise andesite lapilli tuff, augite basalt flow, flow breccia and fine mafic tuff. The Main and Neil showings consist of irregular veins and pods of massive pyrite in silicified and sericitized andesite. The Neil showing is about 100 metres southeast of the Main showing.

The Kena Gold zone occurs in a highly disrupted area along the flank of the Silver King porphyry stock. The section includes a number of dike and sill-like masses of monzodiorite, andesite porphyry and Silver King porphyry. Gold mineralization occurs in

CAPSULE GEOLOGY

silicified and pyritized crackle breccia fracture zones in the volcanics related to subconcordant dioritic intrusions. Grades are variable but the gold appears to be structurally controlled and is related to the pyrite content. Broad zones of pervasive silicification and potassic alteration occur at the diorite intrusive contacts. These zones have assayed between 1.37 to 2.34 grams per tonne gold over 1.5 to 2.0 metres (Assessment Report 15767). Previous property owners believed gold to be associated with a fine grained, yellow, remobilized pyrite that varies from 1 to 90 per cent in content over short widths and which is distinct from the pale brassy pyrite commonly found in adjacent volcanic rocks. Broad zones of potassic alteration and silicification occur at the margins of the intrusions, and the best widths of mineralization occur where silicification intersects strong fracture systems. The most significant and dense fracture system is subvertical and trends at 090 degrees.

Chalcopyrite, sphalerite and galena occur as disseminations in quartz veins, or as massive sulphide veins adjacent to the dioritic rocks. These occurrences carry low gold concentrations, normally less than 3 grams per tonne. Not all of the silicified zones are gold bearing. Some of the quartz occurs as vuggy crystalline veins of the type commonly found around epithermal deposits. The andesite tuff assemblage has been highly sheared along the regional trend and shearing may have dislocated existing mineralization.

Although mineralizing structures trending 090 degrees had been identified by earlier property owners, all of the historic drilling on the Kena Gold zone has been conducted to cross the regional geology and foliation direction of 130 degrees. In 2000, a report by D. Rhys in part states that gold mineralization grading greater than 2 grams per tonne most consistently, although not exclusively, occurs in sets of east-west striking, steeply south dipping pyrite-quartz veins with pale grey potassium feldspar-sericite-quartz-calcite alteration. If continuous veins or vein systems of this type are developed, they could form higher grade vein targets within the broad area of low grade mineralization present in that area (Assessment Report 26503).

Disseminated pyrite is ubiquitous throughout the volcanic stratigraphy but increases in areas which are highly silicified and contain quartz veinlets. Locally, pyrite may comprise up to 10 per cent of the rock and copper mineralization reportedly corresponds to areas of pyrite-silica enrichment. Chalcopyrite with minor bornite occurs sparingly (0.15 to 0.4 per cent copper in bedrock) along foliation planes in the more mafic volcanics and to a lesser extent in intermediate units.

On the Kena Property the monzogabbro intrusive suite and the Silver King pluton host intrusion-related alteration and gold mineralization. Mineralization has been affected by regional deformation and veinlets cutting the volcanic hosts are frequently folded and transposed, those within the Silver King pluton less affected. Hydrothermal biotite associated with the mineralization are aligned in the regional foliation.

Hydrothermal alteration assemblages present in drill core in and around the Gold Mountain Zone are similar to the principal alteration types developed around gold-rich porphyry deposits (potassic, propylitic, intermediate argillic, and sericitic). The mineralization is post Aalenian and pre Bajocian. Gold mineralization occurs in areas of pervasively pyritized Silver King pluton and within 20 metres of the contact. It consists mainly of disseminated pyrite and chalcopyrite and fewer stringers and veinlets (EMPR Fieldwork 2002, pages 133-151).

Mineralization in the Kena property area was first described in a report by G.M Dawson in Geological Survey of Canada Annual Report for 1888-89. Little is known about exploration on the claim area prior to 1973. Post-1973 exploration, however, has identified old prospect pits and trenches, as well as several old adits indicating periods of exploration activity in the early part of the century. Numerous exploration companies carried out geological, geochemical, geophysical surveys, trenching and drilling on the property from 1974-91. These companies explored the Elise Formation volcanics for gold and copper mineralization and discovered the Kena Gold zone (this description), Kena Copper zone (082FSW332) and the Shaft/Cat zones (082FSW331). The Kena Gold zone underwent the most thorough exploration with the Kena Copper and Shaft/Cat zones only being tested minimally. No additional work was done until 1999 when Sultan Minerals Inc. acquired and amalgamated several properties under the name Kena property. Recent exploration work and data compilation by Sultan Minerals have identified four gold-bearing zones on the Kena property. These are: the newly discovered Gold Mountain (082FSW379), Kena Gold, Shaft/Cat, and South Gold soil anomaly located about 1000

CAPSULE GEOLOGY

metres south of the Kena Copper zone.

The Kena Gold zone has been extensively drill tested but much of the previously drilled core was never sampled. In 2000, Sultan Minerals relogged much of the historic core using alteration and mineralization studies in order to get a signature for the gold mineralization, and many unsampled sections were assayed. Also, structural data from outcrop and drill core was assessed and a new structure identified which appears to be the mineralizing control. Currently, remodeling of the Kena Gold zone is underway, utilizing this new mineralizing orientation and alteration assemblage data (Sultan Minerals Inc. Annual Report 2000).

CAPSULE GEOLOGY

The exact location of the Last Chance showing is uncertain. The area is underlain by altered siltstone, hornfelsed siltstone and schist of the Lower Jurassic Elise Formation, Rossland Group. The Rossland Group rocks are crosscut by a major north trending aplite dyke, related to the Middle Eocene Sheppard syenite intrusion.

The Last Chance claim hosts veins which strike northwesterly and dip steeply to the southwest probably paralleling the schistosity in the host rock. Two veins, known as the No. 1 and No. 2, host mineralization.

The No. 2 vein, ranges from 23 to 56 centimetres in width, and hosts streaks and lenses of ore consisting mainly of chalcopyrite,

CAPSULE GEOLOGY

with minor bornite in a gangue of altered country rock, quartz and calcite. The No. 1 vein, paralleling the No. 2 vein and about 37 metres distant, hosts galena, sphalerite and pyrite with minor chalcopyrite in similar gangue. The No. 1 vein is about 91 centimetres wide and hosts ore up to 18 centimetres in width. Both veins follow well-defined planes of fissuring and appear to be persistently horizontal.

In 1928, a grab sample from ore obtained from the No. 2 vein assayed 0.69 grams per tonne gold, 260.6 grams per tonne silver and 3.68 per cent copper. Selected ore from an open-cut on the No. 1 vein assayed 0.69 grams per tonne gold, 510.8 grams per tonne silver, 15.3 per cent lead, and 5.4 per cent zinc. A grab sample from an ore pile from the No. 1 vein assayed 0.34 grams per tonne gold, 246.9 grams per tonne silver, 6.3 per cent lead, 11.6 per cent zinc and 1.92 per cent copper (Minister of Mines Annual Report 1928, page 356).

CAPSULE GEOLOGY

The Atlin-Nome showing is located 2 kilometres northeast of Ymir. The Dundee (082FSW067) and Yankee Girl (082FSW068) mines are just to the south. Workings consist of a shaft and an adit from the turn of the century.

The area is underlain by metamorphosed sediments of the Lower Jurassic Ymir Group near the contact with granodiorite of the Nelson batholith of the Late to Middle Jurassic Nelson Intrusions. The sediments comprise argillite, siltstone, sandstone, quartzite and limestone. The Mt. Elise shear occurs to the west.

The argillites are highly altered and decomposed. A "fairly regular" quartz vein hosting pyrite ("iron sulphides") is hosted in a porphyritic dyke close to the granodiorite mass. Massive sulphide lenses occur locally. Values from sorted ore were 30.3 to 37.9 grams per tonne (\$20 to \$25 per tonne). Production is probably included with the Yankee Girl mine production.

No other information is available.

The property is located at approximately 1097 metres elevation on the north side of Oscar Creek, 1.6 kilometres east of Ymir.

The Yankee Girl, Canadian Girl, and Atlin claims were staked in October 1899 by Messrs. Graham, Grobe, McLeod, Masterton, and Lovell. Development work was done in a series of open cuts, a shaft, and an adit ("Overland Tunnel") which gained a depth of 15 metres on the vein. In 1904 the Atlin and adjacent Nome and Yukon claims were held by Pat Daly, A. Parr, Wm. Coffey and associates. The Atlin-Nome workings included a shaft to 18 metres with a 15-metre crosscut to the north, and a 96-metre crosscut adit and drifts on the vein. On the Yukon claim an adit had been driven 75 metres. The Yankee Girl (Lot 7712) and Canadian Girl (Lot 7072) were Crown-granted in 1907 to David Grobe, Donald McLeod, James Cronin, and Eber Moore. The Yukon Fr. (Lot 5303) was Crown-granted to Messrs. Daly, Coffey,

CAPSULE GEOLOGY

Hughes and Ryan. In 1910 the Atlin (Lot 4800) and Atlin Fr. No. 2 (Lot 9336) were Crown-granted to William Coffey.

The property was bonded in 1907 by a syndicate of American interests. About 305 metres of development work was carried out and a tram line was built from the Yukon claim to the wagon road. The bond was given up in August of that same year. Early in 1908 the property was bonded by H.L. Rodgers, representing New York interests, and development work began in driving the 1235 (No. 4) level adit from the Old Bill claim of the adjacent Dundee property (82 F/6, Au 10). Operations were transferred to Yankee Girl Gold Mines, Limited which was incorporated in South Dakota and registered in British Columbia in 1909.

The Yankee Girl, Canadian Girl and Yukon Fraction were optioned in 1911 by Hobson Silver-Lead Company, Limited of Spokane, which was controlled by Fort Worth Texas interests. An aerial tram 1829 metres long was built from the 1235 level to the railroad at Ymir. Development work continued in the 1235 level and ore was shipped to smelters at Greenwood, Grand Forks, and Trail, the high silica content of the ore making it desirable for fluxing purposes. The company ceased operations in 1919. Ownership of the property was transferred to Texas Yankee Girl Mines, Limited, which was registered in British Columbia in 1920. The Mining Corporation of Canada, Limited optioned the property in the spring of 1920 and carried out 628 metres of drifting and crosscutting and 204 metres of raising in known areas of the mine. The option was given up later in the year. No further activity was reported until 1926 when O.C. Thompson and associates optioned the property and incorporated Yankee Girl, Limited. The mine was reopened and some ore shipped during the year. In May 1927 The Porcupine Goldfields Development and Finance Company, Limited optioned the property. Further development work was carried out and diamond drilling was done to test for ore below the 1235 level. Enterprise Consolidated Mining Company, Limited optioned the property in March 1928 from Texas Yankee Girl Mines, Limited. The company name Enterprise) was changed to Yankee Girl Consolidated Mines, Limited. Further development work was done in the upper levels of the mine. The workings at that time included 2 shafts, 5 adits and 10 levels totalling some 5486 metres of openings. In the fall of 1928 a new crosscut adit was begun on the Ymir (Wildhorse) Creek side of the mountain 233 metres below the 1235 level. When work was suspended late in 1929 the Wildhorse adit had been driven 869 metres.

Early in 1933 E.P. Crawford, F.R. Weekes and associates took over the property under an agreement with Texas Yankee Girl Mines, Limited and incorporated Ymir Yankee Girl Gold Mines, Limited in May 1934. The property included 5 Crown-granted claims, the Yankee Girl, Canadian Girl, Lakeview, Black Diamond, Yukon Fr., and Klondyke No. 1 Fr. The company installed a 100 t.p.d. mill which began production in January 1935. A winze was sunk to 91 metres below the 1235 level, extending the workings to a depth of 495 metres and comprising eleven levels. The company continued operations during 1938 while lessees carried out the mining of ore remnants in pillars and stopes in the less accessible parts of the mine. In 1939 the company carried out a salvage mining operation in pillars and stope remnants. A crosscut adit was driven from the 1235 adit level to the Dundee ore zone in 1940. The mill operated on Dundee ore, and on mill tailings from former operations, until June 1942 when the company ceased work. Lessees operated the mill until near the end of the year, treating backfill from old stopes. Lessees continued intermittent mining and clean up operations into 1950.

Yankee Dundee Mines Limited was incorporated in November 1952 to develop the Yankee Girl and Dundee properties. Rehabilitation and extension of the Wildhorse adit began and in 1954 the adit reached a length of 1417 metres. At 1247 metres from the portal the Bonus vein was intersected and drifted on for 20 metres. At 1417 metres the Yankee Girl vein was encountered and drifted on for 14 metres. In December 1954 a raise was started on the vein but only driven 11 metres when work stopped.

Newmont Mining Corporation of Canada Limited optioned the property in August 1960. Diamond drilling was done in 2 holes to test the Bonus vein. The option was given up in December.

Cayzar Athabaska Mines Limited in August 1961 optioned the property from Yankee Dundee and drove a raise on the Yankee Girl vein for 144 metres to intersect the old workings at the 1625 level. Drifting totalling 126 metres and some 678 metres of diamond drilling in 5 holes was done on the Yankee Girl vein from the Wildhorse adit. The option was given up in 1965. The company name (Yankee Dundee) was changed in 1963 to Dundee Mines Limited.

Burlington Mines Ltd. by an agreement dated July 1966 acquired from Dundee Mines 24 Crown-granted claims. Rehabilitation and

CAPSULE GEOLOGY

Sheared argillites and limestones of the Middle to Lower Ordovician Active Formation contain a fault related vein deposit. The fault zone strikes 150 degrees with a steep southwest dip along the ridge between Active and Howard creeks. Within the sheared argillites a quartz gangue hosts pyrite, pyrrhotite, sphalerite, galena, and minor chalcopyrite across widths of 1 to 2 metres and along a strike length of about 600 metres. Analysis indicates the across 2.06 to 3.12 per cent zinc from surface trenches along the zone (Assessment 6474).

CAPSULE GEOLOGY

The Rosa showing is located near the confluence of Skilet and Erie creeks, about 14 kilometres southwest of Ymir. The area was first explored in the 1890's. The workings, comprising 2 adits, are now included in the Erie Creek property. The Copper King (082FSW213), the Arnold (082FSW301), Ben Hassen (082FSW300) and Hattie (082FSW226) occurrences are also part of this property.

The area is underlain by the Lower Jurassic Rossland Group, Elise Formation volcanics and Archibald Formation sediments. The Rossland Group rocks are intruded by the Middle to Late Jurassic Nelson Intrusions, locally known as the Erie stock. The Erie stock is comprised of a light grey quartz monzonite with associated aplitic and feldspar porphyry dykes. Biotite hornfels is apparently a contact metamorphic effect related to both the Nelson batholith and the Erie Creek dyke swarm. It is mainly developed in argillite and

CAPSULE GEOLOGY

siltstone. Chlorite occurs mainly on fractures and in shear veins in augite andesite and hornfels.

Mineralization on the property occurs roughly in four concentric zones. An inner quartz-molybdenum plus scheelite zone followed by a chalcopyrite zone, a pyrite-pyrrhotite zone and an outer sphalerite-galena zone. The inner zone is approximately 600 metres in diameter and is centered on the east side of Erie Creek (Hattie). The host rocks are quartz monzonite dykes, stocks and white rhyolite. The chalcopyrite zone occurs over an area of 1.5 to 2 kilometres and occurs in quartz and sulphide veinlets as fracture coatings and in shear veins with pyrite, pyrrhotite and minor amounts of scheelite. The best copper values obtained, up to 1.3 per cent, were from vein and dump samples mainly from old workings on the west side of Erie Creek (Drum Lummon, Copper King, Dora, Homestake). Pyrite and pyrrhotite, in an area about 1.5 by 2.5 kilometres, occurs finely disseminated and as fracture coatings. Sphalerite and galena with some gold occurs in shear veins beyond the inner zone, such as the Arnold and Ben Hassen showings.

Sphalerite and galena in quartz gangue occur in shear veins on the Rosa Reverted Crown Grant. In 1987, a sample taken from an old adit along Skilet Creek assayed 213.2 grams per tonne silver and 0.015 gram per tonne gold (Assessment Report 15510).

The mineralization is believed to be part of a zoned porphyry type deposit which has a central quartz vein stockwork zone containing molybdenum-copper-tungsten mineralization and a peripheral zone with veins containing copper, lead, zinc and silver mineralization. This showing is interpreted as occurring in the peripheral zone.

TERRANE:	Quesnel	RELATIONSHIP:	Plutonic Rocks
METAMORPHIC TYPE:	Contact		RELATIONSHIP: Syn-mineralization Post-mineralization
		GRADE:	Hornfels

CAPSULE GEOLOGY

The claim is underlain by rocks of the Lower Jurassic Rossland Group, Elise Formation, which have been altered to a banded hornfels. The magnetite-rich hornfels or magnetite-skarn occurs along the contact between the Rossland Group rocks and the Early Jurassic Rossland monzonite. This intrusive stock consists of a mass of biotite-hornblende-augite monzonite and contains epidote, chlorite, magnetite with pyrite and pyrrhotite.

Mineralization, which occurs along the monzonite contact, is considered part of the south belt vein system and consists of pyrite, pyrrhotite and magnetite in veins and in semi-massive form. In 1967, very minor amounts of galena were observed in association with native bismuth in a pit northeast of the Deer Park mine (082FSW122). The two minerals were intimately intergrown in a specimen that was examined. The intergrowth may have resulted from simultaneous deposition or, since a number of lead-bismuth sulphosalt minerals are known, from a later breakdown of a single parent material (Thorpe, 1967).

CAPSULE GEOLOGY

The Mayflower is part of the same mineral exposure as the Lucky Boy (082FSW005) immediately to the north and within the same dolomitized zone of Reeves Member limestone of the Lower Cambrian Laib Group. The Mayflower contains an old 9 metre shaft sunk on a vein of oxidized, soft, red material and brown clay about 1 metre in width. The oxidized zone is reported to assay about 6 per cent zinc. Cominco Ltd. drilled the property in 1988. Refer to the Lucky Boy occurrence for details.

SAMPLE TYPE: Grab

COMMODITY

GRADE

Silver 34.0000 Grams per tonne

Gold 19.0000 Grams per tonne

Copper 0.0336 Per cent

COMMENTS: The sample contains quartz with massive pyrite (highest assay).

REFERENCE: Assessment Report 12119.

CAPSULE GEOLOGY

The Wolf Lake (Waldie Lake) showing is within an east trending fault zone which has been intruded by a quartz-porphyry dyke of the Middle to Late Jurassic Nelson Intrusions. The fault and dyke system also host a late stage quartz vein which carries massive to disseminated pyrite and chalcopyrite. Country rocks are the siliceous sediments and quartzites of the Hadrynian Three Sisters Formation of the Windermere Supergroup (correlative with rocks of the Horsethief Creek Group).

Grab samples of quartz and massive pyrite assayed up to 34 grams per tonne silver and 19 grams per tonne gold although the sampling showed generally lower values and the erratic metal distribution typical of such vein deposits (Assessment Report 12119). The 1 to 3 metre wide dyke has fault gouge developed along both contacts with the country rock.

CAPSULE GEOLOGY

The View Crown-granted claim is underlain, on its western part, by the Pennsylvanian and possibly Permian Mount Roberts Formation siltstone, hornfelsed siltstone, hornfels and a breccia complex. The siltstone is rusty, sooty and massive or thinly bedded with minor disseminated pyrrhotite and pyrite. The hornfels and hornfelsic siltstones are thinly laminated and massive cherty rocks which locally contain brown garnet and epidote. The Mount Roberts succession overlies augite porphyry of the Rossland sill, which underlies the eastern part of the Crown grant, and is thought to have been thrust over the sill. The Rossland sill intrudes the upper part of the Elise Formation (Rossland Group) and is considered part of that formation.

The Rossland Group rocks are intruded to the south by the Rossland monzonite stock and to the north by the Cretaceous Trail Pluton which is comprised of a granodiorite stock.

The View claim adjoins the St. Elmo property (082FSW134) near the summit of Red Mountain. A 14-metre tunnel was driven along a 38 centimetre wide mineralized vein which widens at depth to nearly 0.9 metres of mixed ore comprised of pyrrhotite and chalcopyrite. More ore shoots exposed along the walls show 38 centimetres of solid ore which in 1915 typically assayed 15 per cent copper (Geological Survey of Canada Memoir 77, page 135).

CAPSULE GEOLOGY

The Feeney tungsten zone is located on the east side of the granitic Emerald stock of the Middle to Late Jurassic Nelson Intrusions. The zone forms a relatively shallow ore body within the Lower Cambrian Laib Formation along the contact of the Reeves Member limestone and Emerald Member argillite and along the granite-limestone contact.

The mineralization consists of scheelite with minor powellite, rare wolframite and traces of molybdenite in a green and brown garnet-diopside skarn containing augite, actinolite, epidote, pyrrhotite and quartz. Both the Emerald (082FSW010) and Feeney orebodies are transected by the Granite fault and drilling east and north of the fault located the Invincible tungsten zone (082FSW218).

Most of the scheelite occurs as fine, disseminated grains in lenticular skarn zones which extend from the granite contact out into the limestone-argillite country rock conformable to bedding. The skarn zones are up to 6 metres long and average about 2 metres in width. Grades are about 0.5 to 1.5 per cent tungsten.

The Feeney mine lies north of and along strike of the Emerald mine and south of the Invincible mine. The Dodger (082FSW011) workings lie to the east. The Feeney mine operated between 1951 and 1955 and produced about 54,000 tonnes of ore (Bulletin 41, page 119). It is not known if production recommenced after this period. The production data is included with that of the Jersey mine (082FSW009).

CAPSULE GEOLOGY

The Paradise showing is located immediately south of Blewett between Eagle and Fortynine creeks. Old workings comprise a tunnel and some trenches from around 1926.

The area is underlain by Jurassic pseudodiorite and pyroxenite of unknown affinity.

Mineralization is confined to a quartz vein of variable width up to 1 metre which hosts pyrite, chalcopyrite and some free gold. The vein is hosted in pseudodiorite (reported as granite). Best gold values appear confined to streaks and stringers of sulphides within the vein.

A sample across 0.15 metre of quartz and sulphides in the tunnel assayed 38.4 grams per tonne gold and 34.3 grams per tonne silver (Minister of Mines Annual Report 1926, page 282). In 1926, it was reported that 36 to 45 tonnes of material was put through the Granite-Poorman mill (082FSW086) with "disappointing" results.

CAPSULE GEOLOGY

orebody continued into 1926. The option was subsequently given up and P.F. Horton one of the owners, carried out some work on the property in 1927. Exploration work to that date was all done in the heavily oxidized zone at the north and on No. 1 orebody where the flat-plunging ore was exposed on surface. Oxidation here extended to the full depth of the ore zone, about 91 metres below surface.

The Consolidated Mining and Smelting Company returned in 1927 to purchase the 18 Crown-granted claims and fractions, but the property remained idle until 1948. Starting about 1946, the company began geological investigations that led to an intensive diamond drilling program beginning in 1948. Large bodies of 9, low-grade disseminated sulphides plunging gently south from the oxidized orebody were indicated by this drilling. In June, 1949 an underground program began to investigate the drill results. The No. 4 level was rehabilitated and from the face the adit was extended south for nearly 457 metres. A parallel drive was subsequently made about 70 metres to the west and connected to the main drive by 3 crosscuts at 61 metre intervals. Diamond drilling from these two drives and from exploration raises in 1950 partly delimited two orebodies - the No. 1 and No. 2 - and work until 1953 was aimed at developing these orebodies for production. In 1951 construction of a 1,000 ton per day concentrator began and a new adit level (No. 8) was driven 823 metres north from the Sheep Creek valley millsite to the ore zone. The concentrator was completed early in 1953 but due to low lead and zinc prices, was not put into operation. All work ceased on March 31 and was not resumed until April 1955; milling began in May.

The Garnet zone outcrops on the Garnet and Legal Tender claims between elevations of 1067 and 1158 metres on the Sheep Creek slope about 0.5 kilometre north of the concentrator. The Legal Tender claim (Lot 10823) was staked on this showing in about 1899. In 1912 the claim was Crown-granted to George Klavano. Development work at that time apparently consisted of a few short adits. In 1926 the claim was part of the Black Jack group of 4 claims. This group was optioned by P.F. Horton & associates in 1926 and late in the year exploration work was done in about a dozen trenches crosscutting the zone. The Legal Tender was part of the group sold to Cominco in 1927; the Black Jack claims, lying to the west of the Legal Tender, were apparently abandoned. Diamond drilling by the company in 1948-49 in more than 30 holes delimited a more or less continuous mineralized zone 15 metres wide lying 46 to 61 metres west of the Garnet fault. Mining of the Garnet zone began in 1965 as an open pit operation and was later incorporated with the underground operation. The mine and mill closed on November 1, 1966. The company name was changed in 1966 to Cominco Ltd. Plans to re-open the mine were announced late in 1972. The mill and underground workings were rehabilitated and production resumed in February 1973. Mining and milling operations continued until August 1978 when the mine closed. Measured and indicated reserves, as of December 31, 1978, were reported at 409000 tons, at 0.1 per cent lead and 4.1 per cent zinc (Canadian Pacific Limited, Form 10-K, December 31, 1978).

David Minerals Ltd. by an agreement dated May 8, 1981 purchased the mine, mill and adjacent properties from Cominco Ltd. for \$750,000; a 20 acre parcel was subsequently sold to Goldbelt Mines Inc. for a millsite. Renovation of the H.B. mill was carried out to prepare a flotation circuit to custom mill gold-bearing sulphide ores, and a second circuit to treat molybdenite-gold ore from the company's Rossland properties (82 F/4, Mo 2 and 3). The gold circuit was put into operation on ore from the Gold Belt property in December 1981.

The Garnet zone includes showings previously reported as Blackjack and Legal Tender. They are all part of a continuous mineralized horizon associated within the HB mine (082FSW004) and contributed to that mine's production.

The HB orebodies are currently thought to be Kootenay Arc-type carbonate hosted sedimentary exhalative (sedex) deposits. The orebodies are located within dolomitized limestone of the Lower Cambrian Laib Formation, Reeves Member (correlative with limestone of the Badshot Formation). The east side of the Laib Formation is in contact with argillites of the Lower to Middle Ordovician Active Formation, on a fault contact, with the Active rocks overthrust from the east over the Reeves carbonates.

Fine-grained sphalerite, pyrite, and minor galena occur as scattered lenses and as disseminated grains in dolomite. The main Garnet zone ores are about 15 metres wide and outcrop between 1050 and 1160 metres elevation, about 50 metres west of the Garnet fault.

CAPSULE GEOLOGY

The Bobbi showing is located 2 kilometres northwest of Ymir.

CAPSULE GEOLOGY

The Bobbi and Stewart 2 (082FSW229) occurrences are the most significant porphyry showings in the Nelson-Ymir area. Numerous small pits and adits occur on the property mainly from tungsten exploration carried out on the Alabama and Atlanta Crown Grants.

The area, on the east limb of a north trending syncline, is underlain by sediments of the Hall Formation and volcanic rocks of the Elise Formation (unit Jell) both of the Lower Jurassic Rossland Group (Open File 1989-11). The Hall Formation sediments consist of a sequence of argillite, shale, siltstone and sandstone. The volcanic rocks are primarily tuffaceous conglomerates but andesite, flow breccia, tuff and augite porphyry are present to the east. These are intruded by quartz monzonite to quartz diorite plugs and dykes of the Late to Middle Jurassic Nelson Intrusions and Tertiary rhyolite dykes.

The most common intrusion is an albite porphyry of quartz diorite composition. Other intrusions include plagioclase porphyry and quartz monzonite. The quartz monzonite is a medium-grained, light grey to white coloured plug which contains phenocrysts up to 1.5 centimetres in length of quartz, feldspar, biotite and hornblende.

Molybdenite, scheelite and minor chalcopyrite are found along with sericite in quartz veins and in fractures within the quartz monzonite plug. Fluorite is a common accessory mineral within the intrusive. Low lead and zinc values were noted from Hall sediments near the intrusive margin. Pyrite is ubiquitous in both sediments and volcanics and disseminated pyrrhotite and minor chalcopyrite are hosted in Hall sediments. Prospecting indicated very minor disseminated chalcopyrite, sphalerite and galena in quartzitic sediments. No anomalous silver, gold or tin values were reported. Reported radioactivity is due to the presence of potassium feldspar within the quartz porphyry intrusive.

A sample from trench 6 in 1980 assayed 0.07 per cent copper, 0.115 per cent molybdenite, 0.03 per cent W_3O_8 and less than 0.1 grams per tonne gold with 0.078 per cent fluorine (Assessment Report 8448).

CAPSULE GEOLOGY

The Fresno showing is located on Quartz Creek, about 1.5 kilometres due west of Ymir. The showing was originally staked in 1902.

The area is underlain by basalt flows, flow breccias, subvolcanic intrusions and tuffaceous conglomerate of the Lower Jurassic Elise Formation, Rossland Group. These have been intruded by Late to Middle Jurassic Nelson Intrusions and Eocene Coryell Intrusions.

Molybdenite mineralization, with associated pyrite, is observed to occur as selvages on fracture surfaces within sheared, felsic intrusives.

The Trask workings are about 1 kilometre west of the Fresno showing but no specific details of the mineralization are recorded. The Lion was staked in 1949 and may in fact be the same as the Fresno showing.

CAPSULE GEOLOGY

Anomalous uranium showings are reported from coarse-grained "pegmatoid" layers within the fine-grained quartz-biotite schists and gneisses of the Late Cretaceous Kinnaird Orthogneiss (Castlegar Gneiss). The pegmatoid horizons consist of coarse feldspars and quartz. Background radioactivity is about 3 times regional levels.

ORE ZONE: DRILLHOLE

REPORT ON: N

CATEGORY: Assay/analysis
SAMPLE TYPE: Drill Core
COMMODITY: Limestone

YEAR: 1955

GRADE: 55.6000 Per cent

COMMENTS: From hole #1 at 82.3 metres depth. Grade given is for CaO.

REFERENCE: Minister of Mines Annual Report 1955, page 95, Section 6.

CAPSULE GEOLOGY

Limestone of the Middle Cambrian Nelway Formation forms a 137 metre high hill on the north end of Lots 9056 and 9280, 2 kilometres northeast of Nelway. A dolomite bed striking 137 degrees and dipping 35 degrees southwest outcrops along the north side of the hill. The dolomite thickens from a metre on the northwest corner of the hill to a hundred metres 0.4 kilometres to the west. Much of the limestone is underlain by this dolomite bed.

Diamond drilling encountered white to dark grey, occasionally argillaceous, limestone beds with some interbedded argillite. Pyrite was found to be negligible. Hole 1 drilled from the top of the hill in an easterly direction at minus 40 degrees intersected 29 metres of white, granular limestone starting at a depth of 68.58 metres. A sample taken from this section at 82.30 metres contained 55.6 per cent CaO, 0.4 per cent MgO and 0.6 per cent insolubles (Minister of Mines Annual Report 1955, page 95, Section 6). This hole bottomed in 15 metres of dolomite starting at 133.5 metres depth. A sample of the dolomite taken at 136.55 metres contained 31.0 per cent CaO, 21.4 per cent MgO and 0.80 per cent insolubles (Section 9).

Purex Lime Company attempted to develop the limestone deposit. The company drilled two holes in 1955.

Gold	1.3700	Grams per tonne	
Copper	2.8000	Per cent	

COMMENTS: Sample taken from ore pile.
REFERENCE: Minister of Mines Annual Report 1919, page 133.

CAPSULE GEOLOGY

The Jack Pot showing is located on Eagle Creek, about 7.5 kilometres west of Nelson. Old prospect tunnels and adits are present on the property.

The area is underlain by Jurassic pseudodiorite and pyroxenite of unknown affinity. Middle to Late Jurassic Nelson intrusions and volcanic rocks of the Lower Jurassic Elise Formation (Rossland Group) occur to the east and west.

A quartz vein carrying pyrite and chalcopyrite is hosted by pseudodiorite and siliceous granite (?). The quartz material contains limonite and malachite staining and assays of selected samples reported in 1919 indicate 2.8 per cent copper, 34.3 grams silver and 1.37 grams of gold (Minister of Mines Annual Report 1919, page 133).

It is believed that the showing is an extension of the Hardscrabble vein (082FSW086) which formed part of the Granite-Poorman deposit immediately to the north.

Skarn

GEOLOGICAL SETTING

TECTONIC BELT: Omineca
TERRANE: Kootenay Plutonic Rocks

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The Jackpot West prospect is located on the ridge between Hidden and Porcupine creeks, 10 kilometres northeast of Salmo. See also Jackpot Main (082FSW012), Jackpot East (082FSW013) and Jackpot Lerwick (082FSW256).

The Jackpot orebodies are currently thought to be Kootenay Arc-type carbonate hosted sedimentary exhalative (sedex) deposits. The orebodies are located within dolomitized limestone of the Lower Cambrian Laib Formation, Reeves Member (correlative with limestone of the Badshot Formation). The carbonate is complexly folded and faulted close to the north margin of the granitic Hidden Creek stock of the Middle to Late Jurassic Nelson Intrusions.

Mineralization on the Jackpot West zone occurs near the base of the dolomite along the northwest margin of a large unit of limestone which strikes northeast and dips south. The mineralized zone has a maximum width of 2 metres and has been traced along strike for about 138 metres. Sphalerite and pyrite occur in banded serpentinitized dolomite, and locally sphalerite and minor galena are found in a diopside skarn. The zone is discordant to the northeast with metasediments of the Lower Cambrian Quartzite Range and Reno formations and is likely in fault contact with them. To the southwest the mineralized dolomites are cut by a north trending fault. For reserves and work history refer to the Jackpot Main (082FSW012) occurrence.

Tombstone Explorations Co. Ltd. acquired the Jackpot property from New Jersey Zinc Explorations Company (Canada) Ltd. in 1997.

CAPSULE GEOLOGY

The Jackpot Lerwick prospect is located on the ridge between Hidden and Porcupine creeks, 10 kilometres northeast of Salmo. The Jackpot Lerwick zone is within dolomitized limestones of the Reeves Formation of the Lower Cambrian Laib Formation (correlative with the Badshot Formation). The dolomite is intruded immediately to the west by a tongue of diorite from the Hidden Creek stock of the Middle to Late Jurassic Nelson Intrusions. Most contacts with other rock types are discordant. The showing area contains rock units with complex structural and stratigraphic relationships. The Jackpot orebodies are thought to be Kootenay Arc-type carbonate hosted sedimentary exhalative (sedex) deposits. Mineralization consists of disseminated sphalerite, pyrite, and pyrrhotite in a west dipping zone of dolomite which is extensively oxidized at surface. Sulphides occur in layers more massive than the East Zone. Mineralized bands are in the order of 1 to 3 metres thick and outcrop over a width of about 75 metres interbanded with barren dolomites. The mineralized zone has been traced over 153 metres on surface although individual sulphide bands are not known to continue for more than about 30 metres. Pyrrhotite is the dominant sulphide in the Lerwick zone. This occurrence has had extensive exploration work carried out but no significant production has been documented. Reserves and work history are reported in the Jackpot Main (082FSW012) deposit. Tombstone Explorations Co. Ltd. acquired the Jackpot property

CAPSULE GEOLOGY

from New Jersey Zinc Explorations Company (Canada) Ltd. in 1997.

CAPSULE GEOLOGY

The Davne is a fissure vein which is the strike extension of the Lucky Strike (082FSW062) with the same mineralization and general setting. The vein is associated with the northeast trending Black Bluff fault and contains a quartz gangue which carries galena, tetrahedrite, pyrite, sphalerite, and some chalcopyrite. The width is an average of 5 centimetres but very locally it may be as wide as 50 centimetres. The vein on the Davne is within dolomites of the Middle Cambrian Nelway Formation as well as phyllites and argillites of the Lower Cambrian Laib Group. Near surface and to a depth of about 5 metres the vein is oxidized and alteration minerals are present. These include cerussite, chalcocite, covellite, malachite and azurite. Cerussite commonly occurs as veinlets within galena, and exhibits ragged replacement outlines. Many areas of tetrahedrite are almost entirely replaced by chalcocite and covellite. No free gold or silver is reported and metal values are highly erratic ranging from nil or trace up to as high as 65 grams per tonne gold and 13 kilograms per tonne silver in selected grab samples.

Lead 0.1500 Per cent

COMMENTS: The sample was taken from a trench from a quartz vein; width is not known.

REFERENCE: Assessment Report 7799.

CAPSULE GEOLOGY

The area of the Gold 1-2 showing is underlain by the Lower Jurassic Rossland Group Elise Formation volcanics and by a package designated as Unit Cs which is of probable upper Paleozoic age and may be correlative with the Milford Group (Fieldwork 1990, page 21). These upper Paleozoic rocks consist of argillite, slate, phyllite, chert, greenstone and limestone. The strata are intruded by a mass of the Middle Eocene Sheppard Intrusions comprised of granodiorite to syenite.

CAPSULE GEOLOGY

The area prospected is underlain predominantly by leucocratic granodiorite of the Sheppard Intrusions with occurrences of syenite and monzonite in the vicinity of Goodeve Creek. The intrusives cut interlayered argillites, shale and the volcanics of the Elise Formation exposed along Goodeve Creek.

A number of quartz veins were found in the leucocratic intrusive, ranging from 1 centimetre to 1 metre in width and hosting traces of gold with disseminated pyrite and galena. The veins, exposed in 5 test pits, varied in width from 0.3 to 1.0 metre. They strike between 110 to 180 degrees with a near vertical dip and are traceable for 75 metres in length. In 1979, a sample from a quartz vein assayed: 92.64 grams per tonne gold, 82.28 grams per tonne silver, 0.15 per cent lead (Assessment Report 7799). In 1982, sample values ranged up to 8.7 grams per tonne gold, 28.8 grams per tonne silver, and 0.44 per cent lead (Assessment Report 11178).

CAPSULE GEOLOGY

The Joint vein is an east-west trending quartz vein within limestone of the Lower to Middle Ordovician Active Formation. The limestones and argillites of the Active Formation are in fault contact with Lower Cambrian Laib Formation sediments to the east and host a stock of Middle to Late Jurassic Nelson Intrusions southwest of the occurrence.

Mineralization consists of minor disseminated galena, sphalerite, and pyrite in quartz gangue. Both walls of the vein contain minor streaks of limonite and have spotty gold and silver values over narrow widths.

See Gold Belt (082FSW044) for exploration and development details.

REPORT ON: N

CATEGORY: Assay/analysis
SAMPLE TYPE: Chip

YEAR: 1938

COMMODITY: Gold
GRADE: 2.0600 Grams per tonne

COMMENTS: From a 20 to 25 centimetre chip sample of felsite dyke material.

REFERENCE: Property File - Maconachie, 1938.

CAPSULE GEOLOGY

The Heather showing occurs at an elevation of 1974 metres on the north face of Middle Sister peak, one of three peaks forming the Three Sisters Peak. The peak areas of Three Sisters Peak are underlain by the Hadrynian Three Sisters Formation (Windermere Supergroup) which comprises quartzite, conglomerate and schist. Within a few hundred metres to the west is the north trending contact with the Lower Paleozoic Quartzite Range Formation composed chiefly of quartzite (correlative with rocks of the Hamill Group).

The showing is located within a shear zone that strikes 35 to 45 degrees and dips almost vertically. A composite felsic and lamprophyric dyke system, now highly sheared and shattered, in the order of 3.5 metres wide, has intruded the shear zone. Although the latest map of the area would indicate that the occurrence is located in rock of the Three Sisters Formation early documents report that the dykes are intruded into quartzite of the Quartzite Range Formation. The quartzites have a strike of about 045 degrees with a steep northwesterly dip.

CAPSULE GEOLOGY

Silicification and quartz veining within the shear zone is common. An adit has been driven as drift for over 50 metres on the zone. The old workings expose as much as a 1.2 metre width of quartz along the side of the dyke. Sulphide mineralization is sparse to non-existent but visible gold has been observed in the quartz. A sample taken across 20 to 25 centimetres of felsite dyke material assayed 2.06 grams per tonne gold and a trace of silver. A 4 centimetre wide quartz vein assayed 4.80 grams per tonne gold and a trace of silver (Maconachie, 1938).

CAPSULE GEOLOGY

A small quartz vein striking 057 degrees and dipping 35 to 40 degrees southeast is hosted by black argillites of the Lower and Middle Ordovician Active Formation. Mineralization consists of pyrite, pyrrhotite, galena, and sphalerite and has been exposed in a short adit and a number of surface trenches.

The vein produced 1,992 tonnes of ore in 1938, 1939 and 1940 with all but 52 tonnes being mined in 1940. From the total mined 511 grams of gold and 829 grams of silver were recovered.

GRADE: 52.4000 Per cent

YEAR: 1955

COMMENTS: Taken across 12 to 15 metres of strata. Grade give for CaO.
REFERENCE: Industrial Mineral File - Fyles, 1956.

CAPSULE GEOLOGY

Limestone of the Lower Cambrian Reeves Member of the Laib Formation outcrops 250 to 1200 metres north of the Salmo river just east of Wallace Creek. The unit strikes 050 degrees for 950 metres and dips 45 degrees southeast. Exposed widths vary from 250 to 320 metres.

The limestone is fine to medium grained and uniform grey to thinly banded black and white in colour. Two samples, each taken across 12 to 15 metres of strata assayed as follows (in per cent) (Fyles, 1956 - Samples 9228, 9229):

Sample	CaO	MgO	Insolubles
9228	52.4	1.71	3.28
9229	42.2	5.09	14.3

The two samples were collected along the lowest limestone bluffs 180 to 270 metres north of the Salmon Valley logging road.

CAPSULE GEOLOGY

The Jero 5 showing consists of pyritic argillite of the Lower Jurassic Rossland Group, Elise Formation. These rocks are intruded within 500 metres to the northwest by a stock the Middle Eocene Coryell Intrusions which varies in composition from syenite to monzonite and granite. A chip sample of the argillite taken over an unspecified length assayed 0.68 grams per tonne gold and 14.2 grams per tonne silver (Assessment Report 13449).

CAPSULE GEOLOGY

The area of interest is in the vicinity of Ivanhoe Ridge and Sophia Creek, some 6.4 kilometres southwest of Rossland. From incomplete information it appears that two chromite showings have been prospected, one located on Crown-grants at about 1341 metres elevation on Ivanhoe Ridge, and the other, about 1.6 kilometres to the south, at about 1250 metres elevation on the ridge

CAPSULE GEOLOGY

between the two main forks of Sophia Creek and about 300 metres southeast of the natural gas pipeline (Vandot, 082FSW130).

Crown-grants were obtained on two claims, the Burlington West (Lot 2715) and Burlington (Lot 4359); the latter was Crown-granted to Bob Lamont in 1901.

The reverted Crown-grants were leased and additional claims staked in 1918 by A. Cameron, J.H. MacDonald and associates. Work was apparently confined to trenching and stripping. The Vandot group of 5 recorded claims, reported to be located on the Cascade highway at the first summit west of Rossland, were owned in 1966 by V.M. Van, of Rossland. Old trenches were deepened and sampled.

Noranda Exploration Company Limited held the property in 1984 as the Ross, Ross 2-3, and Cal claims. Work included magnetometer surveys over 16 kilometres, induced polarization and electromagnetic surveys over 1 kilometre, a geochemical soil survey comprising 177 samples, and trenching.

The claims are underlain by ultramafic rocks, of probable Permian age, that are in contact with Lower Jurassic Elise Formation volcanics of the Rossland Group. The rocks lie in fault contact with the Tertiary Marron Group volcanics comprised of trachyandesite and trachyte. A Middle Eocene Coryell pluton comprised of a mass of syenite intrudes the suite of rocks.

A base metal showing lies at the north end of the Cal claim within discontinuous shears striking 330 to 015 degrees and dipping 75 degrees west. The showing, known as the Constantine prospect, lies within shears in fine-grained feldspar porphyry with rusty, vuggy quartz infilling hosting pyrite, chalcopyrite, malachite, limonite and manganese oxide. In 1980, three samples assayed an average 0.8 per cent copper, 0.4 per cent lead, and 0.4 per cent zinc (Assessment Report 7162). The samples also contained a trace of gold and from 12 to 80 grams per tonne silver.

In 1946, a shaft was sunk 30 metres along the shear which strikes 320 degrees and dips 70 degrees southwest. In 1982, exploration in the old shafts on the Ross 2 claim showed lenticular quartz veins with a quartz lense striking 330 degrees and dipping 75 degrees northeast at a depth of 20 metres hosting disseminated chalcopyrite and sphalerite in white quartz gangue. A 20 centimetre metre sample from the old shaft sunk in 1946 along the vuggy quartz averaged 0.6 grams per tonne silver and 17.0 grams per tonne gold with one sample at 22.6 grams per tonne gold. A 20 centimetre sample taken in 1982 assayed 30.59 grams per tonne gold, 7.20 grams per tonne silver and 0.02 per cent copper (Assessment Report 10799).

Three samples from sheared fine-grained porphyry dykes in contact with serpentinized ultramafics averaged 319 grams per tonne silver and 2.35 per cent copper across 90 centimetres (Assessment Report 10799). Mineralization consisted of colourless blebs of quartz with disseminated pyrrhotite and pyrite with manganese oxide and limonite coatings. Mineralized sheared bands varying from less than 5 centimetres to greater than 1 metre in serpentinized andesite (?) host abundant malachite with trace sphalerite, galena and nodular pods of chalcopyrite. A 30-centimetre sample of black, serpentinized andesite (?) hosting a 3-centimetre band of malachite encrusted in talc schist assayed 0.8 grams per tonne gold, 35.7 grams per tonne silver and 0.45 per cent copper (Assessment Report 10799).

There are chromite showings on the property in black serpentinite. The showings host visible chromite and nickeliferous magnetite and are described in the Vandot showing (082FSW130).

CAPSULE GEOLOGY

Granite of the Middle to Late Jurassic Nelson Intrusions intrude sediments of the Lower Cambrian Reno Formation (correlative with rocks of the Hamill Group). Quartzites, argillites and schists near the contact with the intrusives are silicified locally and contain pyrite, pyrrhotite, sphalerite and chalcopyrite.

These deposits are erratic in location and extent and carry low but consistent gold values. Grab samples from the dump carry gold in the range of 3 to 6 grams gold. One sample assayed 6.17 gram per tonne gold, 5.49 grams per tonne silver, 0.09 per cent copper, 0.01 per zinc and 0.004 per cent tungstic oxide (Assessment Report 8652).

COMMODITY

COMMODITY	GRADE	
Silver	130.0000	Grams per tonne
Gold	13.0000	Grams per tonne
Copper	0.0100	Per cent
Lead	0.2700	Per cent
Zinc	0.0300	Per cent

COMMENTS: A 3 metre sample.
 REFERENCE: Assessment Report 12762.

CAPSULE GEOLOGY

The area is underlain by argillite, greywacke, sandstone and minor limestone lenses and basaltic flows of the Lower Jurassic Archibald Formation, Rossland Group. Granodiorite of the Middle to Lower Jurassic Nelson Intrusion occupies most of the area to the north of the occurrence. A plug or sill of dioritic augite porphyry of the Rossland Group also intrudes the strata.

Mineralization is restricted to a north trending zone of gossanous hornfels in argillite and wacke, and recrystallized limestone, an area roughly 60 by 500 metres along the contact with the dioritic feldspar porphyry. Pyrite and pyrrhotite occur

CAPSULE GEOLOGY

throughout the gossanous zone as disseminations or seams. Minor galena, sphalerite and rare chalcopyrite accompany pyrite in siliceous southeast trending small shears containing discontinuous lenses of quartz up to 0.5 metres width and probably no more than 10 metres in length. Several such siliceous zones occur. The limestone is locally altered to weak garnet-epidote-calcite skarn. Some free gold has been observed in the area.

One sample reported as a 3 metre grab sample assayed 130.0 grams per tonne silver, 13 grams per tonne gold, 0.01 per cent copper, 0.27 lead and 0.03 per cent zinc (Assessment Report 12762).

The old Beaver Creek prospect was staked in 1910 and has a similar description to that of the Relay property of the 1980's. These two deposits are thought to be the same. The Reliance past producer, in the same general area, has no description but is recorded as having 55 tonnes of production in 1940 and 1941 with recovery totalling 560 grams of gold and 4976 grams of silver.

CAPSULE GEOLOGY

At the Armstrong occurrence, granite of the Middle to Late Jurassic Nelson Batholith contains four widely spaced, parallel, silicified fracture zones which strike 305 degrees and dip about 50 degrees northeast.
 The principle working consists of a silicified zone or vein that is coincident with and on the footwall of a basic dyke about 0.7 metres thick. Galena, sphalerite, pyrite, and arsenopyrite are sparsely disseminated throughout the silicified zone and stibnite is streaked on fracture surfaces. The mineralized fracture zone is in the order of 2 metres thick. A 30-centimetre sample assayed 0.69 grams per tonne gold, 459.43 grams per tonne silver, 3.7 per cent lead and 0.5 per cent zinc (Minister of Mines Annual Report 1928, page 338).
 Prior to 1902, four adits are known to have been driven on the zones of the Black Knight Crown grant. The adits were cleaned out in 1928 with apparently only minor underground development occurring at that time. In 1939, 13 tonnes of ore were shipped from the mine and

CAPSULE GEOLOGY

The Meadows showing lies at the western end of an elongate granite plug of the Middle to Late Jurassic Nelson Intrusions. The intrusive is cut by several steeply dipping faults, striking about 110 degrees, and two quartz-eye porphyritic aplite dykes. The granite is cut by a weak quartz-sericite stockwork and molybdenite occurs as selvages within the stockwork, painted on fracture surfaces and as minor disseminations in the granite. It also occurs within the aplite at a few points. The granite is weakly altered while the aplite dykes appear relatively fresh. Minor tungsten and copper have also been reported. One sample assayed 0.0035 per cent molybdenum and another assayed 7.8 grams per tonne silver and 0.17 grams per tonne gold (Assessment Report 10155).

In 1967, an 18 metre adit was driven. Below the adit a 90 metre open cut was made.

CAPSULE GEOLOGY

The Acorn showing is located on Fortynine Creek, downstream from the Royal Canadian and Nevada occurrence (082FSW088). Scheelite was reported to be found within the gravels along Fortynine Creek on the Acorn group. In 1942, a shaft was sunk in the creek bed to a depth of 35 metres and encouraging amounts of gold and scheelite were recovered in a sluice operation. No other information is available.

CAPSULE GEOLOGY

Disseminated grains of uraninite are reported to occur within pegmatoid material associated with the Upper Cretaceous Kinnaird Orthogneiss (Castlegar gneiss). The pegmatitic horizons occur as 1 metre thick sheets within micaceous schists and gneiss. Some drag-folds in the layering have been observed on the northeast side of China Creek. Uraninite occurs within feldspar crystals which commonly have a rusty halo on weathered surfaces; it is associated with smoky quartz. Some pyrite and pyrrhotite is also present. Four drums of sample were analysed and contained an average of 0.0156 per cent uranium (Assessment Report 7609).

SAMPLE TYPE: Grab
COMMODITY GRADE
Silver 240.0000 Grams per tonne
Gold 15.0000 Grams per tonne
Copper 5.0000 Per cent

COMMENTS: Recorded for 1899, no sample details are available, grab is assumed.
REFERENCE: Minister of Mines Annual Report 1899, page 601.

CAPSULE GEOLOGY

The Josie showing is located on the south side of Kootenay River, south-southeast of Beasley. The claim was crown granted in 1900. An old portal was reopened and open cuts were developed in 1976.

The area is underlain by Jurassic pseudodiorite and pyroxenite of unknown affinity.

An east-west striking quartz vein, dips 45 degrees to the south and hosts scattered chalcopyrite. The vein is about 10 metres in width and cuts psuedodiorite.

The Minister of Mines Annual Report for 1899 (page 601) records an assay from this Crown Grant as 5 per cent copper, 240 grams per tonne silver and about 15 grams per tonne gold (\$10.00/ton).

No other information is available.

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The Jackass showings consist of three pegmatite rich areas within the Middle to Late Jurassic Nelson Intrusions and Valhalla complex plutonic rocks on the southeast flank of the Passmore Dome. The granitic intrusions have background radioactivity in the order of 30 to 50 counts per second by scintillometer (GRS 101A). Flat lying pegmatite sills, consisting of about 50 per cent plagioclase, 25 to 30 per cent quartz and lesser amounts of muscovite, biotite, garnet and opaques, contain erratic zones of radioactivity up to 5000 counts per second near the hanging wall contacts in relation to coarser-grained pegmatite sections. Disseminated uraninite is the primary uranium mineral, which is generally associated with biotite within the pegmatite.

CAPSULE GEOLOGY

The North Star showing is located about 6 kilometres southwest of Nelson on the south slopes of Morning Mountain. Old workings date back to the early 1900's.

The area is underlain by schistose volcanic rocks comprising augite basalt flows, flow breccias, subvolcanic intrusions and mafic tuff of the Lower Jurassic Elise Formation, Rossland Group. These are intruded by plagioclase porphyry of the Jurassic Silver King Porphyry. The Silver King shear zone, trending northwest, is immediately to the south and west.

A pyritized and silicified shear zone over 12 metres wide parallels the strike and dip of the schistose volcanics. The best mineralized section is 2.4 metres wide between the hanging wall and a

CAPSULE GEOLOGY

0.6-metre thick lamprophyre dyke. Locally the vein parallels the contact. Host rocks to the sheared vein are locally highly silicified.

The best mineralized section averaged 9.26 grams per tonne gold while a 6 metre section of rusty, weathered rock on the footwall side of the lamprophyre dyke assayed about 3.4 grams per tonne gold (Minister of Mines Annual Report 1932, page 183).

Diamond drilling (three holes) was conducted on the claim in 1980, the results are unknown (Property File - Lectus Developments Ltd., Prospectus, Aug. 4, 1987).

GEOLOGICAL SETTING

TECTONIC BELT: Omineca
TERRANE: Quesnel Plutonic Rocks PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The Free Silver showing is located about 4 kilometres southwest of Ymir. It is just west of the May Blossom (082FSW070) showing. The claim was staked in 1896 and trenching is the only work reported on the property.

The area is underlain by volcanic rocks of the Lower Jurassic Elise Formation, Rossland Group which have been intruded by Tertiary rhyolite dykes and monzonite of the Middle Eocene Coryell Intrusions.

A number of relatively parallel veins occur near the contact of the volcanic rocks with the quartz monzonite porphyry. The veins vary from 0.1 to 3 metres wide and trend in a general east-west direction. Mineralization varies from massive pyrite-pyrrhotite to galena with subordinate pyrite and sphalerite. Minor molybdenite is reported locally within the veins.

Sylvanite was found in calcite filled vugs in an andesite host (occurring as a xenolith in monzonite) and appear to be associated with trace amounts of chalcopyrite and galena.

The property is located at 1371.6 metres elevation on the west side of the Salmo River, 3.5 kilometres southwest of Ymir.

The Free Silver claim (Lot 2902) was staked in June 1896 by J.M. McLaren and Crown-granted in 1902 to P.W. Thompson and associates. Adjacent ground was subsequently staked as the Ruby, Silver Fr., Victor, Royal, and Galena claims (Lots 2904 - 2906, 5322, 4553 respectively). Further activity was reported in 1908 and 1915 when the property was owned by T. Bennett, J.H. Schofield and associates; the only work reported is trenching.

CAPSULE GEOLOGY

The May Blossom claim (Lot 5666), which adjoins and lies east of the Free Silver claim, was staked in May 1897 by W. Birmingham. Subsequent staking included the May Day (Lot 13468), May Flower, Big Diamond, and Electric claims. Early development work was by American interests under the name May Blossom Mining & Milling Company. By 1915, the claims were held by J.F. Harbottle and associates. Development work to date included a 12-metre vertical shaft and a 69-metre adit on the May Blossom claim.

Washington interests, under the name Gibraltar Mining Company, optioned the May Blossom and Free Silver groups in 1921 but no work was reported. Harbottle and associates held the May Blossom group until 1930 or later.

The Free Silver claim was owned in 1977 by R. Spain, of Trail; prospecting of old trenches was reported.

CAPSULE GEOLOGY

Quartzite is quarried for flagstone on the Keith claim at the headwaters of Porcupine Creek, 19 kilometres northeast of Salmo. This area is underlain by a sequence of metamorphosed carbonates and clastic sediments of Lower Paleozoic age. These rocks have been folded into a series of north trending anticlines and synclines that have steep to near vertical limbs. The quarried stone is quartzite, with some interbedded schist, marble, argillaceous quartzite and conglomerate of the Lower Cambrian Quartzite Range Formation (correlative with rocks of the Hamill Group). These beds strike north and dip 80 to 84 degrees west. Jointing of moderate intensity is developed perpendicular to bedding. Individual quartzite beds display various colours including white, blue, pink, golden, brown and green. Only the top 6 metres of the deposit is quarried because of an undesirable colour change below this depth. Well developed micaceous partings enable the quartzite to be split into layers as thin as 1.3 centimetres. This flagstone is reported to be of excellent quality with good tooling characteristics (A. Gerun, personal communication, 1991). Quartzite has been quarried here since 1978. The deposit is currently being operated on a seasonal basis (1 to 2 months per year) by Gerex Developments Ltd. of Nelson. The stone is hand split along micaceous partings to produce flagstone of variable thickness. Thin flagstone (up to 5 centimetres thick) is sold for building facings, patio walkways and fireplaces. Thicker flagstone (wallrock) is used in the construction of retaining walls. Some material is also crushed for aggregate. Annually, 500 to 1000 tonnes of flagstone are produced and sold throughout western Canada by Gerex Developments (A. Gerun, personal communication, 1991).

CAPSULE GEOLOGY

Quartzite is quarried for flagstone on the Porcupine claims on the north side of Porcupine Creek, 17.5 kilometres northeast of Salmo.

This area is underlain by a sequence of metamorphosed carbonates and clastic sediments of Lower Paleozoic age. These have been folded into a series of north trending anticlines and synclines that have steep to near vertical limbs.

An outcrop, 300 metres long and 30 metres wide, of the Hadrynian-Lower Cambrian Quartzite Range Formation (Hamill Group) occurs on the claims. The outcrop comprises vertically dipping, thinly bedded quartzite with some interbedded argillaceous quartzite and conglomerate. Well-developed micaceous partings enable the stone to be split into plates ranging from less than 1 to 5 centimetres thick. Individual quartzite beds exhibit various colours including buff, red, grey, green, beige and brown, over widths ranging from 6 to 15 metres. A sample of quartzite assayed 99.6 per cent SiO₂ (I. Bakken, personal communication, 1991).

Jim Bakken and Associates began quarrying this deposit in 1964. The quarry is currently being operated by Porcupine Mines Ltd. (subsidiary of the Kootenay Stone Centre). The quartzite is sold in western Canada and used in building facings and various other decorative and architectural purposes.

CAPSULE GEOLOGY

The main areas of interest on the property are underlain by argillites, limy argillites and limestones of the Lower to Middle Ordovician Active Formation adjacent to the contact of the Lost Creek stock of the Middle to Late Nelson Intrusions. Disseminated molybdenite and scheelite associated with pyrite and pyrrhotite and traces of powellite occur within small garnet-diopside skarns within hornfelsed areas of the sediments. Tungsten is erratic but spot highs of 0.5 per cent or greater occur. Molybdenite and scheelite also occur as disseminations in quartz veins within the sediments and aplite dykes. Minor sphalerite and anomalous fluorite are associated with the quartz veining. The main showings are within the Mut adit on Lost Creek and west of the Molly mine (082FSW021) and also at the top of the ridge on what is referred to as Mut Hill. Mineralization is scattered throughout the claims and part of the Lost Creek granite stock is postulated to underlie the Active Formation sediments within the claim group. Autunite or uranophane is reported to occur within argillites (Assessment Report 7041, plan 10).

CAPSULE GEOLOGY

The Shiloh showing is located 1.5 kilometres east of Ymir. The Shiloh and Royal claims were Crown Granted sometime prior to 1917. Two adits occur on the Shiloh claim, only one of which (the western one) was driven on mineralization.

The area is underlain by argillite, siltstone, chert, wacke and grit of the Lower Jurassic Ymir Group. Middle to Late Jurassic granitic rocks of the Nelson Intrusions occur to the east and west.

A mineralized shear zone from 1.2 to 2.1 metres wide crosscuts argillites. The shear strikes north 310 degrees and dips about 50 degrees northeast. It contains crushed country rocks with veinlets of quartz containing pyrite, sphalerite and galena and some calcite.

A sample taken across 1.4 metres of the shear zone in the west adit containing minor pyrite and sphalerite mineralization assayed 1.03 grams per tonne gold, trace silver, 0.03 per cent zinc and trace lead (Assessment Report 8924).

CAPSULE GEOLOGY

This property is located at the 1219-metre elevation between Falls and Garrity creeks, about 14.4 kilometres west of Nelson. The Iron King group is north of and adjoining this property.

The Monarch claim (Lot 2082) was Crown-granted to M.C. Monaghan, and the Elk claim was Crown-granted to Alex McDonald, in 1904. Early exploration work consisted of open cuts and a 9-metre shaft.

During 1917-18 the Spokane Mining & Development Corporation carried out exploration work on the property under the management of C.M. Mohr. At about this time the property was acquired by the Sterling Trust Corporation of Toronto, for which Mr. Mohr was agent. The Falls Creek Mining Company reportedly worked the property in 1919; further work was reported done in 1922 under the directions of Mr. Mohr. Development work during this period consisted of a tunnel driven 30 metres at a vertical depth of 76 metres below the surface exposure. A mechanics lien was filed against the Monarch and Elk claims in 1924. The defendants specified were the Spokane Mining & Development Company, the Sterling Trust and Middle States Holding Company.

The Sterling Trust Corporation held the property until it was allowed to go on tax sale in 1927; the claims were purchased by M.C. Monaghan.

Queen Victoria Consolidated Mines Limited, reportedly formed to develop the Queen Victoria property located about 1.6 kilometres to the east, is reported to have held the Monarch and Elk claims in 1928, however no work was reported at this time.

The Monarch prospect is located 10 kilometres west-northwest of Nelson. The claim was Crown Granted in 1904 and several shafts and adits were developed at about that time. The property was held by Great West Mining Corporation Ltd. in 1962. Gerhardi Holdings Limited prospected the property in 1980.

The area is underlain by argillites, quartzite and limestone of the Lower Jurassic Ymir Group and mafic to intermediate volcanic rocks of the Lower Jurassic Elise Formation, Rosslund Group. These are intruded by granodiorite and quartz diorite of the Middle to Late Jurassic Nelson Intrusions and Jurassic pseudodiorite and pyroxenite of unknown affinity.

Skarn zones are developed in Ymir Group sediments and Elise Formation volcanics near the contact with granodiorite of the Nelson batholith. Chalcopyrite and pyrite occur in a garnet-epidote skarn. Some molybdenite is associated with epidote in fractures. Traces of galena and sphalerite were noted in exposures immediately north of the main showing. The garnet zone, occurring along the northeast striking granitic contact, is mineralized with chalcopyrite, pyrrhotite and pyrite disseminated in irregular patches. Near one of the basic dykes that intrudes the garnet zone a narrow band of magnetite has been exposed.

In 1918, a 153 tonne sample assayed 3 per cent copper, 201.6 grams per tonne silver and 3.428 grams per tonne gold (Minister of Mines Annual Report 1918, pages 173, 174, 197). In 1980, a grab sample from the main showing assayed 1.02 grams gold, 106.3 grams silver and 7.89 per cent copper (Assessment Report 8661).

Although little geological data is available it is believed that the mineralization at Monarch is similar geologically to the Queen Victoria mine (082FSW082) to the east.

COMMENTS: Sample from an opencut.

REFERENCE: Minister of Mines Annual Report 1922, page 208.

CAPSULE GEOLOGY

The workings are in sheared, decomposed augite porphyry of the Elise Formation of the Lower Jurassic Rossland Group. The shear or fault zone averages 0.5 metres in width, with a strike of 233 degrees and a 60 degree northwest dip. The zone is erratically mineralized with quartz which contains some disseminated pyrite, chalcopyrite, and copper staining (malachite?). The vein is about 400 metres from the Wallack Creek pluton of the Middle to Late Jurassic Nelson Intrusions and is possibly related to the Waneta fault. The pluton is composed of granite and granodiorite. A sample from an opencut is reported to grade 2.74 grams gold, 425.2 grams silver, and 6.1 per cent copper (Minister of Mines Annual Report 1922, page 208).

TERRANE: Quesnel

Plutonic Rocks

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The New York Central showing is located on the slopes of Jubilee Mountain, 3 kilometres southeast of Ymir. The main working on the claim is an old tunnel.

The area is underlain by quartzites and argillites of the Lower Jurassic Ymir Group which occur as roof pendants within Late to Middle Jurassic granite of the Nelson Intrusions (Nelson batholith).

A sheared, pyritic quartz vein, 0.45 to 1.0 metre wide, occurs along the contact of the granite with the sediments. The trend is generally northeast about 015 degrees with a westerly dip of about 50 degrees.

This showing is reported to be similar to the Iowa (082FSW065) and Nevada (082FSW064) occurrences which have pyrite as well as sphalerite and galena, however, sulphide mineralogy and metal grades are not documented.

CAPSULE GEOLOGY

The area of the Cristine occurrence is underlain by dark grey siltstone and sandstone of the Pennsylvanian (and possibly Permian) Mount Roberts Formation. Discontinuous veins or lenses of quartz and carbonate host gold values with minor sulphides which include pyrite and chalcopyrite. The mineralization on the claims is probably associated with discontinuous gold mineralization in the Snowdrop mine (082FSW115) which is adjacent to the claims.

Plutonic Rocks

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The Silverine veins are part of the north belt zone of discontinuous veins. On a regional scale, the veins appear to be continuous but in detail they are lenticular and offset by northerly trending faults. On the claim the veins are hosted by the Lower Jurassic Elise Formation, Rossland Group siltstone, argillite and hornfelsic siltstone. The hornfelsed siltstone is due to thermal metamorphism related to the Early Jurassic Rossland monzonite to the south and the Middle to Late Jurassic Trail pluton to the north.

Mineralization consists of vein infillings hosting pyrrhotite, arsenopyrite, magnetite, pyrite and minor chalcopyrite. Between 1934 and 1944, 82 tonnes of ore was mined from the showings and produced 1493 grams gold, and 2178 grams silver.

In 1967, Thorpe described mineralization north of Monte Cristo (082FSW101) as hosting native gold and bismuth associated with arsenopyrite and magnetite in the Intermediate zone.

Plutonic Rocks

CAPSULE GEOLOGY

The Kirkup showing is mainly underlain by Lower Jurassic Rossland Group (Elise Formation) volcanic breccia, volcanic conglomerate, sandstone and greenstone. Underlying these are siltstone shales, limestone and greywacke of the Pennsylvanian to Permian Mount Roberts Formation. Intruding the strata are granodiorite of the Jurassic Nelson Intrusions (Trail pluton). East of the area, the Rossland Group rocks are intruded by monzonite of the Middle Eocene Coryell Intrusions.

The showings lie within the zone of thermal metamorphism associated with the intrusion of the Trail pluton. Mineralization, within an old shaft on the Gold Star Crown grant, consists of massive bands and/or pods of pyrrhotite, pyrite and minor chalcopyrite in volcanics (Elise Formation) or hornfelsed sediments of the Mount Roberts Formation. Also, an adit was driven westwards into granodiorite for approximately 30.5 metres; material on the dump shows disseminated molybdenite and scheelite.

CAPSULE GEOLOGY

Micaceous quartzite of the Hadrynian-Lower Cambrian Quartzite Range Formation (Hamill Group) was quarried between 1966 and 1971 from talus slopes in the vicinity of the confluence of Sheep and Waldie creeks, 12 kilometres southeast of Salmo.

Quartzite of various colours including buff, brown, green, red and grey was hand-sorted before being sold to local markets as facing stone. Well-developed micaceous partings enabled the stone to be split into slabs ranging from 1.3 to 10 centimetres thick.

A total of 453 tonnes of quartzite was quarried between 1966 and 1969.

CAPSULE GEOLOGY

Limestone was once quarried for marble on the south side of Sheep Creek, 6 kilometres west of its confluence with the Salmo River.

The quarry is developed in limestone, with some interbedded quartzite, of the Lower(?) and Middle Ordovician Active Formation (correlative in part with the Glenogle Formation of the western Rocky Mountains). The limestone strikes 020 degrees and dips between 60 and 70 degrees east. The band can be traced southwest from Sheep Creek up the valley side to a considerable height above the valley floor. It is badly shattered and in places cut by quartz veinlets. An irregular set of joints strike 075 degrees. The limestone produced from the quarry is fine to coarse grained and white to grey banded.

A small amount of limestone, quarried by W. McArthur before 1914, was used in the Nelson Post Office.

CAPSULE GEOLOGY

The Katie alkaline porphyry deposit is located seven kilometers southwest of Salmo. The earliest recorded work on the property occurred in 1980 when Amoco Canada outlined a 0.5 by 1 kilometre soil copper anomaly on their Jim claims. The claims lapsed and in 1985, Ken Murray staked the Katie claim group to cover the Amoco copper anomaly and was able to define a coincident gold soil anomaly. In 1988 Balloil Lassiter Petroleum Limited optioned the property and conducted geological and geophysical surveys and a four-hole, 305-metre diamond drilling program in 1989. The best hole, KT-89-4 intersected 6 meters grading 0.24 per cent copper and 0.2 gram per

CAPSULE GEOLOGY

tonne gold (Assessment Report 20331). In 1990, Yellowjacket Resources Limited acquired Balloil's interest and formed a joint venture with Hemlo Gold and Brenda Mines. As operator, Noranda Exploration Company drilled 8,260 metres in 34 core holes. The soil anomaly was expanded to an area of 1.5 by over 2 kilometres and geophysics included comprehensive grid magnetics and IP surveys. In 1992, Yellowjacket drilled an additional 4,477 metres in 18 holes. John A. Chapman and KGE Management LTD. restaked the property in 2001.

The Salmo area is underlain by an arcuate belt of sedimentary and volcanic rocks of the Lower Jurassic Rossland Group, in fault contact with Paleozoic Kootenay Terrane rocks to the south and the late Jurassic Nelson Batholith to the north, east and west. The Rossland Group includes the Archibald Formation clastic sediments, a thick sequence of volcanic and epiclastic rocks of the Elise Formation and Hall Formation clastics. They are cut by synvolcanic intrusives, Middle Jurassic to Cretaceous granitic intrusions of the Nelson Batholith, the Middle Eocene Coryell intrusions and felsic to mafic Tertiary dikes.

The Katie claims cover intermediate to mafic flows and tuffs of the Elise Formation. These include andesite to basalt flow breccia, lapilli tuff and crystal tuff and latite fine tuff. Synvolcanic intrusive rocks underlie a large portion of the property and range in composition from monzonite to monzodiorite through to monzogabbro and gabbro. Younger intrusive rocks include feldspar porphyry, rhyolite, lamprophyre and diabase.

Drilling has outlined widespread alkaline porphyry copper-gold mineralization within a 1.75 by 2.5 kilometre area, focused on three zones: Main, West and 17. From one percent to greater than 10 percent pyrite and chalcocopyrite occur as disseminations, fracture fillings and veins associated with contacts between monzodiorite dikes and volcanics. Weathering effects have been noted to a depth of 20 metres or more, with secondary malachite, azurite and local chalcocite. Traces of bornite, pyrrhotite, sphalerite and tetrahedrite have also been noted.

Potassic core zones, with copper grades up to one percent and gold in the range of 0.5 gram per tonne are characterized by pervasive, vein and stockwork K-feldspar, with biotite, quartz, chlorite and sometimes coarse magnetite grains. These are enveloped by broad areas of propylitic alteration including pervasive and fracture controlled epidote, chlorite, albite, hematite (goethite) calcite, sericite and magnetite. The potassic and propylitic alteration largely obliterates primary textures, with the exception of feldspar and pyroxene phenocrysts.

Mineralization and alteration are controlled by northwesterly oriented structures and are zoned outwards from highest copper and gold in the potassic cores, followed by lower grade values in the propylitic zone. A late stage of mineralization includes strongly deformed quartz-carbonate-sulphide veins within mylonitic shear structures. Sulphides include pyrite, chalcocopyrite, tetrahedrite, molybdenite and arsenopyrite. Specular hematite has been tentatively identified.

Katie shows two styles of mineralization. One is an alkalic porphyry copper-gold and a later shear hosted gold-silver-copper-antimony-arsenic stage (EMPR Bulletin 109).

The porphyry mineralization (of Lower Jurassic age, consists mainly of pyrite, lesser chalcocopyrite and bornite, and traces of pyrrhotite, sphalerite, tetrahedrite and ? chalcocite. Sulphides occur both disseminated in hosting volcanic beds or intrusive sills or in veins with quartz, calcite, potash feldspar, chlorite and epidote. Magnetite is widespread except in highly altered potash feldspar zones. Propylitic alteration is mainly a mixture of chlorite, epidote, sericite and actinolite. Local calcite epidote and pyrite stringers cut this zone. Potassic alteration is shown by potash feldspar and secondary biotite. The later shear and mylonites with local enrichment of gold, copper, arsenic and antimony cut the earlier porphyritic mineralization. The age of these shears are either pre Middle Jurassic or Eocene in age.

The Main zone is northwest striking, steeply northeast dipping, 70 to 135 metres thick and at least 500 metres long. It is open in both directions and to depth. Copper grades average from 0.25 to 0.3 per cent while gold values range from 0.15 to 0.45 gram per tonne. The 17 zone is geologically similar to the Main Zone and is located 670 metres to the south. It strikes northwest, dips gently to the east and has been outlined by limited drilling over an area 110 by 300 metres. Average grades are 0.28 per cent copper and 0.3 grams per tonne gold (Carlson, 2002 (Property File)).

The drilling has been mostly directed to the northwest, parallel to the main controlling structure. The identified higher grade

CAPSULE GEOLOGY

potassic core zones have not been fully tested. The Main Zone is open to the northwest and southeast, while the best results from drill holes in both the West and 17 zones are on the edge of the areas tested. Soil geochemistry and IP define extensions to these zones as well as a number of other untested targets.

CAPSULE GEOLOGY

The Gus (Swift) area is underlain mainly by basaltic volcanics of the Lower Jurassic Rossland Group, Elise Formation comprised of flow breccia, massive flows, agglomerate, tuff and sill-like intrusives (augite porphyry). A minor amount of laminated, tuffaceous siltstone and shale occurs as interbeds. These are overlain by argillites and quartzites of the Rossland Group, Hall Formation and underlain by black argillaceous siltstone and arenaceous argillite of the Rossland Group, Archibald Formation. The Rossland Group rocks are intruded by the Middle to Late Jurassic Nelson Intrusions comprised of a mass of granodiorite and associated dykes.

Quartz veins fill irregular fractures, ranging from less than 1 centimetre up to 30 centimetres, that cut carbonatized and locally silicified mafic tuffs. Late syenite dykes occur near zones of alteration. The veins contain up to 10 per cent chalcopyrite, sphalerite and galena. Significant gold and silver values were encountered in variably altered tuffs, silicified tuffs and quartz veins.

CAPSULE GEOLOGY

A 2-metre trench sample (trench 21) assayed 100.2 grams per tonne gold and 18.0 grams per tonne silver; another nearby 2-metre sample gave 8.5 grams per tonne gold (Assessment Report 16901, page 13). The sample high in gold consisted of carbonatized tuff and a 0.4 metre wide quartz vein containing chalcopyrite, galena, pyrite and possibly sphalerite. A drill program in 1987 encountered 10 metres grading 1.83 grams per tonne gold (Assessment Report 17296, page i).

CAPSULE GEOLOGY

A 120 to 900 metre wide band of limestone of the Silurian (?) to Carboniferous "Pend d'Oreille Sequence" trends east-northeast along the north side of the Pend d'Oreille River for 7.9 kilometres. The band is bounded to the north and south by argillite, slate and phyllite. The entire sequence lies in fault contact with andesite, basalt, tuff and breccia of the Lower Jurassic Elise Formation to the north. The limestone member dips approximately 50 degrees south. The Pend d'Oreille Sequence is correlated to the Attwood Formation of the Greenwood area to the west.

The carbonate is generally composed of massive, light grey, white to light blue weathering limestone. The limestone is commonly siliceous. In places, buff weathering dolomite masses, up to a hundred metres in diameter are present. A sample of chips collected at random over a 4 square metre area along the limestone bluffs near the Nelway-Waneta road, 317 metres west of Charbonneau Creek contained 52.90 per cent CaO, 2.36 per cent MgO and 0.84 per cent insolubles (J.T. Fyles, 1956, Sample 9230). A similar sample 712 metres east of the creek contained 53.80 per cent CaO, 1.83 per cent

CAPSULE GEOLOGY

Dark coloured monzonite has been produced for monumental stone and building purposes from two small quarries at the north end of a northwest trending ridge close to the derailing switch along the railway line east of Rossland. The quarries are developed in the Early Jurassic Rossland monzonite, an east-trending monzonite stock 8 kilometres long with a width of up to 3 kilometres.

The monzonite consists of dark greenish glistening hornblende phenocrysts up to 8 millimetres in diameter and smaller black glistening mica flakes set in a light coloured matrix of orthoclase and plagioclase. The stone displays uniform texture and is susceptible to polishing, but on weathering it dulls over a few years and turns reddish over longer periods. The monzonite is cut by a pronounced joint set striking 130 degrees and dipping steeply east, together with a sheeting, spaced up to 1.2 metres apart that follows the contours of the ridge, dipping gently east on the east flank and west on the west flank. A sample analyzed as follows (CANMET Report 452, page 119, sample 1515):

PHYSICAL PROPERTIES	
Specific gravity	2.882
Pore space (per cent)	1.304
Crushing strength (dry) (lbs/sq.in.)	28,167
Transverse strength (lbs/sq.in.)	1,692
Shearing strength (lbs/sq.in.)	1,053

The stone was quarried during the early 1900's up to about 1915. The monzonite was used in the base of the Bank of Montreal in Rossland and in the lower storey of the Rossland Post Office.

COMMENTS: Sample 5496 across 2 metres, highest assay from trenching program.
REFERENCE: Assessment Report 19503.

CAPSULE GEOLOGY

The Toughnut showing is located on Toad Mountain, 7 kilometres southeast of Nelson and 2 kilometres southeast of the Star showings (082FSW083). Old open pits, shafts and trenches occur on the property. This is probably a "conformable gold" occurrence. The area, in the Silver King shear zone, is underlain by volcanic rocks of the Lower Jurassic Elise Formation, Rossland Group. These comprise mafic to intermediate flows, tuffs, breccia and quartz feldspar porphyry intruded by lamprophyre dykes. The showing consists of widely disseminated pyrite in volcanic rocks, and quartz veins hosting galena, chalcopyrite, sphalerite and rare tetrahedrite. Mineralization is associated with carbonate,

CAPSULE GEOLOGY

sericite and potassically altered volcanic rocks. The alteration appears to be most prevalent in the tuffs.

The veins are 0.10 to 1 metre wide and many are parallel to the regional foliation, striking 120 degrees and dipping 75 degrees south. One vein, on which the workings were developed, can be traced discontinuously for at least 120 metres.

The highest assay from the 1989 trenching program was 6.2 grams per tonne gold, 1.7 grams per tonne silver, 0.0026 per cent copper, 0.0015 per cent lead and 0.0045 per cent zinc across 2 metres (Assessment Report 19503). Diamond-drilling in 1990 reported variable results (Assessment Report 20063).

CAPSULE GEOLOGY

The Mitzie 1 property is underlain by the Lower Jurassic Rossland Group, Elise Formation, comprised of andesitic flows, tuff, agglomerate, breccia and black siltstone. The showing, located 150 metres south of the Mountain Trail Crown Grant (Lot 4078), consists of a 3.5 metre wide zone which strikes 005 degrees and dips 75 degrees east in andesite. Mineralization is disseminated and in stringers with quartz in a shear zone and consists of galena, sphalerite, pyrite, chalcopyrite and pyrrhotite. Fine-grained, disseminated pyrite occurs on the surface and is pervasive in the wallrock. Silicification extends for 2 to 3 metres beyond both walls of the shear as a hydrothermal alteration halo. In 1983, a chip sample across 3.5 metres assayed 0.17 grams per tonne gold, 27.4

CAPSULE GEOLOGY

grams per tonne silver, 0.29 per cent copper, 2.84 per cent lead, and 1.63 per cent zinc (Assessment Report 12643).

According to the recent assessment reports, shafts were sunk along iron stained and weakly mineralized shears which strike 330 degrees on the Mountain Trail Crown Grant. Apparently, around 1946, 58 tonnes of ore were shipped and produced 239 grams gold, 1131 grams silver and 3538 kilograms of copper with the average grade of the ore approximately 3.7 grams per tonne gold, 17.4 grams per tonne silver and 0.6 per cent copper. These statistics may be associated with mineralized shear zones near the margins of a granitic intrusive and limestone contact on the Sunset property, Lot 6563 (082FSW160).

CAPSULE GEOLOGY

The Nelson clay deposit occurs on the banks of Graham Narrows near the airfield in Nelson and covers an area up to 1 kilometre long.

Limited deposits of silty clay, close to lake level, occur in the vicinity of Nelson. The clay has been used in the past for the manufacture of common brick but no production figures are available. The clay may have originated as lake or glacial deposits.

The clay forms a mass of good plasticity with 28 per cent water and an air shrinkage of five per cent. When wet-moulded the clay burned to a hard, not very dense, brick of red color. The clay is past vitrification at cone 1 and fuses at cone 3.

CAPSULE GEOLOGY

The area of the Helen occurrence is underlain predominantly by leucocratic granite of the Middle Eocene Sheppard Intrusions that has intruded into rocks of the Lower Jurassic Elise Formation, Rossland Group. The intruded rocks are argillites and argillaceous quartzites, on the east side of Grouse Ridge, and minor pockets of red shales with some minor radioactivity near the north end of the ridge. The red shales are in contact with a large mass of conglomerate to the north.

Swarms of quartz veins were found in the leucocratic granite, ranging from a few centimetres to a few metres in width, and hosting traces of gold. Two parallel veins near the International boundary, striking 270 degrees and dipping steeply to the north, were found to

CAPSULE GEOLOGY

carry gold values. The veins are traceable for 275 metres and range up to 30 centimetres in width. Laboratory analyses of this sample assayed 192.9 grams per tonne gold, 98.7 grams per tonne silver with spectrochemical analysis indicating 0.15 per cent lead, 0.01 per cent zinc and 0.02 per cent copper (Assessment Report 7796). Another sample from the quartz veins assayed 54.2 grams per tonne gold, 20.6 grams per tonne silver, 0.27 per cent lead, 0.15 per cent copper, and 0.015 per cent molybdenum (Assessment Report 7796). Up to 0.1 per cent molybdenum was obtained from samples.

In 1979, a sample from the property described as monzodiorite, assayed 2.0 grams per tonne gold, 0.7 grams per tonne silver, 0.01 per cent nickel, 0.02 per cent chromium, 0.015 per cent niobium with 3 parts per million uranium and 28 parts per million thorium (Assessment Report 7796).

Most of the above samples appear to have been taken on the Helen No. 2 Crown Grant (Lot 1151). Before the turn of the century, a vein ranging from 0.5 to 3.7 metres in width was reported to occur on the Helen group of 3 claims on Grouse Mountain. By 1987, an incline shaft was down 24 metres and was to connect with a 61 metre tunnel at a depth of 91 metres (Hodges, 1897). The adit was reported to show from 0.3 to 0.6 metres of ore assaying high in gold and containing some silver and lead.

CAPSULE GEOLOGY

The Rachel showing is located 22 kilometres southwest of Nelson. The area has been extensively explored since the 1800's; this vein was discovered in 1954.

The area is underlain by a granodiorite pluton, the Bonnington pluton, of the Lower to Middle Jurassic Nelson Intrusions. The granodiorite is locally cut by aplite and lamprophyre dykes and quartz veins 0.5 to 3.0 centimetres wide generally trending north and dipping steeply. The granodiorite exhibits two sets of jointing.

The Rachel vein is a north-northeast striking "saddle" vein exposed in an adit on the south side of Grassy Mountain. The vein is 10 to 40 centimetres wide over a strike length of 25 metres and follows the 2 sets of joints to their junction. The vein comprises quartz with lenses and disseminations of galena, free gold as flakes and traces of pyrite. A zone of argillic alteration occurs adjacent to the south side of the vein, and some chloritization and

CAPSULE GEOLOGY

sericitization occur in the wallrock.

In 1980, Kimberley Gold Mines removed 14 tonnes of high grade ore from the adit, yielding an average assay of 66.64 grams per tonne gold, 271.5 grams per tonne silver, and 9.42 per cent lead (Assessment Report 19021). A grab sample taken in 1989 from the middle of the adit assayed 174.5 grams per tonne gold, 331.5 grams per tonne silver and 10.05 per cent lead (Assessment Report 19021).

An extension of the west limb of the vein is exposed 15 metres to the west of the adit. A grab sample taken in 1984 assayed 4.94 grams per tonne gold, 65.13 grams per tonne silver, 2.42 per cent lead (Assessment Report 19021).

CAPSULE GEOLOGY

The Ben Hassen showing is located on the west side of Erie Creek, about 11 kilometres southwest of Ymir. This showing, along with the Copper King (082FSW213), the Arnold (082FSW301) and the Hattie (082FSW226) showings, occur on the Erie Creek property.

The area is underlain by Archibald Formation sediments and Elise Formation volcanics, both of the Lower Jurassic Rossland Group. The Rossland Group rocks are intruded by granodiorite and quartz monzonite of the Middle to Late Jurassic Nelson Intrusions, locally known as the Erie stock. The Erie stock is comprised of a light grey quartz monzonite with associated aplitic and feldspar porphyry dykes. Biotite hornfels is apparently a contact metamorphic effect related to both the Nelson batholith and the Erie Creek dyke swarm. Hornfels is mainly developed in argillite and siltstone. Chlorite occurs mainly on fractures and in shear veins in augite andesite and

CAPSULE GEOLOGY

hornfels.

Mineralization on the property occurs roughly in four concentric zones. An inner quartz-molybdenum plus scheelite zone followed by a chalcopyrite zone, a pyrite-pyrrhotite zone and an outer sphalerite-galena zone. The inner zone is approximately 600 metres in diameter and is centered on the east side of Erie Creek (Hattie). The host rocks are quartz monzonite dykes, stocks and white rhyolite. The chalcopyrite zone occurs over an area of 1.5 to 2 kilometres and occurs in quartz and sulphide veinlets as fracture coatings and in shear veins with pyrite, pyrrhotite and minor amounts of scheelite. The best copper values obtained, up to 1.3 per cent, were from vein and dump samples mainly from old workings on the west side of Erie Creek (Drum Lummon, Cooper King, Dora, Homestake). Pyrite and pyrrhotite, in an area about 1.5 by 2.5 kilometres, occur finely disseminated and as fracture coatings. Sphalerite and galena with some gold occur in shear veins beyond the inner zone, such as the Arnold and Ben Hassen showings.

Slate, near the contact with granodiorite, hosts pyrite, galena and minor chalcopyrite. The mineralization occurs as disseminations and stringers in a zone 4 to 5 metres wide. In 1987, sphalerite and galena were found in shear veins on the Ben Hassen Reverted Crown Grant. Quartz vein material with galena, pyrite and chalcopyrite taken from the south shaft on the claim assayed 223.9 grams per tonne silver and 1.68 grams per tonne gold (Assessment Report 15510). A sample from a 2.0-centimetre wide quartz vein from the north shaft assayed 259.8 grams per tonne silver and 0.305 gram per tonne gold (Assessment Report 15510).

The mineralization is believed to be part of a zoned porphyry type deposit which has a central quartz vein stockwork zone containing molybdenum-copper-tungsten mineralization and a peripheral zone with veins containing copper-lead-zinc-silver mineralization. This showing is interpreted as occurring in the outer zone.

The claim is located at the 1524 metre elevation about 1.6 kilometres east of Erie Creek, opposite Grassy Creek, some 24 kilometres southsoutheast of Nelson.

Early work on the claim, dating from 1896 or earlier, includes a 7-metre shaft and 3-metre drift. The Ben Hassen claim (Lot 3663) was Crown-granted in 1900 to The New North Fork Mining Company, Limited. The Epoch, Titanic and Young Grouse claims (Lots 2328, 2455 and 2456 respectively) were Crown-granted in 1898 to F. Riffle. These claims are located about 1.6 kilometres south of the Ben Hassen on the east side of Young Grouse Creek, a tributary of Burnt Creek.

CAPSULE GEOLOGY

The Arnold showing is located on the west side of Erie Creek, about 13 kilometres west of Ymir. This showing, along with the Copper King (082FSW213), the Ben Hassen (082FSW300) and the Hattie (082FSW226) showings, occur on the Erie Creek property.

The area is underlain by sediments of the Archibald Formation and minor volcanics of the Elise Formation, both of the Lower Jurassic Rossland Group. The Rossland Group rocks are intruded by granodiorite and quartz monzonite of the Middle to Late Jurassic Nelson Intrusions, locally known as the Erie stock. The Erie stock is comprised of a light grey quartz monzonite with associated aplitic and feldspar porphyry dykes. Biotite hornfels is apparently a contact metamorphic effect related to both the Nelson batholith and the Erie Creek dyke swarm. Hornfels is mainly developed in argillite and siltstone. Chlorite occurs mainly on fractures and in shear veins in augite andesite and hornfels.

Mineralization on the property occurs roughly in four concentric

CAPSULE GEOLOGY

zones. An inner quartz-molybdenum plus scheelite zone followed by a chalcopyrite zone, a pyrite-pyrrhotite zone and an outer sphalerite-galena zone. The inner zone is approximately 600 metres in diameter and is centered on the east side of Erie Creek (Hattie). The host rocks are quartz monzonite dykes, stocks and white rhyolite. The chalcopyrite zone occurs over an area of 1.5 to 2 kilometres and occurs in quartz and sulphide veinlets as fracture coatings and in shear veins with pyrite, pyrrhotite and minor amounts of scheelite. The best copper values obtained, up to 1.3 per cent, were from vein and dump samples mainly from old workings on the west side of Erie Creek (Drum Lummon, Cooper King, Dora, Homestake). Pyrite and pyrrhotite, in an area about 1.5 by 2.5 kilometres, occur finely disseminated and as fracture coatings. Sphalerite and galena with some gold occur in shear veins beyond the inner zone, such as the Arnold and Ben Hassen showings.

Cominco drilled several holes in this area in 1926-1927. Old reports document galena, pyrite, sphalerite and chalcopyrite in a poorly defined "zone" of altered volcanics. In 1987, sphalerite and galena were found in shear veins on the Arnold Reverted Crown Grant. Two samples from a quartz vein in an old adit at elevation 1402 metres assayed 41.4 grams per tonne silver, 0.049 grams per tonne gold and 67.3 grams per tonne silver, 0.032 grams per tonne gold, respectively (Assessment Report 15510).

The mineralization is believed to be part of a zoned porphyry type deposit which has a central quartz vein stockwork zone containing molybdenum-copper-tungsten mineralization and a peripheral zone with veins containing copper-lead-zinc-silver mineralization. This showing is interpreted as occurring in the outer zone.

The Arnold claim is located at the 1371.6 metres elevation on the west side of Erie Creek some 22.5 kilometres south-southwest of Nelson. An early settlement about 3.2 kilometres to the south was known as Craigtown or Green City.

Workings on the Arnold claim in 1896 included a 7.6 metre shaft and 16 metres drift. The claim was Crown-granted (Lot 4079) to W.A. Arnold in 1902.

The Arnold and adjacent Gracie R, Rosebud Fr. and Arnold Fr. claims were owned from about 1920 by W. Connolly. The Consolidated Mining and Smelting Company of Canada Limited optioned the property and carried out diamond drilling in 1926-27 on the Arnold and Gracie R claims, and on the St. Louis (Lot 12176) about 1.6 kilometres to the south. The drilling indicated wide zones of mineralization but failed to locate commercial ore.

CAPSULE GEOLOGY

The Rhea (or Reah) showings are located in the Copper Mountain Lookout area, 13 kilometres southwest of Nelson. The earliest known work was done before the 1920's.

The area is underlain by volcanic rocks of the Lower Jurassic Elise Formation, Rossland Group which have been intruded by granodiorite to quartz monzonite of the Middle to Late Jurassic Nelson Intrusions. The Red Mountain fault occurs to the east of the claims area. The volcanic rocks comprise tuffs, plagioclase crystal tuffs, lapilli tuffs and andesite tuffs. The volcanic stratigraphy is intruded by aplite dykes and small stocks.

Several quartz veins occur conformable to the local foliation on

CAPSULE GEOLOGY

the southwestern flank of Copper Mountain. The white quartz veins have been sheared and host erratic metal values. Mineralization consists of pyrite, pyrrhotite, tetrahedrite, chalcopyrite, malachite and arsenopyrite.

The Rhea vein, in a strong vertical shear, is 0.3 to 1.5 metres wide and has been traced for 300 metres. It strikes 47 degrees and dips 76 degrees east. Reported gold values vary from trace to about 1.6 grams per tonne with equally low and erratic base metal values. A sample of high grade material taken from the dump assayed 9939.0 grams per tonne silver, 2.48 per cent copper, 0.15 per cent lead and 0.28 per cent zinc (Assessment Report 12720). Sampling of the vein itself in 1985 resulted in a best assay of 1.37 grams per tonne gold and 25.37 grams per tonne silver (Assessment Report 14280).

The Tetrahedrite or Extension vein, just to the south of the Rhea, is similar in mineralization and trend. This vein, however, dips 40 to 50 degrees east. It has been exposed for 50 metres. The highest assay was 16.45 grams per tonne gold, 1585.8 grams per tonne silver, 0.2 per cent copper, 0.78 per cent lead and 0.04 per cent zinc (Assessment Report 14280).

The O.G.G. vein outcrops about 800 metres to the north and east of the Rhea vein and is parallel to it.

SAMPLE TYPE: Drill Core
COMMODITY Gold GRADE 12.4500 Grams per tonne
COMMENTS: The sample width is 10 centimetres. No other metals were assayed for.
Drill hole 84-4.
REFERENCE: Assessment Report 12937.

CAPSULE GEOLOGY

The Root showing is located 15 kilometres southwest of Nelson. Old workings comprise a shaft, several shallow trenches and some short adits.

The area is underlain by argillite, siltstone and limestone of the Lower Jurassic Ymir Group which have been intruded by granodiorite of the Late to Middle Jurassic Nelson Intrusions near the Bonnington pluton.

The main Root showing appears stratabound on a large scale but locally there is evidence of crosscutting relationships and brecciation within the chloritic and silicified sediments. Mineralization is in the form of bands of semi-massive and massive pyrite, pyrrhotite, chalcopyrite and arsenopyrite intercalated with silicified sediments containing disseminated sulphides. The main showing is 3 to 6 metres wide and 111 metres long. The close spatial relationship of pyrite bearing granodiorite is observed at every mineralized outcrop on the Root property.

CAPSULE GEOLOGY

The True Fissure is a fissure vein, hosted in schist, on the same property. The nearly vertical vein exposed on surface is a nearly continuous streak of ore material for 30 metres. Mineralization consists of galena and sphalerite. A sample across 0.06 metre on the surface assayed 4.11 grams per tonne gold, 6982.84 grams per tonne silver, 15.3 per cent lead and 32 per cent zinc (Minister of Mines Annual Report 1927, page 318). In 1927, 23.6 tonnes of ore were shipped but the grade is not recorded. Some skarn material was observed in old drill core but the actual location of the drill holes is not recorded.

The highest assay from drilling in 1984 came from drill hole 84-4 which intersected chloritic silicified limestone with minor intersections of porphyritic intrusive and graphitic schist. Mineralization was observed as zones of disseminated to massive pyrite, pyrrhotite and chalcopyrite in silicified limestone and disseminated pyrrhotite and pyrite within chloritic limestone. The highest assay of 12.45 grams per tonne gold was from an intersection of 0.10 metre (Assessment Report 12937).

Eagle Plains Resources Ltd. and Miner River Resources Ltd. hold the property. Samples from road cuts returned values up to 5.7 per cent zinc, 1 per cent lead, 0.3 per cent copper, 0.35 per cent cobalt, 0.09 per cent nickel and 0.5 grams per tonne gold (Eagle Plains Resources Ltd. Website, February, 1999).

CAPSULE GEOLOGY

The Lasca 1 showing is located near the headwaters of Lasca Creek, 15 kilometres east of Nelson. Several trenches and adits have been developed on this showing.

The area is underlain by porphyritic hornblende granodiorite of the Nelson batholith of the Late to Middle Jurassic Nelson Intrusions. Small rafts and roof pendants consisting of Lower Jurassic Ymir Group and Lower Cambrian metamorphosed sediments occur in the batholith.

The Lasca number 1 vein is hosted in micaceous quartzites and paragneiss. The vein, 1 to 1.5 metres wide, strikes 146 to 150 degrees, dips 40 to 53 degrees north and has been traced for 390 metres. Mineralization consists of pyrite, pyrrhotite, some galena and rare sphalerite within a quartz gangue. Base and precious metal values from sampling are very low.

CAPSULE GEOLOGY

Grab samples from silicified shear zones in Lower to Middle Ordovician Active Formation argillites were collected from a series of old trenches on the Aspen showing. Sulphide mineralization ranges from disseminated to massive and consists of galena, sphalerite and pyrite. Limonite staining is common. The length of the zone of mineralization is reported to be 180 metres.

Samples assayed as high as 6.7 per cent lead, 7.4 per cent zinc, 272 grams silver and 1.29 grams gold (Assessment Report 12985).

CAPSULE GEOLOGY

At one location a 1-metre wide quartz-clay-lithic breccia sulphide vein is exposed in a trench. It is hosted in a shear trending 168 degrees and dipping 72 degrees north within silicified, variably gossanous andesite. Pyrite, chalcopyrite, galena and sphalerite occur in stringers parallel to the veins margins, as well as isolated blebs and disseminations. A 0.5-metre chip sample (SRR-030) assayed 1.59 grams per tonne gold, 4.9 grams per tonne silver, 0.34 per cent copper, 0.33 per cent lead and 0.14 per cent zinc (Property File - Uptown Industries Corp., Prospectus, May 9, 1989, page 14).

Similar mineralization to the previous sample is exposed along five metres in andesite outcrop located about 700 metres to the northwest. An exposure of quartz-feldspar porphyry is found 10 metres south of this area. A 1-metre chip sample (SRR-036) of the porphyry assayed 0.122 per cent tungsten (Property File - Uptown Industries Corp., Prospectus, May 9, 1989, page 14). About 1.5 kilometres to the northwest on Santa Rosa Creek, about 200 metres upstream from the Swehaw Creek confluence, is another tungsten showing. A zone of pyritized and silicified pods occur, up to 10 cubic centimetres in volume. These zones are hosted by andesite that is cut by granitoid dykes. A grab sample (SRR-101) assayed 0.178 per cent tungsten (Property File - Uptown Industries Corp., Prospectus, May 9, 1989, page 15).

In 1943, Cominco was reported to have prospected a tungsten property located west of Big Sheep Creek about 1.5 kilometres south of the Cascade highway (Minister of Mines Annual Report 1943, page 79). Twenty three metres of trenching was done near an igneous contact that apparently hosted minor disseminated scheelite.

CAPSULE GEOLOGY

Limestone is mined underground on the north side of Lost Creek, 2.85 kilometres northeast of its confluence with the South Salmo River.

The mine is developed in limestone of the Reeves Member of the Lower Cambrian Laib Formation. The unit strikes 060 degrees and dips 45 degrees southeast.

The deposit consists mostly of massive, sugary textured, fine-grained (1 millimetre), white limestone mottled in places with a slight yellow colour. Zones of light to dark grey banded limestone, occasionally with rusty streaks, were encountered in the mine. A sample of fresh fragments contained 52.8 per cent CaO, 0.82 per cent MgO, 1.31 per cent SiO₂, 1.29 per cent Al₂O₃, 0.15 per cent Fe₂O₃, 0.055 per cent MnO, 0.02 per cent TiO₂ and 43.25 per cent ignition loss (Geological Fieldwork 1985, page 240). The ground limestone is reported to have a brightness of 94.85 per cent.

Limestone has been mined here by International Marble & Stone Company since late 1983 after abandoning the quarry on Swift Creek (082FSW215). Between 1984 and 1987, 26,379 tonnes of limestone were mined by IMASCO. The limestone is trucked to Sirdar where it is

CAPSULE GEOLOGY

crushed and ground for a variety of products, including filler applications.

CAPSULE GEOLOGY

The Flying Dutchman is located on the northern side of Hall Creek, about 12 kilometres southwest of Nelson. Development in the 1800's included a 10.7-metre drift at the 1541.2-metre level and a 36.58-metre drift at the 1524.3-metre level. The area is underlain by augite basalt flows and flow breccias of the Lower Jurassic Elise Formation, Rossland Group. These have been intruded by granitic rocks of the Middle to Late Jurassic Nelson Intrusions. Quartz veins, up to 4 metres wide, occur in shear zones in augite porphyry. The Flying Dutchman vein is about 1 metre (?) in width and hosts erratic gold values. The vein strikes between 010 and 050 degrees and dips between 65 and 75 degrees. Mineralization, similar to other showings in the area (such as H.B. - 082FSW181), consists of quartz gangue hosting pyrite, chalcopyrite, free gold,

CAPSULE GEOLOGY

bornite and traces of galena. Pyrite is the dominant sulphide and mineralization is reported to be strongest on the hanging wall side of the vein. Sampling of the vein on the No. 2 level workings resulted in assays ranging from trace to 13.7 grams per tonne gold across 0.45 to 1.46 metres (Minister of Mines Annual Report 1934, page E5).

A sample ((HTR12A)) of quartz veining and stockwork with disseminated pyrite and chalcopyrite in fine-grained andesite (basalt ?) was taken from the southwest corner of Lot 5146. The sample assayed 0.22 grams per tonne gold, 1.8 grams per tonne silver and 0.23 per cent copper (Assessment Report 18939).

COMMENTS: Sampling from a 4 metre trench at the Main showing on Lot 1311.
REFERENCE: Assessment Report 14064.

CAPSULE GEOLOGY

The Star of the West showing is located 5 kilometres south of Nelson on Lot 1311. The claim was Crown Granted in 1897 and workings comprise a 6-metre long adit, a 4-metre trench and a few small pits.

The area is underlain by volcanic rocks of the Lower Jurassic Elise Formation, Rossland Group which have been intruded by granodiorite and quartz monzonite of the Middle to late Jurassic Nelson Intrusions. The volcanic rocks comprise augite porphyry, augite porphyry basalt flows, flow breccias and plagioclase crystal tuffs.

The New Bicycle or main showing consists of slightly

CAPSULE GEOLOGY

crosscutting pyrite-galena-sphalerite-magnetite veins or stringers hosted by dark green, sheared, chloritized tuffs. The tuffs strike 140 degrees and dip 50 to 60 degrees northwest.

The veins or stringers are up to 1 centimetre wide and locally contain massive, fine-grained quartz or massive fine-grained pyrite with some limonite staining. The veins appear stratabound locally but are accompanied by anomalous geochemical values for mercury which may indicate an epithermal environment. The veins carry insignificant gold and low amounts of silver. Grab samples from the 4-metre trench at the main showing assayed up to 3.63 per cent zinc and 2.68 per cent lead with up to 96.8 grams per tonne silver and 0.125 grams per tonne gold (Assessment Report 14064).

CAPSULE GEOLOGY

This property lies on the summit between Sheep & Lost Creeks, about 11.2 kilometres southeast of Salmo. Although the Emerald has in recent years been a tungsten producer (082FSW010), its early history as a lead-zinc producer is mentioned here because the Jersey (082FSW009) workings were later extended into Emerald ground and production figures for the two have not been recorded separately.

Production of lead-zinc ore from the Emerald was begun in 1906 by the owner, J. Waldbesen. In 1917 Iron Mountain Ltd. was formed to operate the mine and a 23 tonne mill was put into operation. The Emerald was a small but steady producer of lead-zinc ore from 1906 to 1925.

A small amount of shallow development work was done on the Jersey claim (082FSW009) from 1916 to 1919 and some ore was shipped, however the main ore deposit was not discovered at this time.

Canadian Exploration Ltd., while operating the Emerald tungsten mine, carried out an extensive diamond drilling program on the Jersey during 1948 and a large tonnage of lead-zinc ore was outlined. During 1948-49 the Emerald tungsten operation was closed down and the mill, beside the Nelson-Nelway Highway, was converted to a lead-zinc operation and production from the Jersey began in March 1949. The mine has operated continuously since that time, development work being done on all seven ore zones. Track mining has been used in A, C, and D zones and trackless mining in A, D, E, F, and G zones. The A zone has been developed from the south end of the Jersey zone to a point north of the Emerald, a distance of 1524 metres.

Ore reserves as of April 1, 1965 are reported at 671,075 tonnes grading 1.2 per cent lead and 4.1 per cent zinc.

The Emerald lead-zinc ores are similar in nature to the HB deposits (082FSW004) except that lead predominates. Galena

CAPSULE GEOLOGY

runs over 40 per cent with about 6 per cent zinc and 50 grams of silver. There is evidence to suggest the Emerald ores are controlled more by flat shears than vertical ones.

The galena-sphalerite-pyrite-pyrrhotite ores occur in several parallel zones and are characterized by their banded nature. They are hosted by dolomitized Reeves Member limestones of the Lower Cambrian Laib Formation.

Skarn with minor molybdenum was noted during underground development in 1915. Records indicate that over 50,000 tonnes of ore were shipped between 1906 and 1925 but details are not available. However, the production data, as recorded for the adjacent Jersey mine (082FSW009), indicates a distinct period of production during the 1906 to 1925 period in which 25,850 tonnes of ore were mined and 705,292 grams of silver, 6,788,936 kilograms of lead and 19,771 kilograms of zinc were recovered.

CAPSULE GEOLOGY

The property is located at approximately 1524 metres elevation on the south side of Stewart Creek 3.2 kilometres west-northwest of Ymir.

Early work on the showings, for which there is no record, included a 7-metre adit. Drysdale, 1917 (GSC Memoir 94) reported molybdenum on a claim towards the headwaters of Stewart Creek.

The Stewart group of 8 claims and the Stewart No. 2 group of 13 claims were staked in 1942 by E.P. Harkedahl, O.P. Anderson, and E. Emilson of Ymir. Premier Gold Mining Company, Limited optioned the property in July of that year. Work by the company included

CAPSULE GEOLOGY

prospecting, stripping, trenching, reopening the old adit, and sampling. The option was given up in November of that year.

The Consolidated Mining and Smelting Company of Canada Limited optioned the property in 1943 and sampled the showings. A bulk sample was taken for a mill test. The option was dropped in July of that year.

The showings were restaked by Harkedahl and associates in about 1948 as the Scheelite and Scheelite 2-6 claims and the adjacent N.H. group of 8 claims. The 14 claims were optioned to K.J. Springer and associates who incorporated Arrow Tungsten Mines Limited in March 1951 to acquire the property. Mineralization in trenched zones A, B and C was estimated at 330 tons per vertical foot averaging 0.50% WO₃. If this continued down dip for 61 metres the probable reserve would be 66,000 tons (DM Cannon 5/04/51 in Arrow Tungsten Mines Limited Prospectus 30/04/51). The company drove an adit southerly for 140 metres. At 58 metres from the portal a raise was driven 27 metres to old surface workings. Diamond drilling at right angles to the adit was done in 3 holes to the east and 7 to the west. Only spotty scheelite and powellite was found in the narrow skarn band which the adit followed for 62 metres when it became indistinguishable. No mineralization was reported encountered by the diamond drilling. Work ceased in March 1952.

The property was held in 1978 as the Stewart 1-4 claims (66 units) by Eric and Jack Denny, of Nelson. A geochemical soil and silt survey was carried out over Stewart 1-3.

The Arrow Tungsten occurrence is located on the north side of Stewart Creek, 3.2 kilometres west-northwest of Ymir. The claims were staked in 1942, but an adit was already present on the property at that time. The occurrence is immediately north of the Phase II Breccia zone of the Stewart 2 (082FSW229) occurrence.

The area is underlain by siltstone, sandstone, conglomerate, argillite and minor limestone units of the Lower Jurassic Hall Formation, Rossland Group. Granitic rocks of the Early to Middle Jurassic Nelson Intrusions outcrop in the area. The area is situated on the eastern limb on the Hall Creek syncline and just north of the Stewart Creek fault.

Fine-grained disseminated scheelite mineralization occurs in skarn bands interbedded with argillite and other sediments. The skarn predominantly comprises diopside with locally abundant garnet. Mineralization also includes minor sphalerite, trace molybdenite and rare chalcopyrite and galena. The mineralization may occur across the entire band or as one or more bands within it.

The skarn averages about 1.5 metres in width but is developed erratically along a north trend, conformable to the regional stratigraphy, on the northwest margin of the intrusive complex that hosts the Stewart 2 occurrence. The best section is about 150 metres long and occurs 45 metres south of the adit. The northern part of this section is a skarn band 1 to 3 metres wide hosting mineralization across an average width of 1 metre. The southern portion is a skarn band 0.60 to 5 metres wide.

Tungsten values vary widely from 0.05 per cent to 0.5 per cent WO₃ with local highs up to two and three per cent. In 1951, mineralization in trenched zones (A,B,C) was estimated at 297 tonnes per vertical foot averaging 0.50 per cent Wo₃, but subsequent drilling failed to prove up these reserves. Drilling in 1980 (DDH 80-3) resulted in a sample that assayed 0.036 per cent Wo₃ across 57 metres (Assessment Report 12251). Sampling indicates 3 ore shoots with an aggregate length of 188 metres and an average grade of 0.50 per cent Wo₃ across 2 metres (National Mineral Inventory card 082F6 W1).

CAPSULE GEOLOGY

Argillite, quartzite and siltstone of the Pennsylvanian (and possibly Permian) Mount Roberts Formation host a narrow quartz vein, up to 0.4 metres thick, which contains pyrite and pyrrhotite. The vein is vertically dipping and strikes 072 degrees. A zone of crushed country rock occurs on the footwall side of vein. The vein is crosscut by a quartz diorite dyke striking across the vein at right angles. Gold and silver values are generally low but selected samples grade as high as 30 grams per tonne gold and 144 grams per tonne silver (Bulletin 1, page 123). One sample taken across 0.46 metres assayed 4.46 grams per tonne gold and 106.29 grams per tonne silver (Bulletin 1, page 123). Some underground development has occurred.

CAPSULE GEOLOGY

The Summit showing is located 8 kilometres northeast of Ymir. The Summit claim was originally staked in 1896. The vein has been developed by 100 metres of underground workings.

The area is underlain by metamorphosed sediments comprising argillite, siltstone, limestone and wacke of the Lower Jurassic Ymir Group. The Middle to Late Jurassic Nelson Intrusions occur to the east (Nelson batholith) and west.

The Summit vein is a milky white, vuggy quartz vein 3 to 4-metres in width exposed over 700 metres along strike. The vein, hosted in argillite, carries minor values in gold, silver, lead, and zinc as pyrite, pyrrhotite, galena, and sphalerite. Manganese oxides occur parallel to the vein walls which vary in strike from 050 to 067 degrees and dip steeply north.

Recent work indicates that the vein, which has a similar attitude, may be part of a larger vein system which includes the Pathfinder, Old Timer (082FSW081) and Elise (082FSW192) veins.

CAPSULE GEOLOGY

The Pingree showing is located near the headwaters of Eagle Creek, southwest of the Eureka mine (082FSW084). A small amount of ore was reportedly removed and shipped from this showing but no record of this exists.

The area, just west of the Silver King shear zone, is underlain by schistose volcanics comprising augite basalt flows, flow breccias and subvolcanic intrusions of the Lower Jurassic Elise Formation, Rossland Group.

In 1910, an adit intersected a sulphide zone in a small quartz vein with gold and copper values. The quartz vein is 0.30 to 1.2 metres wide, contains black iron oxides and is hosted in schistose material. Subsequent work failed to trace the continuation of the vein or to find further mineralization.

CAPSULE GEOLOGY

The Castlegar Junction clay deposit is located along the banks of the Columbia River in Castlegar.

Limited deposits of silty clay occur close to river level and may have originated as either lake or glacial deposits. The material near Castlegar has apparently been used in the past for the manufacture of brick and is similar to the Nelson Clay (082FSW296) deposit.

Northwest of Castlegar along the Arrow Lakes there is a bluish grey laminated clay which outcrops at water level but is covered by thick overburden.

CAPSULE GEOLOGY

The Bluebird showing is located on the summit of Evening Ridge, about 9 kilometres southeast of Nelson.

The area is underlain by granite of the Late to Middle Jurassic Nelson Intrusions (Nelson batholith) near the contact with Lower Jurassic Ymir Group sediments.

A quartz vein about 0.25 metre wide has been traced along a strike of 320 degrees in granite. The vein dips 53 degrees north and contains rusty quartz gangue with disseminations of pyrite and galena. Gold assays are variable from 2 to 30 grams per tonne over widths of 20 to 30 centimetres and silver values vary from 13 to 50 grams per tonne (Minister of Mines Annual Report 1928, page 325).

CAPSULE GEOLOGY

The Sterling showing is located on the north side of Ymir Creek, 7 kilometres northeast of Ymir. The property was worked intermittently up to 1912. Workings consist of 137 metres of tunnels and several opencuts and pits.

The area is underlain by granodiorite of the Nelson batholith of the Late to Middle Jurassic Nelson Intrusions. Roof pendants of Lower Jurassic Ymir Group metasediments occur in the batholith.

Pyrite, sphalerite, and galena in quartz gangue with minor calcite occurs in a vein in a strongly sheared zone within a raft or roof pendant of metasediments. The vein is hosted in, and is parallel to, schist. The shear zone strikes 010 to 015 degrees and dips 060 degrees east to vertical. The zone is crosscut by a series of parallel lamprophyre dykes striking 283 degrees.

A fault zone contains a well developed, 1-metre wide gouge zone containing graphitic, decomposed schist with pyrite, calcite, and clay. Stringers of quartz are present in the footwall rocks of the shear and some stringers contain blue quartz with sulphides.

The Sterling vein is similar to the Blackcock (082FSW076) and Roanoke (082FSW071) veins.

COMMENTS: Sample from vein number 2 at an adit.

REFERENCE: Assessment Report 12940.

CAPSULE GEOLOGY

The Lasca 2 showing is located near the headwaters of Lasca Creek, 15 kilometres east of Nelson.

The area is underlain by porphyritic hornblende granodiorite of the Nelson batholith of the Late to Middle Jurassic Nelson Intrusions. Small rafts and roof pendants consisting of Lower Jurassic Ymir Group and Lower Cambrian metamorphosed sediments occur in the batholith.

The Lasca number 2 vein is a 0.6 to 1.5-metre wide quartz vein exposed for 402 metres along strike within Ymir Group metasediments. The vein at surface is, locally, only 1.4 metres from the contact with the granodiorite. The vein strikes from 160 to 175 degrees with a westerly dip of 35 to 67 degrees. A shear zone occurs up to 0.40 metre in width on each side of the vein. The vein contains less than 5 per cent pyrite, pyrrhotite, and rare sphalerite with possibly some

CAPSULE GEOLOGY

tetrahedrite. The sulphides are distributed erratically within the shear and quartz gangue. A sample from the vein at an adit assayed 2.9 per cent lead and 0.07 per cent zinc, 0.135 gram per tonne gold and 95.4 grams per tonne silver (Assessment Report 12940).

Nearby are a couple of associated and parallel veins from which 1983 samples assayed up to 21.7 grams per tonne gold and 364.74 grams per tonne silver, but these assays were not confirmed by 1984 sampling (Assessment Report 12940).

CAPSULE GEOLOGY

The Lasca 3 showing is located near the headwaters of Lasca Creek, 15 kilometres east of Nelson. The area is underlain by porphyritic hornblende granodiorite of the Nelson batholith of the Late to Middle Jurassic Nelson Intrusions. Small rafts and roof pendants consisting of Lower Jurassic Ymir Group and Lower Cambrian metamorphosed sediments occur in the batholith.

The Lasca number 3 vein is 0.5 to 0.75 metres wide and is enclosed in a long, northerly trending raft of metasediments. The vein strikes 360 degrees and dips 40 to 60 degrees west. Geochemistry indicates some minor arsenic but base and precious metal values are low.

A sample containing pyrite, pyrrhotite and hematite from the probable extension of the number 3 vein in an adit assayed 2.0 per cent lead, 0.22 per cent zinc, 37.4 grams per tonne silver and trace gold (Assessment 12940).

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

Scheelite is reported to occur as disseminations in skarnified limestones of the Reeves Member of the Lower Cambrian Laib Formation. The skarn is exposed the full length of the Calcite, Comet and Contact Crown grants. Scattered values of greater than 1 per cent WO3 were obtained from grab samples but most results of surface sampling were less than 0.5 per cent WO3.

CAPSULE GEOLOGY

Dykes and irregular masses of the Middle to Late Jurassic Nelson Intrusions (Emerald stock) intrude limestones and argillites of the Lower Cambrian Laib Formation and the Lower to Middle Ordovician Active Formation.

Scheelite occurs as fine disseminated grains and narrow veinlets in a garnet-diopside skarn near the base of a grey and white crystalline limestone of the Reeves Member of the Laib Formation. About 300 metres to the northeast of the main showing are tremolitic black argillites and argillaceous limestones cut by aplitic intrusives of the Emerald stock.

COMMODITY GRADE
Silver 3.4000 Grams per tonne
Lead 0.9400 Per cent
Zinc 0.1100 Per cent
COMMENTS: The sample width is 1.53 metres.
REFERENCE: Bulletin 41, page 153.

CAPSULE GEOLOGY

A narrow, siliceous zone of dolomite at the base of the Reeves Member limestone of the Lower Cambrian Laib Formation contains disseminated pyrite, pyrrhotite and minor sphalerite and galena. The dolomitic zone is about 1.8 metres thick near the portal of the old workings but it lenses out rapidly, within 6 metres, into limestone. A chip sample of the dolomite zone assayed trace gold, 3.4 grams per tonne silver, 0.94 per cent lead, and 0.11 per cent zinc (Bulletin 41, page 153).

Lead	0.0800 Per cent
Zinc	0.2800 Per cent

COMMENTS: The sample was collected from a gossanous zone.
 REFERENCE: Assessment Report 10524.

CAPSULE GEOLOGY

Several small quartz veinlets occur within sheared black slates adjacent to the highway on the north side of the Pend d'Oreille River. The claim is close to the Pend d'Oreille thrust and the Waneta thrust fault with associated faulting within units of the Lower Jurassic Elise Formation (Rossland Group) volcanics and adjacent to small syenitic intrusions of the Middle Eocene Coryell Intrusions.

The veinlets are described as being parallel to a northeast trending gossanous shear zone, vary in width from 5 to 80 centimetres and are traceable for about 80 metres along strike. The quartz gangue hosts galena, sphalerite, chalcopyrite and pyrite. Mineralization is erratic and tonnage potential is considered very limited. A sample collected from a gossanous zone assayed 548.58 grams per tonne silver, 6.34 grams per tonne gold, 0.08 per cent lead, and 0.28 per cent zinc in selected samples (Assessment Report 10524).

CAPSULE GEOLOGY

The Tec Gold showing is located approximately 11 kilometres southwest of Nelson, on a logging road just south of the Referendum mine (082FSW177).

The area is underlain by volcanic rocks of the Lower Jurassic Elise Formation, Rossland Group. These have been intruded by granitic rocks of the Middle to Late Jurassic Nelson Intrusions.

A small, thin (up to 0.15 metres wide) discontinuous quartz-carbonate-chlorite vein has visible gold, bornite, malachite staining and botryoidal turquoise mineralization (Hoy, 1987). The gold appears to be associated with bornite. The vein is parallel to the foliation in altered andesitic fragmental volcanics. The vein, a few metres in length, strikes 125 degrees and dips 77 degrees south. On the same road further to the west, a 5-metre wide chlorite schist band hosts disseminated pyrite which is reported to assay 1.5 grams per tonne gold (Fieldwork 1985, page 333).

CAPSULE GEOLOGY

The property is located at the 1432.5 metres elevation at the head of Champion Creek some 22.5 kilometres north-northeast of Trail. The claims were Crown Granted and worked at the turn of the century.

Exploration and development activity began on Champion Creek in 1896. The Maud S claim (Lot 1442) was Crown-granted to B.A. True, C.B. Etnier and David Crombie in 1897. By 1900 the property comprised 5 claim, the Maud S, Yellow Jacket, Touch-me-not, Standard, Eric, and Syracuse, held by The Onondaga Mining Company, of Breckenridge Colorado. About 157 metres of development work was carried out during the year and a 10 stamp-mill installed. No report is known on further activity. The adjacent Touch-me-not (Lot 5202) and Yellow Jacket (Lot 5203) fractional claims were Crown-granted to Louis Will in 1902.

The property was acquired in 1981 by Pearson, Gallagher Ltd., of Nelson.

The area is underlain by granite and granodiorite of the Late to Middle Jurassic Nelson Intrusions and small areas of volcanic rocks of the Lower Jurassic Elise Formation (Rossland Group).

The Maud S. occurrence, hosted in granite, is part of an "important system of siliceous ore-bearing fissure veins" (Minister of Mines Annual Report 1897, page 545). These veins host free gold, auriferous pyrite, chalcopyrite and galena. Values were reported as 20 dollars per ton in 1900 which is 33.4 grams per tonne based on 0.66 dollar per gram (Minister of Mines Annual Report 1900 page 846).

CAPSULE GEOLOGY

The Kimbarb showing is located near the mouth of Tulip Creek about 24 kilometres north of Castlegar, just north of Lower Arrow Lake.

The area is underlain by the Ladybird granite of the Lower Cretaceous (?) Valhalla complex. The complex, comprising granite and granodiorite is cut by pegmatite dykes related to the Middle Eocene Coryell Intrusion.

A sulphide vein, trending 315 degrees and dipping about 60 degrees, cuts the granodiorite. Sulphides consist mainly of pyrrhotite, pyrite and minor magnetite. Minor molybdenite flakes are associated with the mineralization and are disseminated in the granodiorite near the pegmatite dykes.

Xenoliths of skarn were found within the granite. The xenoliths are thought to be remnants of the Pennsylvanian to Permian (?) Mount Roberts Formation limestone now altered to skarn by the intrusives. Garnet, olivine and calcite are reported to be well developed in the skarn and apparently a previous owner used this skarn as a source for semi-precious gemstones (garnet and olivine).

CAPSULE GEOLOGY

The Ymir Graphite showing is located along the north fork of Porcupine Creek, 16.5 kilometres east of Ymir.

The area is underlain by black slate, black limestone, calcareous argillite and quartzite of the Middle Cambrian Nelway Formation. In the black slates, a well developed, steeply dipping cleavage parallels the northerly trend of the creek.

These slates contain fine flakes of mica and locally flakes of graphite on cleavage surfaces. It is considered that the graphite grade and tonnage potential is much too low to be of economic interest.

CAPSULE GEOLOGY

The Belle showing is located east of Taghum, approximately 8 kilometres west of Nelson. The area is underlain by Jurassic pseudodiorite and pyroxenite of unknown affinity. Late to Middle Jurassic Nelson Intrusions consisting mainly of non-porphyrific granite and granodiorite occur to the north. Locally, the rocks comprise coarse pegmatite. Visible mineralization consisting of disseminated molybdenite and pyrite is found within fractures and quartz veins usually associated with the pegmatite.

Zinc	0.0200	Per cent

COMMENTS: Sample taken from old shaft in granitic rock with quartz and muscovite.

REFERENCE: Assessment Report 9531.

CAPSULE GEOLOGY

The Gold Queen showing is located about 3.0 kilometres east of the Salmo River and Porcupine Creek junction, 0.5 kilometres north of Porcupine Creek. The Crown Grant was located in 1896 and workings comprise a shaft, 2 open pits, and an adit.

The area is underlain by granite and granodiorite of the Late to Middle Jurassic Nelson Intrusions near the contact with Lower Jurassic Ymir Group sediments to the west and Lower Cambrian metasediments to the east. The sediments and metasediments comprise quartzite, schist, argillite, slate, siltstone, sandstone and conglomerate.

In 1980, samples were taken from an old shaft on the Gold Queen, Reverted Crown Grant (Lot 1075). The samples were collected from

CAPSULE GEOLOGY

granitic rock containing quartz veins with associated muscovite and fracture fillings which host disseminated pyrite, galena and sphalerite. One of these samples assayed 0.02 per cent lead, 0.02 per cent zinc, 1.71 grams per tonne silver and 0.137 gram per tonne gold (Assessment Report 9531). Other samples assayed 8.9 grams per tonne silver, 0.103 gram per tonne gold and 4.7 grams per tonne silver, 0.103 gram per tonne gold, respectively (Assessment Report 9531). Mineralization is also reported in the altered Ymir Group sediments within the igneous contact zone (refer to the Dewey (Lot 14431) occurrence 082FSW198).

COMMENTS: Sample taken along mineralized limestone-dolomite contact.
REFERENCE: Assessment Report 9094.

CAPSULE GEOLOGY

The Marilyn 1-12 occurrence is located about 5 kilometres southeast of Ymir, 1.0 kilometre north of Porcupine Creek. An old adit and several open cuts are present on the property. The area lies along the faulted contact between Lower Cambrian sediments (possibly correlative with the Hamill Group) and what is believed to be limestones and dolomites of the Ordovician Active Formation. The mineralized showings lie south-southwest of the Oxide showing (082FSW022). Mineralization occurs along a limestone-dolomite contact near faulted contact with white quartzite. Within the mineralized zone is a 30.5 metre long quartz vein which is traceable for approximately 60 metres. Disseminated galena is present in a quartz vein within the old workings. In 1980, a sample from the old adit assayed 173.48 grams per tonne silver and 1.68 per cent lead. Another sample taken

CAPSULE GEOLOGY

The Shaft and Cat showings are located approximately 6 kilometres south of Nelson and are a part of the larger Kena property of Sultan Minerals Inc. Old trenches and adits on the property are believed to have been excavated between 1900 and 1904.

The Kena property hosts a number of porphyry style, gold and gold-copper occurrences. The property lies on the eastern limb of the Hall Creek Syncline, a south-plunging fold associated with intense shearing that dominates the structure of the Nelson map area. The syncline incorporates volcanic and lesser sedimentary rocks of the Lower Jurassic Elise Formation (Rossland Group) which are intruded by a synvolcanic monzodiorite complex and by the younger? Middle Jurassic Silver King Intrusions comprising a coarse grained plagioclase porphyry stock with related dikes and sills.

The area is underlain by basaltic tuffs, andesite flows and augite porphyry of the upper Elise Formation intruded by a complex of fine to medium grained diorite sills. The rocks have been extensively sheared, with foliation dominantly striking northwest and dipping southwest.

CAPSULE GEOLOGY

The Shaft and Cat showings are situated 800 metres apart along a northwest trending diorite unit that cuts Elise Formation volcanics. Mineralization is widespread within this area and is comprised of chalcopyrite, pyrite and magnetite as disseminations and fracture fillings in brecciated and altered andesite and subvolcanic diorite sills in a northwest trending zone of shearing adjacent to the contact of the Silver King porphyry. Two showings are exposed in trenches, the Shaft and the Cat, and if mineralization is continuous between these two, the implied strike length of the zone is in excess of 800 metres. In 2000, Sultan Minerals relogged drill core and conducted sampling which traced this dioritic unit for an additional 700 metres to the south, giving the zone a possible minimum strike length of 1500 metres.

At the Shaft showing, the diorite is locally brecciated and extensively altered to a chlorite-epidote-carbonate assemblage that contains magnetite, chalcopyrite and pyrite. Gold and copper mineralization appear to be associated with malachite and chalcopyrite which occur in the diorite complex as disseminations, patches and fracture fillings. In 1999, trench confirmation sampling by Sultan Minerals yielded 1.14 grams per tonne gold and 0.66 per cent copper over 10.25 metres in the Cat trench, and 5.6 grams per tonne gold and 0.95 per cent copper over 12 metres in the Shaft trench (Assessment Report 26503).

At the Cat showing, sulphides are concentrated within the matrix of a crackle breccia. The mineralization is lensey in nature over 9 by 5.5 metres. Assays from this showing averaged 1.37 grams per tonne gold and 0.7 per cent copper (Property File - South Pacific Gold Corp., June 1988).

Mineralization in the Kena property area was first described in a report by G.M Dawson in Geological Survey of Canada Annual Report for 1888-89. Little is known about exploration on the claim area prior to 1973. Post-1973 exploration, however, has identified old prospect pits and trenches, as well as several old adits indicating periods of exploration activity in the early part of the century. Numerous exploration companies carried out geological, geochemical, geophysical surveys, trenching and drilling on the property from 1974-91. These companies explored the Elise Formation volcanics for gold and copper mineralization and discovered the Kena Gold zone (082FSW237), Kena Copper zone (082FSW332) and the Shaft/Cat zones (this description). The Kena Gold zone underwent the most thorough exploration with the Kena Copper and Shaft/Cat zones only being tested minimally. No additional work was done until 1999 when Sultan Minerals Inc. acquired and amalgamated several properties under the name Kena property. Recent exploration work and data compilation by Sultan Minerals have identified four gold-bearing zones on the Kena property. These are: the newly discovered Gold Mountain (082FSW379), Kena Gold, Shaft/Cat, and South Gold soil anomaly located about 1000 metres south of the Kena Copper zone.

CAPSULE GEOLOGY

The Kena Copper showing is located about 9 kilometres south of Nelson and is part of the larger Kena property of Sultan Minerals Inc. The Kena property hosts a number of porphyry style, gold and gold-copper occurrences. The property lies on the eastern limb of the Hall Creek Syncline, a south-plunging fold associated with intense shearing that dominates the structure of the Nelson map area. The syncline incorporates volcanic and lesser sedimentary rocks of the Lower Jurassic Elise Formation (Rossland Group) which are intruded by a synvolcanic monzodiorite complex and by the younger? Middle Jurassic Silver King Intrusions comprising a coarse grained plagioclase porphyry stock with related dikes and sills.

In the Kena Copper zone, alkalic porphyry style copper-gold mineralization occurs in the southeast section of the property. It is spatially related to a large monzodiorite complex, and to the borders of the complex. Chalcopyrite and pyrite occur as disseminations, fracture fillings and in quartz veinlets in the intrusive rocks, and as weaker disseminations and fracture fillings in basaltic to andesitic tuffaceous rocks of the Elise Formation. The copper mineralization commonly includes malachite. The area is

CAPSULE GEOLOGY

marked by sericitic and limonitic shear zones parallel to foliation, and by zones of moderate to intense fracturing that are variably altered by propylitic assemblages of chlorite, epidote and carbonate. Magnetite occurs as disseminations and fracture fillings, and biotite is locally conspicuous and may be part of a broader zone of potassic alteration centred on the complex.

The area has been variably silicified by quartz veins that both cross and follow the foliation. They vary from weak to strong and occur as narrow fracture fillings, weak stockworks or rarely thick veins up to 0.5 metre wide. Some of the veins are coarse grained and appear barren of sulphide. Others are vuggy and crystalline, contain calcite, and are mineralized with pyrite and chalcopyrite. The nature of the veining combined with results from analytic data appear to reflect more than one period of emplacement.

Sections of the mineralized area have been examined by short underground workings and a few drillholes. This work has resulted in a number of wide intercepts of low grade copper mineralization with low gold content. Typical examples include an 82.0 metre adit that grades 0.16 per cent copper and a nearby drillhole that intersected 0.18 per cent copper over 45 metres. In 1990, drilling by Noramco Mining Corp. resulted in a best intersection of 0.27 per cent copper and 0.2 gram per tonne gold over 57 metres (George Cross News Letter No.30, 1991). A grab sample collected in 2000 yielded 3.99 per cent copper and 2.87 grams per tonne gold. Exploration work has not been sufficiently detailed or comprehensive to either delimit the area of interest, or to determine whether significant ore-grade sections may be present (Assessment Report 26503). The South Gold zone is 1000 metres of the Kena Copper zone and follows the contact between Elise Formation volcanics and Silver King porphyry intrusive rocks. The zone is a large gold-in-soil geochemical anomaly that trends parallel to this contact (Sultan Minerals Inc. Annual Report 2000).

Mineralization in the Kena property area was first described in a report by G.M Dawson in Geological Survey of Canada Annual Report for 1888-89. Little is known about exploration on the claim area prior to 1973. Post-1973 exploration, however, has identified old prospect pits and trenches, as well as several old adits indicating periods of exploration activity in the early part of the century. Numerous exploration companies carried out geological, geochemical, geophysical surveys, trenching and drilling on the property from 1974-91. These companies explored the Elise Formation volcanics for gold and copper mineralization and discovered the Kena Gold zone (082FSW237), Kena Copper zone (this description) and the Shaft/Cat zones (082FSW331). The Kena Gold zone underwent the most thorough exploration with the Kena Copper and Shaft/Cat zones only being tested minimally. No additional work was done until 1999 when Sultan Minerals Inc. acquired and amalgamated several properties under the name Kena property. Recent exploration work and data compilation by Sultan Minerals have identified four gold-bearing zones on the Kena property. These are: the newly discovered Gold Mountain (082FSW379), Kena Gold, Shaft/Cat, and South Gold soil anomaly located about 1000 metres south of the Kena Copper zone.

CAPSULE GEOLOGY

The area is underlain by mafic to intermediate volcanic rocks of the upper Elise Formation, the central volcanic package of the Lower to Middle Jurassic Rossland Group. The rocks are intruded by the Middle to Late Jurassic Nelson Intrusions and many small coeval stocks, by Middle Eocene Coryell Intrusions syenites and by Tertiary rhyolite and lamprophyre dykes.

Structure is dominated by northerly trending tight folds and associated shears. The Hall Creek syncline, a south plunging, west dipping overturned fold, is the most prominent fold in the area. The core of the syncline forms a zone of intense shearing more than a

CAPSULE GEOLOGY

kilometre in width and is informally referred to as the Silver King shear zone.

The Great Western occurrence lies on the eastern margin of the Silver King shear zone and is underlain by upper Elise Formation volcanic rocks which are locally intensely sheared. Augite porphyry flows, mafic fine tuff, intermediate lithic tuff, and felsic intrusive lenses or crystal flows or sills comprise most of the succession on the property; intermediate to felsic units occur only as minor lenses. The succession is interpreted to be inverted as it occurs on the west limb of the overturned Hall Creek syncline (Exploration in British Columbia 1988). The volcanic succession is intruded by the Middle Jurassic "Silver King Porphyry" (Silver King Intrusions) along the northeastern edge of the property. The porphyry predates the intense regional deformation; it is deformed and metamorphosed, with the most intense shearing concentrated along its margins.

Foliation throughout the area generally trends northwest, dips steeply to the southwest and is axial planar to the Hall Creek syncline.

Within the mafic volcanic rocks are a number of zones of intense carbonate-sericite-quartz alteration that are conformable to foliation and contain gold-copper mineralization. A number of these zones are cored by felsic (syenite?) lenses. This is a "conformable gold" occurrence.

The mafic volcanic rocks are predominantly green phyllites and schists. Lapilli tuff units are observed locally. Foliated and sheared mafic flows and flow breccias occur in the footwall of the most northerly mineralized zone (Black Witch). Elsewhere, foliated green phyllite without recognizable clasts is interpreted to be derived from mafic fine tuff.

Gold-copper mineralization occurs in zones of intense carbonate-sericite-quartz alteration in both the mafic units and in the associated felsic units. These alteration zones are 5 to 10 metres in width and several hundred metres in length. They contain 2 to 10 per cent sulphides, dominantly pyrite with minor chalcopyrite. The sulphides occur mainly as stringers parallel to the schistosity but are also pervasively distributed. The sulphide-bearing rocks are deformed together with the host rocks, indicating mineralization predates deformation (Exploration in British Columbia 1988). These mineralized zones are now elongate in the direction of lineation trending 147 degrees and plunging 31 degrees southeast. Some mineralization, however, is also concentrated in late, post-tectonic, crosscutting quartz veins. The best intersection in drill core is 7 metres which assayed 9.7 grams per tonne gold (Exploration in British Columbia 1988).

The three principal mineralized zones are the Giveout Creek North, Giveout Creek South and Black Witch. The Giveout Creek North and South zones appear to occur in the northern part of the White Witch claim (Lot 3595). The Black Witch zone is 250 metres north-northwest of the Giveout Creek zones and appears to be on or close to the southern boundary of the Thistle claim (Lot 2233).

Several small tunnels and pits are present on the property dating back to the early 1900's. The North Star (Lot 4149) occurrence (082FSW276) adjoins the White Witch claim to the south.

CAPSULE GEOLOGY

The Jennie Bell showing is located 16 kilometres southeast of Nelson in a glacial basin. The claim was staked in 1911 and some ore was shipped that year with "80 sacks" of ore reportedly shipped in 1914.

The showing is hosted by Lower Jurassic Lower Elise Formation augite porphyry basalt flows and flow breccias near the contact with Jurassic Ymir Group sedimentary rocks on Mount Elise. The rocks are sheared in the vicinity of mineralized veins with foliation striking north-northwest and dipping steeply southwest. The veins, locally, follow the schistosity.

Gold, silver and lead occur in three narrow (approximately 15 centimetres wide) pyritic quartz veins. The vein exposed in the upper tunnel strikes 335 degrees and dips 65 degrees south. Two veins with intervening schist occur in the tunnel face. The footwall is pyritic schist and the hanging wall is pyritic greenstone schist. Both hanging wall and footwall to the veins are sheared with abundant chlorite alteration. Exploration in 1984 failed to locate the Jennie Bell workings (Assessment Report 12754). The Ymir Mint vein is exposed on the opposite side of the basin from the Jennie Bell vein.

Several tonnes of material were shipped yielding 9.6 grams per tonne gold and 4895 grams per ton silver (Geological Survey of Canada

CAPSULE GEOLOGY

Memoir 94, page 96).

CAPSULE GEOLOGY

The Canadian Pacific showings are located 18.5 kilometres southeast of Nelson between the Ymir mine (082FSW074) to the west and the Sterling mine (082FSW317) to the east. The claims comprising this group were staked in 1896 and 1897. Workings consist of open cuts, tunnels and pits.

The showings are hosted in Jurassic argillites of the Ymir Group which occur as a roof pendant in Middle to Late Jurassic granodiorite of the Nelson batholith.

North trending parallel quartz veins, exposed in the workings, contain thin, discontinuous streaks of pyrite, with lesser amounts of galena and sphalerite. Sericite is a common alteration mineral along shear planes within the veins. Gold content is apparently associated with pyrite and is highest in blue quartz. One open cut exposes a white quartz vein, 2.13 metres wide. No assays or production figures are reported.

CAPSULE GEOLOGY

The Three Friends occurrence is located about 6 kilometres south of Nelson on the north side of Hall Creek. The occurrence comprises workings on two claims (Three Friends 1 and Alice), about 1 kilometre apart.

The area is underlain by augite porphyry flows, flow breccias and tuffs of the Lower Jurassic Upper Elise Formation, Rossland Group, adjacent to sheared Lower Jurassic Silver King plagioclase porphyry. Regionally developed foliation strikes north-northwest and dips steeply to the southwest.

Gold, silver and copper mineralization is confined to 20 to 30-centimetre quartz veins parallel to the foliation.

A 20-metre adit, on the Three Friends showing, was driven on the main vein which squeezed between augite porphyry in the hanging wall and sheared Silver King porphyry in the footwall. The veins contain tetrahedrite and malachite.

The quartz vein exposed in an opencut near the Alice adit is mineralized with tetrahedrite and malachite with lesser chalcopyrite and pyrite. The vein is about 30 centimetres wide, strikes 280 degrees and dips steeply south. This is the same vein exposed in the adit and has been traced for 76 metres. High, erratic gold values were reported.

No assay or production figures are reported.

CAPSULE GEOLOGY

Limestone of the Lower Cambrian Reeves member of the Laib Formation was once quarried at the Reno mine (082FSW036), 11 kilometres east of Salmo. The unit is exposed as a narrow band striking north for 950 metres and dipping approximately 50 degrees east on the west flank of the Sheep Creek anticline. The limestone was burned to produce lime for milling purposes at the mine. A total of 738 tonnes of limestone were quarried between 1930 and 1934.

COMMENTS: Across 3.7 metre thick bed. Grade given for calcium oxide.
REFERENCE: CANMET Report 811, page 207, sample 80A.

CAPSULE GEOLOGY

Limestone with some interbedded shale and schist of the Lower Jurassic Elise Formation (Rossland Group) outcrops along the west side of Highway 22A, just north of Waneta, forming a 50 metre high cliff. The strata strike 165 degrees and dip 45 degrees west. The beds consist of dark blue, fine-grained, grey weathering, occasionally shaley limestone alternating with beds of light grey shale or schist. A few calcite veinlets cut the limestone. Two chip samples analyzed as follows (CANMET Report 811, page 207, Samples 80, 80A):

Sample	CaO	MgO	SiO2	Al2O3	Fe2O3	Sulphur
80	52.30	1.48	2.20	0.92	0.40	trace
80A	53.90	0.44	1.44	0.61	0.23	trace

Sample 80 was taken across a 5.2 metre thick limestone bed, while Sample 80A was from a 3.7 metre thick bed.

CAPSULE GEOLOGY

The Strawberry Pass occurrence is underlain by a generally east striking, steep northwest dipping sequence of dark grey argillaceous limestones, limy siltstones, fine sandstones and andesitic to dacitic volcanics and volcanoclastics of the Pennsylvanian to Permian Mount Roberts Formation. The strata in this area are sandwiched between syenitic to monzonitic rocks of the Middle Eocene Coryell Intrusions, about one kilometre to the south and granodioritic rock of the Middle to Late Jurassic Nelson Intrusions, a few kilometres to the north. Hornblende porphyritic to basaltic dykes intrude all other rocks in the area.

Several trenches exposed a variably mineralized skarn zone containing pods, veins and disseminations of gold-bearing massive pyrrhotite plus or minus chalcopyrite, pyrite, magnetite and

stibnite. The skarn minerals include pyroxene (diopside), quartz, carbonate, epidote, and chlorite. The rocks in the trenches include limestones, shales, calc-silicate hornfels as well as mafic and granodioritic intrusives. Quartz-carbonate veins in one trench are also reported to be rich in pyrite, sphalerite, galena, chalcopryrite and arsenopyrite. A silicified section from this trench assayed 39.16 grams per tonne gold and 6.55 grams per tonne silver over 2 metres (Assessment Report 19741).

CAPSULE GEOLOGY

Wollastonite is exposed on the west slope of a hill adjacent to Highway 3B, 9.5 kilometres north-northwest of Rossland.

The showing is hosted in sediments of the Pennsylvanian to Permian Mount Roberts Formation which are intruded from the west by syenite and quartz monzonite of the Middle Eocene Coryell Batholith. Several mineralized outcrops comprise a zone trending 315 degrees for approximately 150 metres along the north trending intrusive contact. The zone varies from 3 to 50 metres wide and dips 35 degrees west.

Hand specimens show coarse, tabular, subparallel to subradial pearly white wollastonite, weathering light tan to light brown, with minor secondary calcite. Thin sections display coarse tabular prisms of wollastonite cut by thin irregular calcite veins, with traces of clinopyroxene (?) as high relief, moderately high birefringent grains and blebs. Two thin sections averaged 95 per cent wollastonite, 4.3 per cent calcite and 0.75 per cent diopside-hedenbergite (J.M. Huber Corporation, 1990).

The deposit was staked and prospected by Horst Klassen of

CAPSULE GEOLOGY

Building stone and riprap was once quarried by the Canadian Pacific Railway Company at Granite, 5 kilometres west of Nelson. The quarry is developed in granodiorite of the Middle to Late Jurassic Nelson Intrusions on the southeastern margin of the Nelson batholith. Between Nelson and the Kootenay River bridge, west of Nelson, the stone is grey, coarse grained and gneissic in some exposures and shattered in others. The stone is cut by two sets of joints at the quarry, one set strikes 060 degrees and dips vertically and the second set strikes 145 degrees and dips 85 degrees southwest. A dome like sheeting, spaced 2.4 to 3 metres apart, dips north in the middle of the quarry, northwest at the west end of the quarry and northeast at the east end. The middle of the quarry is less jointed, enabling larger blocks to be removed. The granodiorite is fairly uniform in grain and colour throughout and contains black knots and light coloured veinlets. The stone is distinguished by its large feldspar crystals and black mica, distributed in a feathery manner. A sample analyzed as follows (CANMET Report 452, page 109, sample 1523):

MAJOR OXIDES		PHYSICAL PROPERTIES	
SiO2	66.46	Specific gravity	2.705
Al2O3	15.34	Crushing strength (dry) (lbs/sq.in.)	35,512
Fe2O3	1.68	Transverse strength (lbs/sq.in.)	2,543
Fe3O4	1.83	Shearing strength (lbs/sq.in.)	1,418
CaO	3.43		
MgO	1.11		
Na2O	4.86		
K2O	4.58		
TiO2	0.27		
H2O	0.29		

A considerable amount of stone was quarried by Canadian Pacific Railway in the early 1900's, up to about 1915. The resulting quarry measured 260 metres in length with a face up to 30 metres high, trending 070 degrees. The granodiorite was used for culverts and bridge piers along the railway line and a minor amount was also used

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

A small amount of dimension stone was quarried on the south side of Highway 3A, 2 kilometres west of Nelson.

The quarry is developed in a 15 metre high knoll of granodiorite of the Middle to Late Jurassic Nelson Intrusions on the southeastern margin of the Nelson batholith. Between Nelson and the Kootenay River bridge, west of Nelson, the stone is grey, coarse grained and gneissic in some exposures and shattered in others.

A discontinuous sheeting, spaced at 8 to 100 centimetres, strikes southwest parallel to the highway and dips 15 degrees southeast at the quarry site. A major joint set strikes parallel to the sheeting and dips at right angles to it. A second set strikes 005 degrees and dips 85 degrees west.

The stone is a fine to medium-grained, light grey granodiorite with a somewhat variable colour, that takes on a high gloss and shows very few incipient cracks under oblique light. The rock is marred by a number of black knots, up to 2.5 centimetres in diameter, and develops a brown iron oxide stain on weathered surfaces. Good size blocks with a uniform texture and free of blemishes, can still be obtained. A sample analyzed as follows (CANMET Report 452, pages 110, 111, sample 1524):

PHYSICAL PROPERTIES

Specific gravity	2.676
Crushing strength (dry) (lbs/sq.in.)	36,608
Transverse strength (lbs/sq.in.)	2,158
Shearing strength (lbs/sq.in.)	2,610

Canadian Marble and Granite Company quarried a few blocks for monument purposes in the early 1900's, up to about 1916. The quarry was operated intermittently by the Nelson Granite and Monumental Company through the 1950's, producing blocks for monumental dies and bases. Some stone was also used in several buildings in Nelson. In 1955, the quarry was 15 metres long, 12 metres wide and 10 metres high. No production figures are available.

CAPSULE GEOLOGY

The Silver Hill showing is underlain by the Hadrynian Three Sisters Formation, of the Windermere Supergroup, which comprises quartzite, conglomerate and schist (correlative with the upper part of the Horsethief Creek Group). Within a few hundred metres to the west is the north trending contact with the Lower Cambrian Quartzite Range Formation composed chiefly of quartzite (correlative with rocks of the Hamill Group).

Three adits are developed on quartz veins that follow the sides of andesitic dykes that cut north striking, vertically dipping quartzites of the Three Sisters Formation. One vein up to 30 centimetres wide has been traced for up to 60 metres. About 30 metres higher up the bluff another fissure up to 1.8 metres wide contains some quartz. The quartz contains limonite and an unknown grey metallic mineral that is reported to be high in silver.

CAPSULE GEOLOGY

The Sharon quartzite quarry is located on the north side of Porcupine Creek, 11 kilometres northeast of Salmo.

The quarry is developed in a thick unnamed Paleozoic sequence of micaceous quartzite, schist, argillite, slate, phyllite and limestone partly equivalent to the Milford Group.

Individual quartzite beds display various colours including beige, brown and green. The stone is split along micaceous partings to produce slabs that are sold locally for building facings and a variety of other architectural and decorative uses. The quartzite is being quarried intermittently for flagstone by Porcupine Mines Ltd. of Salmo.

HOSTROCK COMMENTS: Quartzite Range Formation correlative to the Lower Cambrian Hamill Group.

GEOLOGICAL SETTING

TECTONIC BELT: Omineca

TERRANE: Ancestral North America

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

Quartzite was quarried on the Riverside Crown granted mineral claim south of Sheep Creek, 15.5 kilometres southeast of Salmo.

This area is underlain by a sequence of metamorphosed carbonates and clastic sediments of Lower Paleozoic age that have been folded into a series of anticlines and synclines that trend north and exhibit steep to near vertical limbs.

The quarry is developed in micaceous quartzite of the Lower Cambrian Quartzite Range Formation. Individual quartzite beds exhibit various colours similar to those on the Porcupine claims to the north (082FSW279), including buff, red, grey and green. The stone is reported to split readily and evenly along cleavage planes containing sericite.

A total of 77 tonnes of quartzite was mined in 1963 and 1964, by A. Endersby of Fruitvale. The stone was sold in the Nelson district for decorative facing stone.

CAPSULE GEOLOGY

The B & B quartzite occurrence is situated 5 kilometres east of Remac, west of Creggan Creek near Nelway.

The quarry is reported to be developed in Lower Cambrian quartzite (Exploration in B.C 1978), presumably of the Quartzite Range Formation. However, Geological Survey of Canada Open File 1195 shows the area to be underlain entirely by carbonates of the Middle Cambrian Nelway Formation.

A total of 360 tonnes of quartzite were produced for facing stone, ashlar and flagstone by T. Brown of Salmo in 1978.

CAPSULE GEOLOGY

The Wewa showing is located 25 kilometres west of Castlegar at the headwaters of Big Sheep Creek.

The area is underlain by monzonite, diorite, granite and granodiorite of the Middle to Late Jurassic Nelson Intrusions and these have in turn been intruded by feldspar-hornblende-biotite porphyry dykes, feldspar porphyry andesite (?) and biotite porphyry andesite(?) of the Middle Eocene Coryell Intrusions. Silicification is common and the monzonite is propylitically altered.

Mineralization, consisting of chalcopyrite, pyrite, fluorite, magnetite and possibly molybdenite, occurs associated with fault breccia. No other information is available.

This is likely the same occurrence as Wewa (082ESE167).

CAPSULE GEOLOGY

The Ace in the Hole is underlain mainly by basaltic volcanics of the Lower Jurassic Rossland Group, Elise Formation comprised of flow breccia, massive flows, agglomerate, tuff and sill-like intrusives (augite porphyry). A minor amount of laminated, tuffaceous siltstone and shale occur as interbeds. These are overlain by argillites and quartzites of the Rossland Group, Hall Formation and underlain by black argillaceous siltstone and arenaceous argillite of the Rossland Group, Archibald Formation. The Rossland Group rocks are intruded by the Middle to Late Jurassic Nelson Intrusions comprised of a rock ranging in composition from granite to quartz diorite.

An old 5-metre deep shaft was sunk on a narrow quartz vein pinching and swelling to a maximum of 0.4 metres. A sample of a sulphide rich pocket graded 0.75 grams per tonne gold, 132 grams per tonne silver, 0.99 per cent copper, 4.65 per cent lead and 0.12 per cent zinc (Assessment Report 14934, page 15). Sulphides include pyrite, chalcopyrite, galena and sphalerite. A trench was later excavated from the shaft (trench 27) within mafic volcaniclastic country rock.

CAPSULE GEOLOGY

The Three Sisters occurrence comprises four kyanite showings in an elongate north trending area, 14 kilometres in length, centered just east of Ymir.

The area occurs on the east flank of the Nelson batholith, where Triassic to Precambrian metamorphosed sedimentary strata are exposed.

Strata of the Hadrynian Three Sisters Formation (Windermere Supergroup) outcrop in the core of an anticline. Kyanite schists contain up to 15 per cent kyanite porphyroblasts that have an average size of 2.5 by 0.5 centimetres.

CAPSULE GEOLOGY

The Vermont showing occurs in the vicinity of Mount Sophia. The west half of the mountain is underlain by the Upper Cretaceous Sophie Mountain Formation consisting of conglomerate with thin interbeds of argillite and siltstone. The east half of the mountain is underlain by volcanics of the Lower Jurassic Elise Formation, Rossland Group. Dykes of the Middle Eocene Coryell Intrusions cut the conglomerate.

The showings were reported to contain copper, lead, zinc, silver and gold in significant amounts; presumably the sulphides are chalcopyrite, galena and sphalerite. The conglomerates are reported to contain minor amounts of silver and gold. One sample from the Vermont claims assayed 0.12 per copper, 20.19 per cent lead, 9.32 per cent zinc, 99.77 grams per tonne silver and 0.07 grams per tonne gold (Assessment Report 17718).

COMMENTS: Sample CT88-04 across 0.25 metre wide quartz vein, from 2 metre pit.
REFERENCE: Assessment Report 18290.

CAPSULE GEOLOGY

The Mor 1 showing is located 6 kilometres southwest of Nelson on the north slope of Morning Mountain, 1 kilometre southeast of the Granite-Poorman mine (082FSW086). The area was explored from 1886 up to the 1940's and old overgrown trenches and adits probably date from this period. The Star showings adjoin to the west (082FSW083).

The area is underlain by mafic to intermediate volcanic rocks of the Lower Jurassic Elise Formation, Rossland Group, Jurassic pseudodiorite (gneiss?) of unknown affinity and biotite monzonite of the Middle to Late Jurassic Nelson Intrusions. The volcanic/diorite contact strikes north.

Mineralization consists of disseminated pyrite and chalcopyrite in diorite and minor sulphides hosted in narrow quartz veins.

CAPSULE GEOLOGY

The Oro Fino showing is located about 10 kilometres west of Nelson. The mineralization is similar to that found at the Granite-Poorman (082FSW086) deposit just to the southwest. It is possible that the Granite-Poorman vein system continues on to this property. The area is underlain by Jurassic pseudodiorite (gneiss ?) of unknown affinity, granitic Middle to Late Jurassic Nelson Intrusions and volcanic rocks of the Lower Jurassic Elise Formation, Rossland Group.
 A vein, 0.15 metre wide, occurs on the Evening Star claim (Lot

CAPSULE GEOLOGY

2014). The vein is fault controlled and has the same attitude as the Granite-Poorman veins (strike 350 degrees, dip 45 degrees east). Samples have assayed up to 9.43 grams per tonne gold from this vein (Assessment Report 14355).

A sample taken from the Oro Fino claim (Lot 2011) assayed 1.03 grams per tonne gold, 0.87 per cent copper and 8.6 grams per tonne silver (Assessment Report 14355). No other information is available on these veins.

CAPSULE GEOLOGY

The Keno 9 showing is located 15 kilometres south-southwest of Nelson between the Mammoth (082FSW211) and Fern (082FSW183) properties. An old adit and open cut from unknown exploration are present on the claim.

The area is underlain by augite basalt flows and flow breccias of the Elise Formation and siltstone, sandstone, conglomerate and argillite of the Hall Formation, both of the Lower Jurassic Rossland Group.

Two east striking quartz veins, in volcanic rocks near the sedimentary-volcanic contact, comprise the showing. The main vein, 1.37 metres wide, is exposed by the old workings. The vein strikes 250 degrees and dips 65 to 70 degrees north. A similar secondary vein, 0.20 metre wide, occurs 2 metres to the north. An adit, 50 metres north of the main vein, is cut on a copper-rich similar quartz vein.

Mineralization consists of chalcopyrite, tetrahedrite, bornite

CAPSULE GEOLOGY

and possibly cuprite as disseminated to semi-massive pods within the veins.

Sample M1 from the adit dump assayed 1.12 grams per tonne gold, 84.5 grams per tonne silver and 5.31 per cent copper (Assessment Report 18235). A selected sample from the main vein dump assayed 5.4 grams per tonne gold, 8.0 grams per tonne silver and 1.106 per cent copper (Assessment Report 18235).

Silver	5.5000	Grams per tonne
Gold	3.6300	Grams per tonne
Copper	0.2000	Per cent

COMMENTS: Drill hole 88-3, sample contained a stockwork in sheared dacite over 61 centimetres.

REFERENCE: Assessment Report 19435.

CAPSULE GEOLOGY

The Debbie showing is located 16 kilometres southwest of Nelson, just south of the Hungary Man (082FSW235) and Whitewater showings (082FSW222). There are two old adits near the headwaters of Connor Creek, probably dating from the 1930's.

The area is underlain by argillite, siltstone, limestone and chert of the Jurassic Ymir Group which have been intruded by diorite of the Middle to Late Jurassic Nelson Intrusions. Roof pendants of Lower Jurassic Elise Formation, Rossland Group volcanic rocks occur in the area. Skarn has been noted in outcrop and in rocks found on the adit dumps.

Massive sulphide mineralization occurs in narrow veinlets/stockworks, over a length of up to 40 centimetres, associated with

CAPSULE GEOLOGY

chloritization and silicification.

The upper adit follows a shear, 1 to 30 centimetres wide, in metavolcanic rock. Mineralization consists of pods of massive sulphides comprising pyrrhotite, pyrite and chalcopyrite. Samples from the adit assayed from 27.4 to 34.28 grams per tonne gold (Assessment Report 12139). The lower adit, 60 metres to the northwest, apparently did not encounter significant mineralization. The highest assay from dump material was 7.2 grams per tonne gold (Assessment Report 19435).

The best intersection encountered from a drilling program in 1988 was from drill hole 88-3 just south of the upper adit. A sample containing a stockwork in sheared dacite assayed 3.63 grams per tonne gold, 0.20 per cent copper and 5.5 grams per tonne silver over 61 centimetres (Assessment Report 19435).

CAPSULE GEOLOGY

The Trillicum showing occurs near the contact of the Eocene Penticton Group, Marron Formation, on the east, and a stock of the Middle Eocene Coryell Intrusions, on the west. The Marron Formation rocks consists of andesitic flows, lapilli tuffs, tuffaceous sandstone and tuffaceous conglomerate. The intrusions are generally coarse grained and range in composition from syenite to monzonite and granite.

In 1990, some old workings consisting of a 20 metre vertical shaft, two caved adits and several pits were discovered. Exposed in the shaft is a silicified and altered structure up to 2 metres wide, striking 010 degrees and dipping 80 degrees east. On the dump near the shaft specimens of massive magnetite and pyrite were found, as were specimens containing up to 5 per cent galena with traces of sphalerite and malachite.

HOSTROCK COMMENTS: Units Je8 and Je8l of the Elise Formation (Open File 1989-11).

GEOLOGICAL SETTING

TECTONIC BELT: Omineca
TERRANE: Quesnel

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The Aurous showing is located on the northeast slope of Mt. Connor, 13 kilometres southwest of Nelson. The Whitewater (082FSW222) deposit is just to the southwest. There is an adit and several trenches on the property that date from the turn of the century.

The area is underlain by andesitic and minor basaltic tuffs of the Lower Jurassic Elise Formation (units Je8 and Je8l), Rossland Group (Open File 1989-11). These have been intruded by granodiorite of the Middle to Late Jurassic Nelson Intrusions.

The andesite is silicified and propylitically altered as evidenced by pervasive epidotization. The altered andesite hosts quartz veins mineralized with disseminated pyrite and chalcopyrite. Disseminated magnetite occurs locally in the altered andesite adjacent to the veins.

Old records report assays of 3.43 to 130.26 grams per tonne gold, 102.84 to 685.6 grams per tonne silver and 5 to 22 per cent copper from these veins (Assessment Report 16161). Geochemical sampling in 1987 returned low values for these metals.

CAPSULE GEOLOGY

The Hattie Brown occurrence is underlain by augite porphyry (diorite) of the Jurassic Rossland sill. The sill intrudes the upper part of the Lower Jurassic Elise Formation (Rossland Group) and is included as a unit of this formation. The rocks lie within several hundred metres to the south of the southern edge of the Lower Jurassic Rossland monzonite, possibly within the zone of thermal metamorphism associated with the intrusion. On the west side of the property, the Middle Eocene Coryell Intrusions, comprised of a monzonite to syenite stock, intrudes the country rock.

In 1909, just over 14 tonnes of ore were reported shipped from the Hattie Brown property (Minister of Mines Annual Report 1909). The character of the ore was described as having a gold-silver-lead nature. A mineralized fracture mapped on the Hattie Brown claim has a northwest strike and a dip of 55 degrees northeast (Bulletin 74, Figures 2 and 3). This fracture is depicted as being hosted by augite porphyry adjacent to a stock of the Coryell Intrusions.

CAPSULE GEOLOGY

The CQ showing is located just south of the contact between the Lower Jurassic Rossland Group (Elise Formation) volcanics and the Early Jurassic Rossland monzonite stock. The Elise Formation in this area has recently been mapped as augite-phyric lapilli tuff and pyroclastic breccia (Unit Je71, Open File 1991-2).

A "vein" occurs near the contact of a north trending pulaskite dyke. A small cut on this vein near the contact of the dyke assayed 4.80 grams per tonne gold and a trace of silver across 56 centimetres (Assessment Report 24, page 5).

CAPSULE GEOLOGY

The area of the Cam 2 occurrence is underlain by monzonite of the Early Jurassic Rossland monzonite. The stock is intrusive into rocks of the Lower Jurassic Elise Formation, Rossland Group which occur just south of the showing. The monzonites have been altered showing chloritization and epidotization. Pulaskite dykes are known to occur in the area of the showings. The rocks are traversed by numerous faults. The major regional fault, Violin Lake fault, traverses the rocks paralleling Cambridge Creek.

A fine-grained quartz vein, with north strike and vertical dip, carries a high percentage of arsenopyrite and pyrite. An old trench had been excavated on the showing and pyrrhotite, malachite and chalcopyrite were noted on dump material. A sample 0.6 metres wide taken across the vein assayed 4.11 grams per tonne gold, 10.29 grams per tonne silver and 23.6 per cent arsenic (Assessment Report 18310). The exposed mineralization terminates against a dyke. Fifty metres to the southwest and on strike with the above vein is another pit with up to 50 per cent arsenopyrite in a siliceous zone (vein?).

CAPSULE GEOLOGY

The area of the Gold Dust occurrence is underlain by rocks of the Elise Formation, Rossland Group consisting of lapilli tuff with plagioclase and augite-bearing volcanic clasts. Contact with granite to granodiorite of the Middle to Late Jurassic Nelson Intrusions occurs within a few hundred metres to the north.

In 1988, two shafts about 25 metres apart and sunk to a depth of at least 30 metres were located on the Gold Dust claim and are considered to be the old G.R. Sovereign workings from the late 1800's. The shafts were apparently sunk on a north striking vein within a broad band of sparsely mineralized volcanics. An old publication from the last century (Hodges, 1897) gives the following account of the G.R. Sovereign: "A shaft was first sunk, following down a body of low grade pyrrhotite in diorite gangue, in which copper pyrites, quartz and calcite gradually came in, with rising gold values, which at 50 feet (15 metres) was about \$50 (about 83 grams per tonne gold). A crosscut is in 175 feet (53 metres) to tap a ledge at a depth of 250 feet (76 metres), and at 90 feet (27

CAPSULE GEOLOGY

metres) struck a cross ledge carrying several feet of ore".

A 0.1-metre wide sample taken across the vein in 1988 assayed 7.41 grams per tonne gold (Assessment Report 18331). One of several drill holes put down on the old workings in 1988 contained one interval grading 1.71 grams per tonne gold over 5.33 metres. The drill section contained arsenopyrite and chalcopyrite in altered monzonite and andesite.

Also relocated in 1988 were some old workings on what is thought to be the lapsed Last Chance Crown Grant (Lot 4611), which occupied the ground west and adjacent to the G.R. Sovereign Crown Grant. The old workings, about 350 metres west-southwest of the Sovereign workings, consist of a shaft and two short pits aligned in a north northwest direction. The dump is large, indicating a significant amount of underground development. The volcanics around the workings are highly oxidized and contain disseminated pyrrhotite. North and northwest fractures contain pyrrhotite, pyrite and chalcopyrite. A sample taken from the north pit in a silicified fracture zone assayed 4.28 grams per tonne gold, 4.0 grams per tonne silver and 0.362 per cent copper (Property File - Tobex Resources Ltd., prospectus, 1988).

REFERENCE: Hodges, L.K. (editor), (1897): Mining in the Pacific Northwest.

CAPSULE GEOLOGY

The area of the Little Giant occurrence is underlain by rocks of the Elise Formation and the southern contact of the Early Jurassic Rossland monzonite. A stock of the Middle Eocene Sheppard Intrusions, varying in composition from granite to syenite, has intruded near the contact. The Elise formation in the Rossland area comprises a succession of augite-phyric flows, tuffs, some epiclastic deposits and minor siltstone and argillite.

Before the turn of the century, 3 veins on the Little Giant group of 4 claims had been developed by extensive open cuts. The ore was reported to be free milling, consisting of arsenopyrite and other sulphides. The veins are between 0.6 to 0.9 metres wide and widen with depth. An average assay from the surface graded 5.7 grams per tonne gold (Hodges, 1897).

CAPSULE GEOLOGY

The area of the Vinon occurrence is underlain by rocks of the Elise Formation, Rossland Group consisting of lapilli tuff with plagioclase and augite-bearing volcanic clasts. Contact with granite to granodiorite of the Middle to Late Jurassic Nelson Intrusions occurs within a few hundred metres to the north.

Little is known of the occurrence except that there is a large surface showing with values, apparently of gold, up to 0.6 grams per tonne (Hodges, 1897). In 1897, a crosscut had been driven in 6 metres. In 1988, disseminated pyrrhotite and a little chalcopyrite in highly oxidized volcanics had been found in the area presumed to contain the old workings but the crosscut had not been located.

GEOLOGICAL SETTING

TECTONIC BELT: Omineca
TERRANE: Quesnel Plutonic Rocks
PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The area of the Red Point occurrence is underlain by rocks of the Elise Formation, Rossland Group consisting of augite-phyric lapilli tuff. Contact with granite to granodiorite of the Middle to Late Jurassic Nelson Intrusions occurs within a few hundred metres to the north. Contact with the Early Jurassic Rossland monzonite is within a few hundred metres to the west.

First staked in 1893, the Red Point was reported to have surface ore that assayed 113 grams per tonne gold and 551 grams per tonne silver (Hodges, 1897). By 1897, a large amount of underground development had occurred on the property.

Loumic Resources Ltd. drilled a total of 1013.1 metres in six holes at its Red Point bulk-tonnage gold prospect on the north end of Lookout Mountain, immediately southwest of Trail. The gold is associated with pyrrhotite and pyrite (with only traces of chalcopyrite) disseminated through and coating hairline fractures in Rossland Group pyroclastics and flows which seem to range in composition from andesite to felsites. Alteration is generally weak, mainly biotitization with more localized albitization (?). The mineralization is believed to represent a gold-rich, copper-poor, porphyry occurrence. It appears to have been deposited very early after deposition of the volcanic host because the best grades occur in fragmental rocks where higher original porosity and permeability may have played a role in channeling the mineralizing fluids. The best assay interval reported was from hole #2 in which 166 metres averaged 0.84 grams per tonne gold (Exploration in BC 1997, page 49).

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The area of the Knight Templar occurrence is underlain by a package designated as Unit Cs, which is of probable Upper Paleozoic age and may be correlative with the Milford Group (Fieldwork 1990, page 21). These Upper Paleozoic rocks consist of argillite, siltstone and limestone. Part of this unit, a northwest trending band of limestone (Unit Csl), is mapped roughly where the southern portion of the lapsed Knight Templar Crown Grant was located (Open file 1991-2). The strata are intruded several hundred metres to the south by a granitic mass of the Middle Eocene Sheppard Intrusions.

The old claim, as of 1897, had a 49 metre adit, from which a winze went down 20 metres. A large body of "low-grade" ore was reported to grade as high as 43 gram per tonne gold (Hodges, 1897). The winze was to be sunk to 30 metre level, where drifts were to be run each way.

REFERENCE: Hodges, L.K. (editor), (1897): Mining in the Pacific Northwest.

CAPSULE GEOLOGY

The area of the Victory-Triumph occurrence is underlain by the southern contact of the Middle Eocene Coryell batholith with the Upper Cretaceous Sophie Mountain Formation. The Coryell Intrusions are generally coarse-grained and range in composition from syenite to monzonite and granite. The Sophie Mountain Formation comprises conglomerate with thin interbeds of argillite and siltstone.

By 1887, a vein or ore mass, showing rich copper ore, had been exposed by stripping for 18 metres and "defined for 6 metres between walls at another point". Samples from a 3.7-metre deep shaft gave assays of: 15.3 per cent copper with a trace of gold, on surface; 22.1 per cent copper with 5.35 grams per tonne gold, at 1.2 metres depth; and 30.4 per cent copper with 5.02 grams per tonne gold, at 2.4 metres (Hodges, 1897). The country rock is stained with malachite and assays 9.7 per cent copper. An adit has also been driven and was in 38 metres by the year 1897.

CAPSULE GEOLOGY

The area of the Olga occurrence is underlain by the southern contact of the Middle Eocene Coryell batholith with the Upper Cretaceous Sophie Mountain Formation. The Coryell Intrusions are generally coarse-grained and range in composition from syenite to monzonite and granite. The Sophie Mountain Formation comprises conglomerate with thin interbeds of argillite and siltstone.

By 1987, two Olga claims were reported under development. Three "ledges" or (veins?) are reported, one averaging about 2 metres in width and another about 2.4 metres in width. The third was not described. Assays of surface ore from the 2.4 metre wide vein range up to 3.35 grams per tonne gold, 448 gram per tonne silver and 54.55 per cent lead (Hodges, 1897).

A parallel vein was reported on the Abe Lincoln group of three claims. The vein strikes northwest and has been traced for over 300 metres. The gangue is quartz carrying gold and galena. By 1897, a 15-metre shaft was down on the footwall and a crosscut had been run at the bottom for 13 metres, from which drifting had begun. The

CAPSULE GEOLOGY

The area of the Falu occurrence is underlain by rocks of the Pennsylvanian, and possibly Permian, Mount Roberts Formation which may be correlative with the Milford Group farther north. The Mount Roberts rocks are comprised of siliceous siltstone, argillite, silty chert, limestone or dolomite and minor sandstone and greenstone. The contact of the Bonnington pluton of the Middle to Late Jurassic Nelson Intrusions occurs within a few hundred metres to the east.

A shaft sunk 21 metres on the hanging wall, from which a crosscut struck the footwall in 6 metres, shows a body of ore reported to assay 64 to 80 grams per tonne gold (Hodges, 1897).

CAPSULE GEOLOGY

The area of the Highland occurrence is underlain by rocks of the Pennsylvanian, and possibly Permian, Mount Roberts Formation which may be correlative with the Milford Group farther north. The Mount Roberts rocks are comprised of siliceous siltstone, argillite, silty chert, limestone or dolomite and minor sandstone and greenstone. The main western contact of the Trail pluton of the Middle to Late Jurassic Nelson Intrusions occurs within a kilometre to the east. A mass of granite related to the Nelson Intrusions occurs along the southern boundary of the Highland Crown Grant.

A large body of low-grade siliceous ore containing a large quantity of copper is reported to occur (Hodges, 1897).

COMMENTS: Highest values from sampling of underground workings.
REFERENCE: Assessment Report 12992.

CAPSULE GEOLOGY

The Independence showing is located 10 kilometres south-southwest of Nelson. A short tunnel and several trenches exist on the property.

The area is underlain by augite porphyry, andesite, basalt and flow breccia of the Lower Jurassic Elise Formation (Units Je5 and Je1), Rossland Group (Open File 1989-11).

Quartz veins, stockworks and silicified zones occur on the property. The veins are 0.01 to 1.5 metres wide and 2 to 50 metres in length.

Two quartz veins are exposed in the workings hosted in a shear zone in augite porphyry. The veins are mineralized with minor pyrite and chalcopyrite. The vein exposed by trenches is approximately 1 metre wide. The vein exposed in the tunnel also has bornite mineralization, up to 2 per cent by volume in grab samples. Smaller veins and a hematite occurrence, occur to the south.

CAPSULE GEOLOGY

Chip samples from the underground workings assayed up to 7.54 grams per tonne gold, 123.41 grams per tonne silver and 17.2 per cent copper (Assessment Report 12992).

CAPSULE GEOLOGY

The area of the Erie occurrence is underlain by siltstone and conglomerate of the Archibald Formation and argillite and siltstone of the Hall Formation, both of the Lower Jurassic, Rossland Group. The northwest trending Erie Creek fault forms the boundary of the two formations east of Erie Lake with the Hall Formation on the east. A small mass of granitic rock of the Middle to Late Jurassic Nelson Intrusions disrupts the strata to the immediate north. The location of two adits are marked on Map 1145A just east of the Erie Creek fault in Hall Formation rocks.

A small vein, up to 25 centimetres wide, containing galena, sphalerite and chalcopyrite in a siliceous gangue, occurs in schistose rocks. In 1928, the vein was drifted on for 53 metres with two winzes developed for an additional 9 and 12 metres respectively. A grab sample from a pile of sorted ore assayed 229.72 grams per tonne silver, 21.8 per cent lead, 2.26 per cent copper and 4.3 per cent zinc (Minister of Mines Annual Report 1928, page 338). A sample from a wide iron-capping exposed in an open cut near the adit assayed 0.69 grams per tonne gold, 20.57 grams per tonne silver, 0.5 per cent lead and 0.6 per cent zinc (Minister of Mines Annual Report 1928,

REFERENCE: Mining in British Columbia 1988, page 94.

CAPSULE GEOLOGY

The South Fork Silica deposit is located adjacent to Highway 3, 26 kilometres south of Salmo.

The area is underlain by quartzite (Nugget Member) of the Hadrynian to Lower Cambrian Quartzite Range Formation. The quartzite, ranging from phyllitic to purer white, has a high silica-low contaminant content. In 1987, a 2000-tonne shipment of quartzite was sent to Trail to test for use as a silica flux (P. Wilton, personal communication, 1992).

This is an open pit operation with a production capacity of 64,000 tonnes per year. Production in 1988 was 22,750 tonnes; the product is transported by truck to the Cominco smelter at Trail, British Columbia. Reserves are estimated at 9 million tonnes (Mining in British Columbia 1988, page 94).

PHYSIOGRAPHIC AREA: Selkirk Mountains

CAPSULE GEOLOGY

The McPhee property is located 12 kilometres southeast of Castlegar, southwest of Grassy Mountain. The Second Relief (082FSW187) lies 9.5 kilometres to the northeast and the Maud S. (082FSW325) is about 2 kilometres to the southwest. The property is are located between 1200 and 1600 metres elevation, along a ridge which divides the Champion and McPhee Creek drainages.

The area is underlain by a roof pendant of Lower to Middle Jurassic Rossland Group rocks enclosed by monzonite and hornblende diorite of the Middle Jurassic Bonnington Pluton. Quartz pebble conglomerate, probably of the Hall Formation, occurs in the northwest part of the property along the contact with a massive pyrrhotite horizon. Altered andesitic flows of the Elise Formation also occurs on the property.

The zone of massive pyrrhotite and chalcopyrite occurs within the pebble conglomerate. Historical adits and shafts have been driven on the mineralization. The massive sulphide band is 1 to 5 metres wide and has been traced on surface for 1.5 kilometres. Rock samples of the massive sulphide zone assay up to 0.7 per cent copper, 0.06 per cent cobalt, 0.26 per cent tungsten and 0.14 per cent molybdenum. Samples of the quartz pebble conglomerate returned values up to 3.62 per cent zinc, 0.56 per cent lead, 42.5 grams per tonne silver and 0.15 grams per tonne gold. Rock samples of the

CAPSULE GEOLOGY

andesite returned values up to 13 grams per tonne gold, 6.8 grams per tonne silver, 1.5 per cent copper, 0.15 per cent nickel, 0.05 per cent cobalt and 3.8 per cent zinc. (George Cross Newsletter #60 (March 26, 1998).

A letter (to the Chamber of Mines in Nelson) dated September 5, 1933 by B.W. Meister describes assays of 85.7 grams per tonne gold on the Wolf claims, about 1.5 kilometres east of the Maud S. Bruce Doyle acquired claims in the area about 1995; these were optioned by Phelps Dodge Corporation of Canada in 1996. They carried out exploration, including soil geochemical sampling, mapping and prospecting on the south-central part of the property in 1997. The option was dropped in 1997. Interest in the property is being acquired by Miner River Resources Ltd. and Eagle Plains Resources Ltd.

CAPSULE GEOLOGY

Cominco's integrated smelting and refining complex is located at Trail, in southeastern British Columbia. Smelting and refining have been carried out at Trail since the turn of the century. More than 700,000 tonnes of concentrates are processed at Trail every year, yielding a wide range of metals and related by-products, including refined zinc, lead, silver, gold, cadmium, bismuth, indium, germanium concentrate, germanium dioxide, copper sulphate, copper arsenate, sodium antimonate and a variety of sulphur products and agricultural fertilizers. The two major metals are zinc and lead. The majority of the zinc and lead concentrates treated at Trail come from the Sullivan mine (082FNE052) in Kimberley, B.C., and the Red Dog mine in Alaska.

Cominco Ltd. intends to process its existing 215,000 tonnes of stockpiled lead smelter slag at Trail by refurbishing and restarting its No. 2 Slag Fuming Furnace before the end of 1999. The slag stockpile is estimated to contain 35,000 tonnes of zinc as well as significant quantities of indium and germanium (Cominco Ltd., June 1, 1999). The refurbishment will cost \$9 million and is expected to pay for itself within a year. Processing of the stockpile should be completed in approximately four years from the slag fuming furnace start up.

The Kivcet lead smelter and its associated slag fuming furnace will continue to process the current output of higher-value Zinc Plant residues and will ultimately consume the 475,000 tonnes of residues that are stockpiled at Trail.

Cominco also markets the slag for cement production and abrasive applications.

REFERENCE: Starr, C.C. (1930) Notes on the Little George and Garfield Claims.

CAPSULE GEOLOGY

The Little George and Garfield Crown Grant claims were located 10 kilometres northeast of Ymir on the northwest flank of Mount Dundee. The claims were crown-granted in 1901 and 1904 respectively (since reverted) with development since then consisting of one "very short" tunnel, a 3-metre shaft and four or five opencuts.

The area is underlain by biotite granodiorite of the Middle to Late Jurassic Nelson Intrusions. Metamorphosed sediments of the Lower and Middle Ordovician Active Formation (Pend d'Oreille schists) occur in a roof pendant within the Nelson batholith.

There are two principal veins on the Little George claim, located roughly along the margins of the schist which strikes at about 025 degrees. The west vein is 3 to 9 metres wide and dips steeply eastward. It outcrops for "several hundred feet" on a steep hillside and passes under soil at both ends. The "filling" is reported to consist of silicified schist and granite cut by numerous stringers and stockworks of quartz. Occasional specks of pyrite and

CAPSULE GEOLOGY

some limonite are visible. The east vein is about 60 metres distant and has similar characteristics.

On the Garfield claim to the immediate southwest, there are several veins. The East vein of the Little George outcrops at several points and at least two other veins outcrop as well. It is not clear whether one of them is the west vein or not. The other vein is a apparently a spur about 1.2 to 1.5 metres thick, striking off into the granite; it is on this that a 3-metre deep shaft has been sunk. These veins are similar to the veins on the Little George claim.

A sample taken on 1.2 metres of quartz in an opencut on the Garfield claim yielded 9.6 grams per tonne gold and 54.86 grams per tonne silver (Starr, 1930 (Property File)).

REFERENCE: Cassidy Gold Corp. website.

CAPSULE GEOLOGY

The Silver Lynx prospect is located about 15 kilometres southwest of Nelson.

The area is underlain by argillite, siltstone and limestone of the Lower Jurassic Ymir Group which have been intruded by granodiorite of the Late to Middle Jurassic Nelson Intrusions near the Bonnington pluton. The rocks hosting the prospect are metamorphosed and the protolith is difficult to determine.

The Silver Lynx property hosts newly discovered zinc, lead, copper, silver mineralization. Bruce Doyle discovered the property in the summer of 2000 after receiving a prospectors assistance grant from the Ministry of Energy and Mines. He completed a soil geochemical program with results delineating highly anomalous polymetallic values over 800 metres long, open on both ends, and up to 300 meters wide with an average width of 125 metres.

The showings consist of poorly exposed massive pods of sphalerite, galena and pyrite with chalcopyrite. A second style of mineralization consists of a network of stringers containing primarily sphalerite. Both are hosted in a silicified light-coloured

CAPSULE GEOLOGY

rock, possibly a felsic volcanic rock, that is locally brecciated in the mineralized area.

An individual selected grab sample from road cut materials assayed 24.59 per cent zinc, 22.35 per cent lead, 0.21 per cent copper and 556.4 grams per tonne silver (16.2 ounces per tonne) (Cassidy Gold Corp. website).

In November 2000, Cassidy Gold Corp. acquired an option to purchase a 100% interest in the Silver Lynx property which comprises 20 contiguous mineral claims covering 500 hectares.

Cassidy plans to initiate a program of geological mapping, prospecting and geophysical surveys in order to initiate a winter drill program. The geophysical survey, consisting of large loop transient electromagnetic (EM) as well as magnetic/VLF-EM will include the area defined by the previously mentioned geochemistry program.

CAPSULE GEOLOGY

The Kena property hosts a number of porphyry style, gold and gold-copper occurrences south of the town of Nelson. The property lies on the eastern limb of the Hall Creek Syncline, a south-plunging fold associated with intense shearing that dominates the structure of the Nelson map area. The syncline incorporates volcanic and lesser sedimentary rocks of the Lower Jurassic Elise Formation (Rossland Group) which are intruded by a synvolcanic monzodiorite complex and by the younger? Middle Jurassic Silver King Intrusions comprising a coarse grained plagioclase porphyry stock with related dikes and sills.

Mineralization in the Kena property area was first described in a report by G.M Dawson in Geological Survey of Canada Annual Report for 1888-89. Little is known about exploration on the claim area prior to 1973. Post-1973 exploration, however, has identified old prospect pits and trenches, as well as several old adits indicating periods of exploration activity in the early part of the century. Numerous exploration companies carried out geological, geochemical, geophysical surveys, trenching and drilling on the property from 1974-91. These companies explored the Elise Formation volcanics for gold and copper mineralization and discovered the Kena Gold zone (082FSW237), Kena Copper zone (082FSW332) and the Shaft/Cat zones

CAPSULE GEOLOGY

(082FSW331). The Kena Gold zone underwent the most thorough exploration with the Kena Copper and Shaft/Cat zones only being tested minimally. No additional work was done until 1999 when Sultan Minerals Inc. acquired and amalgamated several properties under the name Kena property.

The Kena property is underlain by volcanic rocks of the Elise Formation which are intruded by porphyritic bodies of the Silver King Intrusions. A large number of mineral occurrences, including the Kena Gold (082FSW237) and Shaft (082FSW331) on the east and the former Silver King mine (082FSW176) on the west, are spatially related to the Silver King porphyries. Recent exploration work and data compilation by Sultan Minerals have identified four gold-bearing zones on the Kena property. These are: the Gold Mountain (this description), Kena Gold, Shaft/Cat, and South Gold soil anomaly located about 1000 metres south of the Kena Copper zone (082FSW332).

The upper Elise Formation in the vicinity of the Gold Mountain zone is a sequence of mafic to intermediate flows, tuffs and minor epiclastic deposits. A number of cyclical sequences of pyroclastic rocks that typically grade upward from lapilli tuff to crystal tuff or fine tuff are common. Augite porphyry flows and flow breccias are a minor constituent. The dominant lithology is a plagioclase-augite lapilli tuff of andesitic composition. A number of generally highly deformed feldspar porphyries (Silver King Intrusions) occur within the Elise Formation. They have been dated as Aalenian to Toarcian (Middle Jurassic) and many are associated with copper, gold and silver mineralization. Outcrops of Silver King intrusions are typically cream coloured and form resistant ridges. Contacts with Rosslund Group rocks are either sharp and discordant or intensely sheared. The Silver King plutonic rocks are porphyritic, characterized by 30 to 60 per cent euhedral to subhedral plagioclase phenocrysts, 5-10 millimetres in size, set in a fine grained greenish grey groundmass.

In the Gold Mountain zone, the eastern margin of a Silver King porphyry body is in contact with Elise Formation volcanics on a relatively flat plateau where poor outcrop exposure occurs. In this zone, the Silver King unit is a coarse to medium grained plagioclase-hornblende porphyry. It is locally siliceous and in places weakly to strongly flooded with secondary potash feldspar. The plagioclase is weakly to moderately sericitized, and hornblende is weakly to locally highly chloritized. Epidote alteration is evident in many places. The porphyry is locally mineralized with 1 to 5 per cent disseminated pyrite, traces of chalcopyrite and malachite, and stringers and disseminations of magnetite and specular hematite. Mineralization in the Gold Mountain zone appears to be associated with classic porphyry-style alteration. In the area of the 2000 discovery trenches, the Silver King porphyry is intensely fractured and altered. Sulphide mineralization consists of 1 to 5 per cent disseminated and fracture coating pyrite with trace chalcopyrite (and accompanying malachite) and molybdenite. Heavy limonite and/or goethite and occasional pyrolusite occur on many of the fractures. Petrographic studies indicate that native gold occurs as clusters within quartz veinlets and as particles along the margins of pyrite grains.

The Gold Mountain zone was discovered by Sultan Minerals in 2000 and lies in the northwest portion of the Kena property, within the Silver King porphyry unit, adjacent to Elise Formation volcanics. The showing is about 600 metres north of the Shaft occurrence and is in a previously unexplored area and represents a new and unique style of gold porphyry mineralization. A gold soil anomaly from a soil geochemical survey completed in September 2000 over the Silver King porphyry unit was followed up by a program of prospecting and rock chip sampling. The rock samples yielded up to 5.48 grams per tonne gold along the intrusive-volcanic contact and up to 2.71 grams per tonne gold from outcrops within the intrusion. Late in 2000, an excavator trenching program was conducted in the Gold Mountain zone and chip sample results from the six discovery trenches yielded an average assay of 1.43 grams per tonne gold over their combined length of 181.7 metres. The best 3 metre chip sample assayed 11.38 grams per tonne gold; the six trenches tested an area measuring 120 by 100 metres. An induced polarization survey was completed in November and results show a large chargeability anomaly coincident with the gold soil geochemical anomaly (Sultan Minerals Inc. Annual Report 2000).

Sultan Minerals Inc. had drilled 45 holes by September 2002 and expanded the zone to include mineralization paralleling the western contact of the Silver Ring intrusion as well as the eastern contact (PR REL Sultan Minerals Inc., September 25, 2002).

SUMMARY TOTALS: 082FNE043

NAME: **BLUEBELL**

	<u>Metric</u>	<u>Imperial</u>
Mined:	4,820,029 tonnes	5,313,172 tons
Milled:	4,774,123 tonnes	5,262,570 tons
Recovery:		
Silver:	221,011,383 grams	7,105,671 ounces
Gold:	8,864 grams	285 ounces
Cadmium:	1,141,943 kilograms	2,517,553 pounds
Copper:	2,855,381 kilograms	6,295,036 pounds
Lead:	233,800,528 kilograms	515,441,788 pounds
Zinc:	249,022,008 kilograms	548,999,397 pounds

Comments:

1982: Tailings.
 1974: 8 tonnes lead conc. shipped.
 1973: Lead conc. 59 tonnes, salvage from Kootenay Bay.
 1957: Includes 530 tons tailings recovered from Kootenay Lake.
 1956: Includes 3397 tons of tailings recovered from Kootenay Lake.

SUMMARY TOTALS: 082FSW009

NAME: **JERSEY (L.9070)**

	<u>Metric</u>		<u>Imperial</u>	
Mined:	8,134,702 tonnes		8,966,974 tons	
Milled:	8,128,809 tonnes		8,960,478 tons	
Recovery:				
Silver:	21,483,869 grams		690,721 ounces	
Cadmium:	2,011,236 kilograms		4,434,015 pounds	
Lead:	114,935,331 kilograms		253,388,959 pounds	
Tungsten:	6,232,298 kilograms		13,739,861 pounds	
Zinc:	263,715,580 kilograms		581,393,169 pounds	

Comments:

- 1970: The Jersey mine ends production in this year.
- 1959: All tungsten values (1944-1958) are actually tungstic oxide (WO3).
- 1958: The Dodger mine (082FSW011) ends production.
- 1956: 1955 prod. - 144,873 t. of 1955 total is from Emerald (Dodger?)
- 1955: The Feeney mine (082FSW247) ends production.
- 1953: 1952 prod. - 390,745 t, Jersey. All else Emerald, Feeney, Dodger.
- 1952: Feeney (082FSW247) and Dodger (082FSW011) commence production.
- 1951: No shipment from Emerald Tungsten mine.
- 1949: Jersey mine commences production in this year.
- 1944: Emerald Tungsten mine (082FSW010) production - 1944 and 1947-1958
